HOLOHEDRAL CRYSTAL. A crystal in which the full number of faces are developed, corresponding to the maximum and complete symmetry of the system. See also **Mineralogy**.

HOMOGENEOUS. (Latin, "the same kind"). This term, in its strict sense, describes the chemical constitution of a compound or element. A compound is homogeneous since it is composed of one and only one group of atoms represented by a formula. For example, pure water is homogeneous because it contains no other substance than is indicated by its formula, H_2O. Homogeneity is a characteristic property of compounds and elements (collectively called substances) as opposed to mixtures. The term is often loosely used to describe a mixture or solution composed of two or

more compounds or elements that are uniformly dispersed in each other. Actually, no solution or mixture can be homogeneous; the situation is more accurately described by the phrase "uniformly dispersed." Thus so-called homogenized milk is not truly homogeneous; it is a mixture in which the fat particles have been mechanically reduced to a size that permits uniform dispersion and consequent stability.

See also **Heterogeneous**.

HOMOGENIZING. A process for reducing the size of particles in a liquid and useful in the preparation of numerous food substances, including milk, ice cream, salad dressings, various fruit juices, flavor concentrates, infant foods, among others.

A reduction of particle or globule size in a mixture of two immiscible liquids makes an emulsion possible. If an emulsifying agent is present, a more stable emulsion can be produced and coalescence of the dispersed phase is prevented. The homogenizer is also used to produce dispersions by reducing the particle size in solid-in-liquid mixtures. As in the preparation of an emulsion, a dispersing agent is needed to maintain a homogeneous mixture.

Typically, a homogenizer consists of a high-pressure, positive-displacement pump and an adjustable orifice. The pump is a piston or plunger type, usually consisting of three plungers, although some homogenizers are made with five or even seven plungers. The cylinder for each plunger has an inlet and discharge valve. The plunger pump must push the product through the homogenizing valve (adjustable orifice). For two-stage homogenization, two valves are arranged in series.

A typical homogenizing valve consists of a seat and plug of very hard abrasion-resistant materials (alloys such as Stellite are used). The seating surfaces must be lapped smooth and be parallel. In operation, the plug is spring-loaded against the seat. Spring compression is adjusted so that when the product flows, energy in the form of pressure is required to lift the plug. Although many products can be homogenized at pressures below 3000 pounds per square inch (204 atmospheres), machines are made to develop pressures in excess of 8000 pounds per square inch (544 atmospheres). In another design, a valve uses a compressed cone of stainless-steel wire inserted into a socket, the product being homogenized by flowing between the wires.

A number of theories have been proposed as to what actually breaks up the particles in the homogenizer. (1) As the product enters the area between the lapped surfaces, it is suddenly accelerated to velocities as high as 30,000 feet per minute (9,144 meters per minute) at a pressure of 5,000 pounds per square inch (340 atmospheres). When acceleration is this sudden, the particle (especially the liquid particle) is stretched or elongated to the point of breaking. (2) At this high velocity, there are shear forces between layers of liquids under flow that break up particles. (3) Cavitation may be the major cause of homogenization. When the pressure energy is converted into velocity energy, the vapor pressure of the product exceeds product pressure, resulting in the formation of vapor cavities, which collapse upon leaving the valve at higher pressures. This collapsing, or implosion, of cavitation exerts tremendous force, breaking up the particles. Most homogenizers are designed to incorporate one or more of the foregoing principles.

HOMOLOGOUS SERIES. Two organic compounds are said to be homologous if their molecular formulas differ by CH_2, or a multiple of CH_2. For example, the alkane series has the general formula, C_nH_{2n+2}, its first three members being methane, CH_4, ethane, C_2H_6, and propane, C_3H_8.

HOMOPOLYMER. A natural or synthetic high polymer derived from a single monomer. An example of a natural homopolymer is rubber hydrocarbon, whose monomer is isoprene; a synthetic homopolymer is typified by polychloroprene or polystyrene, whose monomers are, respectively, chloroprene and styrene.

HOOKE'S LAW. When a load is applied to any elastic body so that the body is deformed or strained, then the resulting stress (the tendency of the body to resume its normal condition) is proportional to the strain. Stress is measured in units of force per unit area; strain is the extent of the deformation. For example, when a bar of metal is subjected to a stretching load, the extent of the increase in length of the bar is directly proportional to the force per unit area, i.e., to the stretching load or stress. In general, Hooke's law applies only up to a certain stress called the *yield strength*.

HORMONES. During the past few years, the classical concept of hormone has been undergoing revision and expansion. A half-century ago, when only a few hormones were reasonably well understood, it was generally believed that there were a comparatively few very important complex biological substances generated by a few glands that stimulate and inhibit principal body functions. Investigators have learned, particularly since the early 1980s, that the creation of hormones is not an exclusive process for the endocrine glands, that receptors for any given hormone are not usually simply concentrated in relatively limited locations of the body, but are found sometimes where they were least suspected. For example, a few years ago when J. Roth and J. Kova (National Institutes of Health) confirmed insulin receptors in the human brain, they sought and found receptors in the testes and liver. In the case of insulin, this had led investigators to explore the possibility of insulin synthesis occurring, not just in the pancreas, but elsewhere in the body.

Researchers have also commenced studies of other life forms, insects and annelida for example, in a search for hormone receptors and, indeed, have found material similar to insulin and receptors that are reminiscent of human insulin receptors. That hormone production is not limited to the endocrine glands has been suspected for a number of years, but such cases were considered the exception rather than the rule. Modern investigators no longer accept this hypothesis. Suspected earlier, but not well confirmed until the mid-1980s, the human heart, once simply considered as a pump, is now known to create at least one hormone, *atrial natriuretic factor* (ANF). A few years earlier, researchers found that the human brain synthesizes important substances, such as endorphins and enkephalins.

Thus, the study and indeed the definition of hormones is departing rapidly from the former exclusive association with endocrinology. The field is becoming broader and more complex and the number of previously unidentified substances playing some form of hormonal role is increasing. More hormones are being found and in more locations in the living process, both human and other life forms. The field no longer is limited to a comparatively exclusive few sophisticated substances.

In connection with a new hypothesis for hormones, Roth has suggested that cell hormones and neurotransmitters began as what cell biologists term *tissue factor*—substances that stimulate cells to grow or come together or otherwise react biochemically. Only when animals evolved to have extreme cell differentiation and cellular organization did glands evolve to overproduce these hormones so the animals could use them in more clever and sophisticated ways. This theory would explain why many mammalian hormones are also tissue factors. As examples, insulin and glucagon, in addition to playing roles as hormones, also act locally as tissue factors on cells within the pancreas. Exocrine and endocrine functions overlap—there is no difference between exocrine and endocrine functions at the level of unicellular organisms. Roth points out that such a hypothesis would explain the finding that many classical messenger molecules, such as prostaglandins, nerve growth factor, and the hormonal substances are found in exocrine fluids such as saliva, intestinal secretions, milk, and semen.

Investigations are also being conducted apace in what might be called hormone genetics. It has been found, for example, that guinea pigs produce two different insulins, one type made in the pancreas, the other type synthesized in the brain and other organs. Thus, there are differences in gene expression. New findings may explain why cancer cells sometimes secrete hormones that cause severe metabolic disturbances. Lung cancers, for example, are prone to produce vasopressin, a cause of water retention. Perhaps the tumor-generated vasopressin is not normal vasopressin, but a slightly different hormone that has escaped detection by radioimmunoassays. There may be numerous other instances where investigators are seeking one of the better understood hormones, when a somewhat different, uncataloged hormone should be the target. Admittedly, the thoughtful speculation involved in the reevaluation of hormone science will require considerably more research and proof.

In studies of the immune system, investigators have reported on the finding of a heretofore unknown immunoregulatory hormone, 1,25-dihydroxyvitamin D_3. The substance was found to be effective in suppressing interleukin-2.

By applying recombinant DNA techniques, a group of researchers has produced two human fertility hormones, human chorionic gonadotropin (hCG) and human luteinizing hormone (hLH). This is one of the first examples in which recombinant DNA techniques have been used to produce molecules that are a combination of proteins and carbohydrates

in mammalian cells. The two hormones are similarly structured, consisting of two polypeptide chains that are put together inside cells and processed. It has been suggested that the hormones will be useful in the treatment of infertility because they can induce both ovulation and sperm production. Past hormone treatments have involved extracts from pituitaries, urine, or placentas which do not yield a pure product.

Hormone Science in the Traditional Sense

In animals, hormones are organic compounds (usually of considerable complexity and even after years of research not fully understood) that are secreted by endocrine (ductless) glands, such as the adrenal gland, the thyroid and parathyroid glands, the pituitary gland, and the gonads, among others Hormones are sometimes commonly called by the names of the glands that secrete them. Thus, there are adrenal cortical hormones, thyroid and parathyroid hormones, etc. Hormones are regulators of physiological processes within the body, exerting control over such processes as metabolism, growth, reproduction, molting, pigmentation, and electrolytic and osmotic balance, among other processes. Apparently, hormones achieve these objectives chemically and electrically, although the mechanisms are not fully understood and, in fact, the mechanisms may vary from one situation to the next. At one time, hormones were loosely called "chemical messengers" because they are transported from point to point within the organism and thus effect actions at distances from the region where they are made. If one visualizes secreting glands as sensors of a type detecting need for correction of some physiological process, then the hormones might be visualized as both the transmitters or carriers of this information and the initiators of actions as well. The conventional concept is that cells have receptors on their surfaces, which sense the presence of specific hormones. At one time, it was firmly believed that hormones, particularly polypeptide hormones, such as insulin, prolactin, and growth hormone, all of which are large charged molecules, could not penetrate through the cell's membrane and actually enter the cell. This belief has since been altered because researchers have shown that insulin, for example, can enter into the cell. Referring to this process as "internalization," one investigator in 1978 suggested that the internalization of polypeptide hormones will be one of the most active topics in cell biology for a number of years.

Research has shown that hormones and/or their receptors may be degraded. As gross examples of this type of situation, it is known that many obese people with high concentrations of insulin in their blood also have normal concentrations of blood sugar. Why doesn't the insulin decrease the blood sugar concentration in these cases? It is well known that pregnant women produce much angiotensin II, which normally increases blood pressure, but these women usually do not have hypertension. What alterations in the hormone-cell mechanism provide this result? There are also instances where males have tumors that secrete large quantities of a hormone that stimulates the production of testosterone, and yet there is no evidence of abnormal amounts of testosterone. At least two questions can be posed: Do certain hormones lose their effectiveness with time? Or, are there changes in target receptor cells? Research has indicated that there may be a relationship between concentration of hormones and the surface receptors which bind them, such receptors being inactive for a time or possibly disappearing from the cell surface altogether. A number of investigators have observed that a better understanding of the manner in which hormones affect their own and other receptors possibly may result in new ways to treat certain diseases, including insulin-resistant diabetes.

In recent years, it has been shown that a wide variety of receptors are regulated by hormones. Some receptors are sensitive to only one hormone; this appears to be the case with insulin. Others appear to be regulated not only by one hormone, but others as well. For example, it has been shown that the receptors for TRH (thyrotropin-releasing hormone) are not exclusively regulated by TRH, but also by other hormones. Receptors for gonadotropins (pituitary hormones that act on the gonads) appear to be regulated by hormones in addition to gonadotropin. There are numerous other instances of this kind.

Hormones display not only great variations in function, but also in their chemical nature, of which there is a great diversity. Some are steroids, such as estrogen, progesterone, cortisone, etc., while others are amino acids (thyroxine), polypeptides (vasopressin), low-molecular-weight proteins, and conjugated proteins. Amino acid and steroid hormones have been isolated and many, including insulin, have been synthesized. Other types are prepared directly from the endocrine organs of animals.

Hormones produced by one species usually show similar activity in other species. The hormones showing greatest species specificity are proteins or conjugated proteins.

Hormones are markedly affected by deficiencies or excesses of the various vitamins and other dietary essentials.

Because of the great complexity of a number of the natural hormones, conventional approaches of organic synthesis which have been used so successfully over the years in connection with many drugs have not proved viable to date with some of the hormones. Insulin is an example. Presently, millions of diabetics still depend upon animal insulin as extracted from the pancreatic glands of slaughtered pigs. If diabetes mellitus continues to become more prevalent, as it has over the past several years, natural sources may not be sufficient.

Recombinant DNA technology was applied to the problem the first time a few decades ago. One group has been successful in inducing the bacterium *Escherichia coli* to manufacture and secrete rat proinsulin, an immediate precursor of rat insulin that incorporates insulin itself. Research like this is an important step toward the objective of developing bacterium-based industrial systems that can replace animal and human tissues as the source of medically useful proteins, such as insulin, growth hormone, and clotting factor.

Classes of Hormones

Hormones may be grouped into two distinct types: (1) *direct-acting*; and (2) *stimulating*-substances that stimulate other organs to produce their own characteristic hormones. The latter group is sometimes called the *tropic hormones*. See summary of hormones in Table 1.

Thyroid Hormones. These are compounds of the amino acid *thyronine*. They are present in the free form only to a slight extent, existing chiefly as constituents of the protein thyroglobulin. The most important of these acids in terms of hormone action are the 3,5,3′-tri, and the 3,5,3′,5′-tetraiodocompounds, *triiodothyronine* and *thyroxin*, the structures of which are given in Part 1 and Part 2 of Table 1. The action of thyroid hormones is to accelerate cellular reactions and to increase the metabolic rate and oxygen consumption of tissues. They effect this action by stimulating many of the enzyme systems, not only the glucose oxidation system and the cytochrome chain for dehydrogenating the coenzyme NADPH, but other processes, such as the synthesis of proteins from amino acids. Their effects are clearly apparent in the pathological changes in the organism caused by their excess or deficiency. The thyrotrophic hormone and other biochemical interactions with the thyroid gland are discussed later in this entry.

Parathyroid Hormones. The influence of the parathyroid glands on the regulation of calcium concentrations in the blood of mammals was first recognized by MacCullum and Voegtlin in 1909.

More recently, several groups of investigators have succeeded in purifying and partially identifying the structure of the hormone, variously called *parathormone* and *parathyroid hormone*. This is a single chain peptide hormone with a molecular weight of about 8,000. A second parathyroid hormone, *calcitonin*, was postulated by Copp (1961). Subsequent research has indicated that this hormone is actually the hormone produced by the thyroid gland. However, a parathyroid calcitonin may exist in certain species.

The more classical function of parathyroid hormone is concerned with its control of the maintenance of constant circulating calcium levels. Its action is on (1) the kidney, where it increases the phosphate in the urine, (2) the skeletal system, where it causes calcium resorption from bone, and (3) the digestive system, where it accelerates (stimulates) calcium absorption into the blood. The hormone and gland exhibit characteristics of feedback control; when the concentration of calcium ions in the blood falls, the secretion of the hormone increases, and when their concentration rises, the secretion of hormone decreases.

Adrenal Cortical Hormones. The adrenal gland is made up of two parts, the medulla and the cortex, each of which secretes characteristic hormones. The hormones of the adrenal medulla are the catecholamines, epinephrine (adrenalin) and norepinephrine (noradrenalin), which are closely related chemically, differing only in that epinephrine has an added methyl group. See Table 1. In fact, animal experiments have established a metabolic pathway for the biosynthesis of both compounds from the amino acid phenylalanine, which involves enzymatic oxidation and decarboxylation reactions. It is also to be noted that the isomeric form of norepinephrine is most important; the natural D-form (which incidentally, is levorotatory) has many times the activity of the synthetic isomer. Epinephrine has a pronounced action upon the circulatory system, increasing both blood

TABLE 1. REPRESENTATIVE HUMAN HORMONES

Hormone Common names, (synonyms), Structure and production site	Principal physiological functions	Interrelationships with vitamins
Adrenocorticotropic Hormone (ACTH) (Adrenocorticotropin; corticotropic hormone) Straight-chain, simple, polypeptide, 39 amino acids, no S—S bridges. (See text, Fig. 1.) Molecular Weight ~ 4500 Production Site: Anterior pituitary	Maintenance of adrenal cortex Promotes secretion of steroids, oxidative phosphorylation in adrenal cortex Mobilizes and increases oxidation of free fatty acid in adipose tissue Increases gluconeogenesis in liver; increases cyclic adenosine monophosphate (AMP) in adrenal cortex Decreases urea formation in liver	Ascorbic acid: depleted in adrenal cortex on stimulation by ACTH Biotin and vitamin A: adrenocortical insufficiency noted in biotin and vitamin A deficiency Niacin: production of reduced nicotinamide adenine dinucleotide (phosphate) (NADPH) by ACTH via cyclic adenosine monophosphate (AMP) Niacin and pantothenic acid: synergistic with ACTH in steroid hormone synthesis Vitamin D: antagonized directly by ACTH via cortisol action
Aldosterone (Aldocortin; electrocortin; mineralocorticoid; 18-oxocorticosterone)  Molecular Weight 360.4 Production Site: Adrenal cortex	Maintenance of normal electrolyte blood balances Prolongs survival of adrenalectomized animals Accelerates gluconeogenesis Regulates kidney function	Ascorbic acid: adrenal cortex depleted of ascorbic acid on production of aldosterone Biotin: prolongs life in adrenalectomized rats Niacin: nicotinamide adenine dinucleotide (phosphate) (NADPH) involved in synthesis of aldosterone
Cortisol (Hydrocortisone, 17-hydroxycorticosterone)  Molecular Weight 362.5 Production Site: Adrenal cortex	Increases (1) protein catabolism (excepting liver) gluconeogenesis; (2) carbohydrate anabolism (liver); (3) blood sugar; (4) glucose absorption; (5) brain excitation; (6) spread of infections; (7) urinary glucose and nitrogen; (8) stress tolerance; (9) lactation; (10) water diuresis Regulates general adaptation syndrome, water balance, blood pressure, and hormone release. Decreases (1) fat anabolism; (2) growth rate; (3) inflammation; (4) eosinophils; (5) lymphocytes; (6) antigen sensitivity; (7) respiratory quotient; (8) ketosis; (9) wound healing; (10) skin pigmentation; (11) RBC hemolysis	Ascorbic acid: may be required for steroid hormone biosynthesis; depleted from adrenal cortex on cortical secretion Biotin: adrenocortical insufficiency noted in biotin deficiency Folic acid and pantothenic acids maintain secretions of steroids by adrenal cortex Niacin: nicotinamide adenine dinucleotide (phosphate) (NADPH) required for steroid hormone biosynthesis Vitamin A: deficiency causes cortical necrosis Vitamin D: action antagonized by cortisol by reducing calcium absorption in intestine
Epinephrine (Adrenaline, adrenin, suprarenin, vasotonin, vasoconstrictine, adrenamine, levorenine)  Molecular Weight 183.2	Blood circulation: increases blood pressure; peripheral vasodilator; increases heart output and rate; flow increases in brain, liver, and skeletal muscle Central nervous system: causes restlessness, anxiety Kidney: reduces glomerular filtration rate Lung, intestine, genital system: inhibited motility	Ascorbic acid: maintains reduced state of epinephrine Ascorbic acid, folic acid, and vitamins B_6, and B_{12} are cofactors in synthesis of epinephrine from phenylalanine

TABLE 1. (*continued*)

Hormone Common names, (synonyms), Structure and production site	Principal physiological functions	Interrelationships with vitamins
Production Site: Adrenal medulla and chromaffin cells in gut	Metabolic effects: increases oxygen consumption, temperature, basal metabolic rate, gluconeogenesis Pituitary effects: stimulates production and release of ACTH and corticoids	
Estradiol (Female hormone; dihydrotheelin; dihydrofollicular hormone dihydrofolliculin)  Molecular Weight 272.4 Production Sites: Ovarian follicles; tests; corpus luteum; adrenal cortex; placenta	Regulates menstrual cycle, female sex behavior Maintains secondary sex characteristics Affects antibody properties Induces estrus, uterine hypertrophy, vaginal cornification; potentiate sand stimulates calcitonin secretion	Folic acid: involved in mitotic effect of estradiol Niacin, diphosphopyridine nucleotide (DPN), triphosphopyridine nucleotide (TPN): involved in increased respiration and in cholesterol precursor synthesis Pyridixine: competes as cofactor with estrogen sulfate in kynurenine aminotransferase activity Vitamin D: synergistic in calcium metabolism with estradiol Vitamin E: involved in follotropin production or release
Follicle-Stimulating Hormone (FSH) (Follotropin, luteoantine, thylakentrin, Prolan A, gonadotropin 1, gametogenic hormone, follicle ripening hormone, gametokinetic hormone) Structure: Not fully definitized. Production Site: Anterior pituitary.	Female: stimulates ovarian follicles to grow and to develop, forming multiple layers and antra Male: stimulates seminferous tubules; stimulates spermatogenesis	Ascorbic acid: depletion in ovary due to follicle-stimulating hormone and luteinizing hormone action Vitamin E: required to maintenance of membranes in sex organs
Glucagon (HGF) (Hyperglycemic-glycogenolyltic factor; glucagon; HG-factor) Structure: Polypeptide, 29 amino acids (structure determined). No S—S bridges Molecular Weight ~3500 Production Site: Alpha cells in pancreas.	Increases: blood sugar; blood K^+, oxygen consumption, liver glycogenolysis, gluconeogenesis, nitrogen and salt excretion Decreases: liver glycogen, protein formation, gastric juice, fatty acid synthesis	Ascorbic acid: depletion of adrenal ascorbic acid by glucagon
Insulin (no synonyms) Structure: 51 amino acids. Known and synthesized. 3 S—S bridges. (See text, Fig. 4) Molecular Weight 5,734 (monomer); 12,000–48,000 (polymer), depending upon pH. Production Site: Beta cells of islets of pancreas.	Regulates carbohydrate and fat metabolism, especially glucose and fat oxidations Stimulates amino acid and glucose transport into cells and protein synthesis Female: promotes estrogen and progesterone secretion, ovulation; maintains ovarian tissues Male: stimulates Leydig cells to secrete testosterone; gametogenic with follotropin (FSH)	Ascorbic acid: acts similarly to alloxan (i.e., antagonist) Ascorbic acid: ovarian depletion on LH stimulation Vitamin E: involved in spermatogenesis
Luteinizing Hormone (LH) (Luteotropin, ISCH) Structure: Globular glycoprotein with S—S bridges. Molecular Weight 26,000 Production Site: Anterior pituitary.		
Melanocyte-stimulating Hormone (MSH) (Melanotropin, chromatophorotropic hormone; pigmentation hormone) Structure: Polypeptide: purified, synthesized; alpha and beta forms; straight chains. Molecular Weight: 1500 (alpha) 2100–2600 (beta) Production Site: Intermediate lobe of pituitary.	Mammals: exerts small effect on skin pigmentation (protection from sunlight not fully proved) Expands or contracts pigments in various chromatophores Expands melanophore pigments with color changes in amphibia (adaptation to environment) Lower vertebrates: increases sensitivity to light; decreases dark adaptation time.	Ascorbic acid: adrenal cortex depleted on ACTH and MSH activity Vitamin A: MSH decreases dark adaptation time.
Norepinephrine	Blood circulation: increase blood pressure; peripheral vasoconstrictor without change or slight decrease in output and heart rate. No flow increase in brain, liver, or muscle	Ascorbic acid: protects against oxidation of norepinephrine

(*continued overleaf*)

TABLE 1. (*continued*)

Hormone Common names, (synonyms), Structure and production site	Principal physiological functions	Interrelationships with vitamins
(Arterenol; noradrenaline; levarterenol)  Molecular Weight 169.2 Production Site: Adrenal medulla; adrenergic nerve endings; chromaffin cells.	Central nervous system effects: adrenergic transmitter agent at synapses; no brain excitation Kidney: decreases glomerular filtration rate Lung, intestine, genital system: inhibited Metabolic effects: weak epinephrine effect	Ascorbic acid, folic acid, and vitamin B_6 are cofactors in synthesis of norepinephrine from phenylalanine
Oxytocin (Oxytocic hormone; pitocin; uteracon; α-hypophamine) Cys— Tyr — Ile — Gln — Asn — Cys— Pro— Leu—Gly NH_2 Molecular Weight 1007 Production Site: Hypothalamus.	Uterine contraction, milk ejection, facilitates sperm ascent in female tract Decreases membrane potential of myometrium, basic metabolic rate, and liver glycogen Stimulates oviposition in hen, releases luteinizing hormone (LH) Increases blood sugar and urinary sodium and potassium	Findings on interrelationships with vitamins are not extensive
Parathyroid Hormone (PTH) (Parathormone) Structure: Simple polypeptide (83 amino acids), sequence determined; straight chain; No S—S bridges. Production Site: Parathyroid glands.	Increases blood calcium, kidney calcium reabsorption, phosphate excretion, and blood citrate level Mobilizes calcium and phosphate from bone Activates calcium and phosphate absorption from the gastrointestinal tract (for which vitamin D is required) Increases osteoclast formation	Vitamin D: synergistic with PTH in maintenance of serum calcium
Progesterone (Progestin, luteosterone)  Molecular Weight 314.5 Production Sites: Ovary (follicles, corpus luteum); testicles; adrenal cortex; placenta	In low concentrations: prepares uterus for blastocyst implantation; promotes ovulation and mammary gland development; regulates female sex accessory organs; weak corticosteroid properties; precursor to sex hormones In high concentrations: maintains pregnancy; represses ovulation and sex activity; inhibits vaginal cornification and parturition; decreases myometrial excitation	Ascorbic acid: depleted from adrenal cortex or ovary on progesterone formation Niacin: diphosphopyridine nucleotide (DPN) involved in progesterone synthesis
Prolactin LTH (Lactogenic hormone; lactogen; galactin; mammotropin) Structure: Single-chain protein, 205 amino acids Molecular Weight 23,000–25,000 Production Site: Anterior pituitary	Initiates lactation Develops mammary glands in female Increases weight and growth (similar to somatotrophin in some species) Protein anabolism (some species) Growth and secretion of crop gland (birds) Luteotropic (only in mouse, rat) Promotes maternal behavior	Not fully determined. Generally participates with other substances having growth action Participates in nidation of zygote
Relaxin (Releasin, cervilaxin) Structure: Polypeptide (4 peptides with activity have been isolated); about 30–40 amino acids in each peptide Molecular Weight 4000–5000 Production Site: Corpus luteum in pregnancy	Enlarges birth canal in preparation for parturition Separation of symphysis pubis, loss of rigidity in pelvic bones Decreases uterine motility Maintains pregnancy Increases sensitivity to oxytocin; release oxytocin Stimulates mammary gland	Ascorbic acid: maintains mucoprotein ground substance in connective tissue, affected by relaxin

TABLE 1. *(continued)*

Hormone Common names, (synonyms), Structure and production site	Principal physiological functions	Interrelationships with vitamins
	Stimulates inhibition of water in uterus Inhibits uterine contraction	
Somatotropin (STH) (Growth hormone, GH; somatotrophic hormone; hypophyseal growth hormone) Structure: Known and synthesized; coiled, unbranched protein; 188 amino acid residues; 2 S—S bridges Molecular Weight 21,500 Production Site: Anterior pituitary	Promotes general growth of organism Promotes skeletal growth, protein anabolism, fat metabolism, carbohydrate metabolism, water, and salt metabolism	Relates with all vitamins in connection with growth actions
Testosterone (17 beta-hydroxy-4-androsten-3-one)  Molecular Weight 288.4 Production Sites: Interstitial cells of ovary and testis; adrenal cortex; embryonic placenta	Controls secondary male sex characteristics Maintains functional competence of male reproductive ducts and glands Increases protein anabolism; maintains spermatogenesis; inhibits follotropin Increases male sex behavior; increases closure of epiphyseal plates	Ascorbic acid, folic acid, vitamins A and E are synergists with testosterone for maturation of germ cells and increased anabolic activity
Thyroid-stimulating Hormone (TSH) (Thyrotrophic hormone, thyrotropin) Structure: Glycoprotein (300 amino acids) Molecular Weight 26,000–30,000 Production Site: S^2 type cell, anterior pituitary	Regulates body temperature via thyroxine Maintains thyroid gland and its secretory activity (colloid discharge) Maintains iodine uptake by thyroid gland Promotes differentiation in embryo during development via thyroxine Stimulates coupling of diodotyrosine to form thyroxine	Ascorbic acid, thiamine, riboflavin, and vitamin B_{12}: requirements increase in hyperthyroidism; tissue concentrations reduced Vitamin A: massive doses of vitamin A inhibit secretion of TSH; thyroid hormones required for carotene and retimene conversions Vitamins A, D, E, and K: requirements increased in hyperthyroidism; tissue concentrations reduced in Vitamin B_6, niacin: conversion to phosphorylated reactive forms impaired in hyperthyroidism
Thyroxine (T_4) (3,5,3′,5′ tetraiodothyronine)  Molecular Weight 776.9 Production Site: Thyroid gland	Regulates growth, differentiation, oxidative metabolism, electrolytic balance Increases carbohydrate metabolism, calorigenesis, protein anabolism, basal metabolic rate, oxygen consumption, fat catabolism, fertility Sensitizes nervous system	Ascorbic acid: synergist in cold survival Niacin: synergist in mitochondrial metabolism Vitamin A: T_4 is required for vitamin A synthesis in liver Vitamin B_{12}: T_4 aids in B_{12} absorption B complex vitamins: deficiencies develop in hyperthyroidism
Vasopressin (Arginine vasopressin; antidiuretic hormone; ADH; pitressin; tonephin; vasophysin) Cys – Tyr – Phe – Glu NH_2 – Asp NH_2 – Cys – Pro – Leu – Gly NH_2 Vasopressin Molecular Weight 1084 (arginine-vasopressin) Production Site: Hypothalamus	Elevates blood pressure (mammals) (reverse effect in birds) Decreases kidney blood flow Antidiuretic, releases ACTH Increases sodium chloride and urea excretion Regulates water balance Stimulates contraction of smooth muscles Increases renal tubular water reabsorption Releases anterior pituitary hormones	Not fully determined

pressure and pulse rate, and hence the cardiac output by its direct action upon the heart muscle, and especially because it causes constriction of the arterioles. However, its effects upon smooth muscles vary: it relaxes the muscles of the digestive system, but contracts the pyloric sphincter.

Norepinephrine does not affect the cardiac output, although it does raise the blood pressure by constricting the arterioles. Its muscular effects are less pronounced. Both epinephrine and norepinephrine release free fatty acids from adipose tissue, so raising its level in the blood. This effect is due to the action of the hormones in accelerating enzymatic reactions whereby the esters of the fatty acids are hydrolyzed. The third type of action of epinephrine is its effect upon the carbohydrate metabolism, notably the acceleration of the hydrolysis of glycogen in muscular tissue and the liver. It raises the glucose level in the blood, and the rate of glucose oxidation, with resulting increase in oxygen utilization, carbon dioxide production, and body temperature. See also See also **Adrenal Cortical Hormones**; and **Adrenal Medulla Hormones**. The hormones of the adrenal cortex are steroids. See also **Steroids.** Among them there are a number of hormones with androgenic activity, such as adrenosterone and 17α-hydroxyprogesterone, which are discussed under the sex hormones later in this entry. In all, over ten steroids have been identified in the adrenal cortex, including seven of characteristic cortical activity. These are corticosterone, from which the others are named, 17α-hydroxyl-11-dehydrocorticosterone (cortisone), 17α-hydroxycorticosterone (cortisol or hydrocortisone), and 18-oxocorticosterone (aldosterone). Only two hormones, cortisol and corticosterone, are normally released in fairly large quantities, and another, aldosterone, deserves mention because of its somewhat different effects, even though it is released to a far lesser extent.

All of these hormones are synthesized from cholesterol in the adrenal cortex, by an extended series of reactions, which include many related compounds. Although these hormones have widespread effects throughout the organism, their primary mechanism is not known, so that many of the effects may be indirect. Much of the knowledge of their action arises from studies of insufficiency or hyperactivity of the adrenal cortex, which produces a wide variety of pathological conditions. See Table 1.

It is generally considered that aldosterone, and to some extent the other hormones, have a regulatory effect upon the metabolism of electrolytes and water, particularly upon the concentration of the ions of the alkali metals in intracellular fluids. Administration of steroids also increases the concentration of calcium ions in those fluids. However, all three of these hormones have a number of other effects, roughly in the order of potency—cortisol, corticosterone, aldosterone. They produce changes in the metabolism of carbohydrates, proteins, and fats.

For the carbohydrates alone, three major effects are evident—increase in the rate of formation of glucose, increase in the rate of release of glucose from the liver, and increase in the rate of utilization of glucose. These hormones affect the digestive system, increasing the secretion of hydrochloric acid, pepsinogen, and trypsinogen. They prevent inflammatory responses to bacterial or even chemical stimuli; they counteract anaphylactic shock, and other effects of hypersensitivity. Obviously, these properties have led to their widespread therapeutic use.

There are relationships between the adrenal cortical hormones and the thyroid and pituitary glands. Depression of the function of the adrenals produces thyroid deficiency, whereas administration of thyroxine stimulates the ACTH-adrenal cortical mechanism.

Pituitary Hormones. The hormones of the hypophysis (pituitary gland) are quite numerous, being secreted variously in three parts of the gland—the neurohypophysis (posterior lobe), the adenohypophysis (anterior lobe), and the *pars intermedia*, which connects the other two.

The chief hormones of the neurohypophysis are the polypeptides oxytocin and vasopressin. The hormone characteristic of the *pars intermedia* is the melanocyte-stimulating hormone. It is usually spoken of in the plural, since in most mammals both alpha and beta forms are known. The structures of the first two are shown in the Table 1. The most prominent effect of oxytocin is the contraction of smooth muscle, especially of the uterus. It also has a major effect upon the muscles about the breast, and so stimulates the ejection of milk in lactating animals. It has a definite stimulating effect upon the muscles of the ureter, urinary bladder, intestine, and gall bladder.

The most prominent effect of vasopressin is upon the kidneys, where it stimulates the resorption of water in the tubules (which by repeated release and absorption concentrate the urine). It also constricts the coronary arteries, raises the blood pressure, and exhibits the effect of oxytocin upon smooth muscles, but generally to a lesser degree.

The action of the melanocyte-stimulating hormones has been established by studies of animals, in which they cause dispersal of certain black pigments from the cells that contain them, with resulting darkening of the skin.

The adenohypophysis is the part of the gland in which the tropic hormones are secreted. They include the adrenocorticotropic hormone (ACTH), the thyrotropic hormone (TSH), and somatotropin, as well as three hormones with pronounced effects upon the gonads: the hormone prolactin, the follicle-stimulating hormone (FSH) and the luteinizing or interstitial cell stimulating hormone (LH or ISCH).

ACTH. Adrenocorticotropin (ACTH) in humans is a polypeptide containing a sequence of 39 amino acids, although work with animal forms of it and with degradation products of the human form have shown that not all of them are essential to the activity of the hormone. This sequence for the human ACTH is shown in Fig. 1.

The primary function of ACTH is the stimulation of the adrenal cortex to produce its hormones, which have already been discussed. This is evident from the therapeutic effect of administration of ACTH, which is closely similar to that of these hormones, so that if the action of only one of them is sought, its administration is preferable. Moreover, ACTH stimulates secretion of the androgenic substances mentioned as produced by the adrenal cortex.

Thyrotropic Hormone. This hormone (TSH) stimulates the development of the thyroid and controls its secretion. Although purified preparations of it have been obtained, they consist of a mixture of proteins of high mean molecular weight (about 30,000). Some of their amino acids have been determined, as well as their carbohydrates, but the structures have not been elucidated.

Growth Hormone. Somatotropin is the growth hormone. Purified preparations of extracts of it from the human adenohypophysis have been crystalized. They are known to be proteins, of mean molecular weight 21,000, and containing a single polypeptide chain. This hormone differs from the others of its group in not acting primarily upon the other endocrine glands, but in controlling the gain in body weight and the rate of skeletal growth. The growth abnormalities, such as dwarfism and giantism, have been shown to result from its hypo- and hypersecretion. In addition to its effect upon growth and anabolism generally, it has been found to affect the kidneys and pancreas, and to influence glucose, galactose, and lipid metabolism.

Gonadotropic Hormones. These include follicle stimulating hormones (FSH), luteinizing or interstitial cell stimulating hormone (LH or ISCH), and prolactin. Their structures are not known; the molecular weight of human LH is about 26,000, that of human FSH is about 30,000, and that of human prolactin is uncertain. They are proteins, with variable amounts of carbohydrates. FSH induces the growth of Graafian follicles in the ovary and the production of spermatozoa in the testis. LH stimulates the final development of the ovarian follicles, the appearance of estrus, and the change of the follicles to corpora lutea. In the male, it stimulates the secretion of testosterone. Since these effects are due to the effect of this hormone upon interstitial cells, it is also called ISCH. Prolactin stimulates lactation after birth, acts with estrogen to promote the growth of the mammary gland, and influences the activity of the corpora lutea.

Male Hormones. The androgenic hormones produced in the testes (and adrenal gland) have a widespread effect upon the development of secondary sexual characteristics (musculature, facial hair, larynx, etc.), as well as upon the sexual organs and responses themselves. They also promote anabolism to a marked degree by their effect upon nitrogen and calcium metabolism. The structure of testosterone is shown in the Table 1.

Female Hormones. Closely related to the male androgenic hormones, and probably synthesized from them in the female organism, are the estrogenic hormones which are produced principally in the ovary. Although β-estradiol is the normally secreted ovarian hormone, a number of other estrogenic substances have been isolated from urine and from animal studies. They include α-estradiol, estriol, and estrone. The structures of these hormones are given in Fig. 2.

These hormones are important in both the menstrual cycle and the reproductive cycle, and of course play an important role in oral contraceptives (the "pill"). They induce growth of the vaginal epithelium, secretion of mucus by the glands of the cervix, and initiate the growth of the endometrium, which is taken over by progesterone (from the corpus luteum) later in the cycle. They activate the proliferation of the mammary gland during pregnancy. As the androgens do for the male, the estrogens bring about the secondary sexual characteristics of the female. They have a number of effects upon metabolism, notably that of calcium and phosphorus, and of lipids and proteins. A number of other estrogens, some made synthetically and others obtained from animals, are known.

The corpus luteum produces two hormones, progesterone and relaxin. The structures of these hormones are shown in Part 1 and Part 2 of table.

Progesterone acts to complete the proliferation of the endometrium, which was initiated by the estrogenic hormones, and to prepare it for the ovum. In pregnancy the continued action of progesterone is necessary. It aids the growth of the breasts and has a definite effect against ovulation. It is also the biosynthetic precursor of some of the estrogenic hormones. Relaxin has been shown to have a relaxing effect on the cartilaginous junction of the pubic bones in preparation for parturition.

Feedback in Hormone Control Systems

Not only do the hormones initiate or stimulate biological processes, both directly and by bringing about production of other hormones in other glands, but they also act to maintain the organism in a steady state, or *homeostasis*. Thus the gonadotropic hormones from the hypophysis stimulate the testes, but the resulting production there of androgens like testosterone, inhibits the action of the hypophysis in producing the gonadotropic hormones. The complicated cycle of adjustment in the human female is shown in the cycle illustrated in Fig. 3.

As shown in the figure, the regulation of the ovarian hormones in the human female involves both positive and negative feedback. The follicle-stimulating hormone (FSH) from the adenohypophysis stimulates the Graafian follicles, which thus produce estrogens. These not only inhibit FSH production through negative feedback, but also stimulate the adenohypophysis to increase its production of luteinizing hormone (LH) through positive feedback. This hormone in turn brings about ovulation from the Graafian follicle. After the ova are discharged, the LH stimulates the empty follicle, now the corpus luteum, to produce progesterone.

This hormone brings about the changes in the reproductive organs required for the development of the embryo. Then the progesterone partly inhibits the adenohypophysis from producing further LH, an example of negative feedback; as a result, there is no further ovulation. The progesterone also acts as a positive feedback and stimulates the production of FSH.

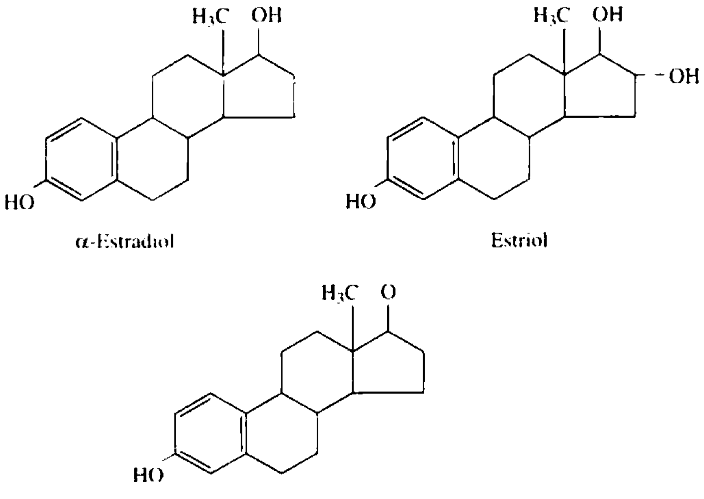

Fig. 2. Major ovarian hormones

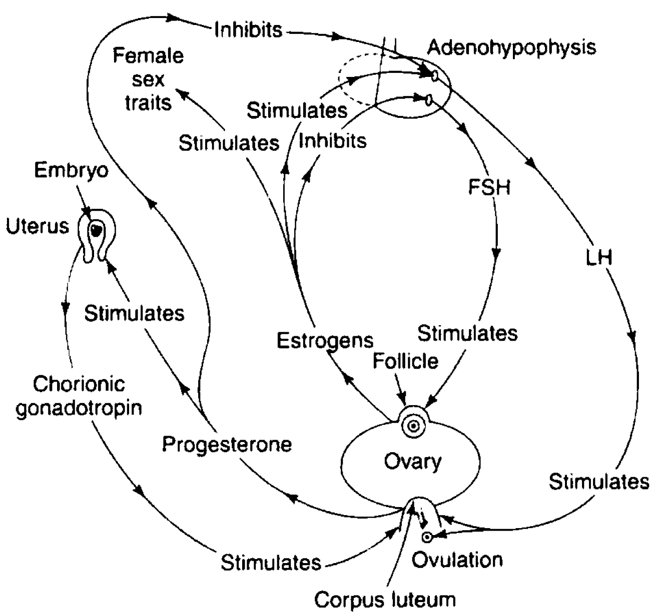

Fig. 3. Cycle of hormone adjustment in human female

When pregnancy intervenes, a new feedback mechanism must be introduced, or the embryo would be expelled, by the shedding of the lining of the uterus in menstruation. Here the placenta (chorion) of the embryo itself produces hormones, as already noted. Its LH stimulates continuing production of progesterone from the corpus luteum, thus preventing menstruation and stimulating the continuing development of the uterus as needed by the growing embryo. The extra progesterone also inhibits further ovulation in spite of the presence of the gonadotropin from the placenta (chorion).

Pancreas and Nonendocrine Hormone Sources. In addition to producing hormones, the pancreas also generates digestive fluids (*pancreatic juice*). It is the hormone function that makes the pancreas a part of the endocrine system. The pancreas secretes *insulin* and *glucagon*, both hormones. The structure of glucagon consists of a single chain of amino acids. See Figs. 4 and 5.

These two hormones have two opposing effects. That of insulin is *hypoglycemic*, i.e., it increases the rate of utilization of glucose, the probable process being an effect of insulin to increase the penetration of glucose through the cell walls as well as increased phosphorylation. The overall result of action of insulin in its relation to glucose is to increase the rate of the reactions by which glucose is oxidized, but also its transformation to glycogen. The enzyme glucagon raises blood glucose levels by increasing the rate of hydrolysis of glycogen (in the liver) to increase the formation ultimately of glucose. Insulin increases the rate of entry of amino acids into cells and their rate of protein biosynthesis. Insulin also accelerates the formation of lipids from carbohydrates, whereas glucagon stimulates the formulation of keto compounds from lipids, inhibits the synthesis of fatty acids, and accelerates the breakdown of various phosphorus and nitrogen compounds. The primary result of insulin deficiency is diabetes mellitus.

Hormones may be produced by organs other than the endocrine glands. Conspicuous among such organs is the placenta, the organ on the wall of the uterus to which the umbilical cord is attached. It has been found to produce the same estrogenic hormones as the ovary, the same hormones (progesterone and relaxin) as does the corpus luteum, and gonadotropic hormones (and luteinizing hormones) similar to, but not identical with, those produced by the adenohypophysis.

Other hormones which do not originate in endocrine glands are the cholecystokinin of the intestine, and the enterogastrone and gastrin of the stomach. The first is produced by the upper intestinal mucosa and causes the gall bladder to contract; the enterogastrone is produced in the same tissue and inhibits gastric motility and secretion; it also excites secretion of digestive fluids, principally hydrochloric acid.

In plants, a *plant hormone* or "phytohormone" is an organic compound produced by the plant, controlling growth and other functions at sites

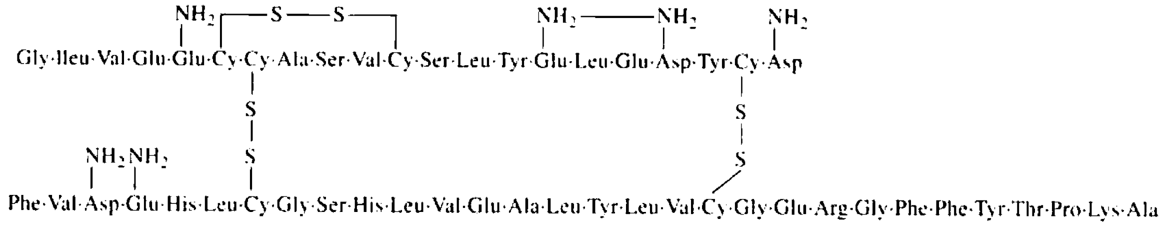

Fig. 4. Primary structure of bovine insulin

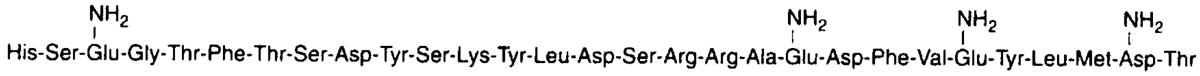

Fig. 5. Glucagon

remote from where the hormone is produced. Plant hormones also act in very minute amounts. Plant hormones include the auxins, gibberellins, and kinetins. These are described in the entries on **Gibberellic Acid and Gibberellin Plant Growth Hormones**; and **Plant Growth Modification and Regulation**.

HORNBLENDE. The mineral hornblende is a complex silicate. It is probably an isomorphous mixture of three molecules, a calcium-iron-magnesium silicate, an aluminum-iron-magnesium silicate and an iron-magnesium silicate. A general formula is

$$(Ca, Na, K)_{2-3}(Mg, Fe^{2+}, Fe^{3+}, Al)_5(Al, Si)_8O_{22}(OH)_2.$$

Manganese and alkalies are sometimes present as is also titanium. It is monoclinic, with prismatic crystals, often pseudo-hexagonal. Bladed, fibrous, columnar, granular and compact massive varieties also are common. It has a perfect prismatic cleavage; hardness, 5–6; specific gravity, 3.02–3.27; color, green, greenish-brown, brown and black; luster, vitreous to silky; transparent to opaque.

Hornblende is a common constituent of many of the igneous rocks such as granite, syenite, diorite, or gabbro, of gneisses and schists and is the principal mineral of the amphibolites. Hornblende alters easily to chlorite and epidote. A variety of hornblende that contains little (less than 5%) of iron oxides is gray to white in color and named edenite, from its locality in Edenville, New York. Very dark brown to black hornblendes, which contain titanium, ordinarily are called basaltic hornblende from the fact that they are usually a constituent of basalts and similar rocks.

Well-known localities for hornblende are in The Czech Republic and Slovakia, Mount Vesuvius, Italy, Norway, Sweden, and, in the United States, in Massachusetts, New Hampshire, and New York. Black hornblende is found in Renfrew County, Canada. The word hornblende is derived from the German horn, and blende, to blind or dazzle. The term blende was often used to refer to a brilliant nonmetallic luster, i.e., zinc blende.

See also terms listed under **Mineralogy**.

ELMER B. ROWLEY
Union College
Schenectady, New York

HORNBLENDITE. A coarse-grained rock related to gabbro that consists almost wholly of hornblende. Olivine being present, this rock may grade into a hornblende-peridotite (cortlandtite). Hornblendite is a rare rock type and of relatively little importance. See also **Gabbro**.

HOT WORKING. Plastic deformation of metals at temperatures sufficiently elevated so that the effects of the working are nullified by concurrent softening processes. Thus, when steel is hot worked by rolling at a white heat, the metal recrystallizes and softens almost immediately after it is deformed. Similarly, the deformation of lead at room temperature is also hot working and accounts for the fact that it is not possible to work-harden this material at this temperature. An empirical rule states that the lower limit of the hot-working temperature range is the recrystallization temperature.

Forging, rolling, pressing, extruding, swaging, drawing, or forming of metals at temperatures above their recrystallization temperatures are examples of hot working.

HUBER, ROBERT (1937–). Awarded the Nobel prize for chemistry in 1988, along with Johann Deisenhofer and Hartmut Michel, for work that revealed the three-dimensional structure of closely linked proteins that are essential to photosynthesis. Doctorate awarded in 1963 by Technical University of Munich, Germany.

HUMECANTS AND MOISTURE-RETAINING AGENTS. Substances that have affinity for water, with stabilizing action on the water content of a material, are called *humectants* or moisture-retaining agents. Ideally, a humectant maintains within a rather narrow range the moisture content caused by humidity fluctuations. These materials are widely used in certain food products, as well as tobacco, and in recent years have taken on increasing importance in the case of intermediate-moisture foods. Traditionally, humectants have been used to retain moisture in foods like coconut and marshmallows which otherwise would quickly dry and become tasteless. For example, flaked coconut is kept moist in the container by adding glycerine and glyceryl monostearate.

Among the most commonly used humectant are glycerine, potassium polymetaphosphate, propylene glycol, sodium chloride, sorbitol, sucrose, and triacetin. Also, phosphates are added to the pickling solutions used to treat cured meats, such as ham, bacon, corned beef, etc., by soaking or injection. Their principal purpose is for moisture binding to reduce the loss of fluids during curing and cooking.

During the last few years, important research has gone into the addition of multiple humectants and water to food systems. Studies have shown that a hysteresis effect may occur with certain humectants, i.e., a different rate of moisture absorption than the rate for moisture desorption. Multiple humectants tend to compensate these hysteresis effects, giving uniform rates in both directions.

HUME-ROTHERY RULES. When alloy systems form distinct phases, it is found that the ratio of the number of valence electrons to the number of atoms is characteristic of the phase (e.g., β, γ-, ϵ-) whatever the actual elements making up the alloy. Thus, both $Na_{31}Pb_8$ and Ni_5Zn_{21} are γ-structures, with the electron-atom ratio 21:13. The rules are explained by the tendency to form a structure in which all the Brillouin zones are nearly full, or else entirely empty.

HUMIDITY. Generally, some measure of water-vapor content of air. *Absolute humidity* is the ratio of the mass of water vapor present to the volume occupied by the mixture; that is, the density of the water vapor component. The percentage of water vapor in the total composition of the air may be determined by passing a measured quantity of air through a tube containing an absorbing substance that removes all the vapor, and which can be weighed before and after the absorption.

Absolute humidity is usually expressed in grams of water vapor per cubic meter or, in engineering practice, in grains per cubic foot. Because this measure of atmospheric humidity is not conservative with respect to adiabatic expansion or compression, it is not commonly used by meteorologists. As occasionally used in air-conditioning practice, absolute humidity refers to the number of grains of water vapor per pound of moist air, which is dimensionally identical with the specific humidity (defined below).

Critical humidity is the point at which the partial pressure of water vapor in the atmosphere is equal to the saturation vapor pressure. Condensation on suitable nuclei will occur when the humidity reaches or exceeds this value.

Relative humidity is the ratio of the actual vapor pressure of the air, at any temperature, to the maximum of saturation vapor pressure at the same temperature. It expresses the vapor content as a fraction or percentage of the concentration necessary to render the vapor saturated at the given temperature. At the dew point, the relative humidity is 100%. A rise of temperature without the addition of more vapor reduces the relative humidity (but not the absolute humidity), while a fall of temperature increases it and may bring about saturation. Relative humidity is measured by the hygrometer.

Specific humidity is the (dimensionless) ratio of the mass of water vapor to the total mass of the system. It may be approximated by the mixing ratio for many purposes:

$$q = \frac{w}{1 + w}$$

where q is the specific humidity and w the mixing ratio.

See also **Hygrometry and Psychrometry**.

HYATT, JOHN WESLEY (1837–1920). Hyatt is generally credited as being the father of the plastics industry. In 1869, he and his brother patented a mixture of cellulose nitrate and camphor which could be molded and hardened. Its first commercial use was for billiard balls. The TM "Celluloid" was the first ever applied to a synthetic plastic product; it flammability hazard limits its use.

HYDANTOIN AND ITS DERIVATIVES. Hydantoin is an accepted name for 2,4-imidazolidinedione. This ring system rarely occurs in nature, although some natural products with hydantoin substructures are known. A huge number of derivatives have been prepared.

Physical Properties

Hydantoins are crystalline solids with high melting points, particularly those compounds in which nitrogen is unsubstituted, because this allows intermolecular association by hydrogen bonds. Hydantoins are weak acids which dissociate at the imidic N – 3–H atom because this allows more efficient delocalization of the negative charge than ionization at N-1.

Several structure—acidity relationships have been established for hydantoin derivatives. Thus, ionization is known to be unaffected by alkyl substituents at N-1 and at C-5. However, aryl and other electron withdrawing groups can considerably enhance the acidity of hydantoins. Introduction of an arylmethylene side chain at C-5 increases the acidity of the N-1 hydrogen, making it measurable. This is due to delocalization of the negative charge at N-1 into the C-5 substituent.

Solvent variation can greatly affect the acidity of hydantoins. Water provides a better stabilization for the hydantoin anion and hence an increased acidity when compared to DMSO. 2-Thiohydantoin (pK_a 8.5) is a slightly stronger acid than hydantoin (pK_a 9.0). 4-Thiohydantoins appear to be weaker acids.

Spectral Properties. Hydantoin derivatives show weak absorption in the uv-visible region, unless a part of the molecule other than the imidazolidinedione ring behaves as a chromophore; however, pK_a values have been determined by spectrophotometry in favorable cases. Absorption of uv by thiohydantoins is more intense. Several pK_a values of thiohydantoins have been determined by uv-visible spectrophotometry.

Chemical Properties. Hydantoins can react with electrophiles at both nitrogen atoms and at C-5. The electrophilic carbonyl groups can be attacked by nucleophiles, leading to hydrolysis of the ring or to partial or total reduction of the carbonyl system. Other reactions are possible, including photochemical cleavage of the ring.

Synthesis

Synthesis From α-Amino Acids and Related Compounds. Addition of cyanates, isocyanates, and urea derivatives to α-amino acids yields hydantoin precursors. This method is called the Read synthesis, and can be considered as the reverse of hydantoin hydrolysis. Thus the reaction of α-amino acids with alkaline cyanates affords hydantoic acids, which cyclize to hydantoins in an acidic medium.

In a modification of the original method, Read replaced α-amino acids with α-amino nitriles. Chlorosulfonyl isocyanate is an excellent alternative to alkaline cyanates in the preparation of hydantoins from sterically hindered or labile amino nitriles.

Substitution of alkaline cyanates by isocyanates allows the preparation of 3-substituted hydantoins, both from amino acids and amino nitriles.

A variety of α-amino acid derivatives, including the acids themselves, halides, esters, and amides can be transformed into hydantoins by condensation with urea. α-Hydroxy acids and their nitriles give a similar reaction.

Synthesis From Aldehydes and Ketones. Treatment of aldehydes and ketones with potassium cyanide and ammonium carbonate gives hydantoins in a one-pot procedure (Bucherer-Bergs reaction) that proceeds through a complex mechanism. Some derivatives, like oximes, semicarbazones, thiosemicarbazones, and others, are also suitable starting materials.

Synthesis From Thiohydantoins. A modification of the Bucherer-Bergs reaction consisting of treatment of an aldehyde or ketone with carbon disulfide, ammonium chloride, and sodium cyanide affords 2,4-dithiohydantoins. 4-Thiohydantoins are available from reaction of amino nitriles with carbon oxysulfide. Both thiocompounds can be transformed into hydantoins.

Health and Safety Factors (Toxicology)

The acute toxicity of hydantoin derivatives seems to be low. Most studies on long-term toxicity of hydantoins deal with phenytoin, due to the wide use of this compound as an anticonvulsant. Long-term toxic effects of phenytoin include folate deficiency due to impaired folate absorption, hypocalcemia and osteomalacia, alterations of carbohydrate metabolism, gingival hyperplasia, and teratogenic effects. These are grouped under the term fetal hydantoin syndrome, which is associated with continued use of hydantoins during the early stages of pregnancy, and consists of mild retardation of physical and mental indexes, dysmorphic faces and, occasionally, cleft palate, cleft lip, and cardiac defects. Formation of cyanide by degradation of hydantoin derivatives used as antiseptics for water treatment has been described, and this fact might have toxicological relevance.

Applications

Halogenated Hydantoins. Halogenation has been achieved by use of a variety of halogenating reagents. These derivatives are employed as

reagents in synthesis and analysis and also as disinfectants and biocides in water treatment.

***N*-Methylolhydantoins.** 1,3-Bis(hydroxymethyl)-5,5-dimethylhydantoin is used extensively as a preservative in cosmetic and industrial applications, and carries EPA registration for the industrial segment. 1-Hydroxymethyl-5,5-dimethylhydantoin is used as an odorless donor of formaldehyde for adhesive applications.

Epoxy Resins. Urethane and ester-extended hydantoin epoxy resins cured with several compounds seem to have better properties than the previous ones.

5-Substituted Hydantoins. 5-Methylhydantoin has been elected from several structures as a formaldehyde scavenger for color photosensitive materials and water-thinned inks and coatings. Although the hydantoin ring itself does not present any medicinal activity, many 5,5-disubstituted hydantoins have shown interesting biological properties, and some of them are used in medicine, particularly as anticonvulsants. Several types of hydantoin derivatives find use as herbicides.

HYDRATE. Excluding the loose usages in which the term hydrate indicates merely the presence of water or of its elements in 2:1 ratio, as in carbohydrate, the term hydrate denotes the appearance of water in compounds. There are a number of ways in which water may appear in stoichiometric proportions in compounds. Moreover, these ways may be described from more than one point of view. A somewhat systematic approach is to view these compounds from the point of view of the extent of integration of the water, or its elements, into the compound.

The term "water of constitution" is a somewhat old usage, applied to compounds in which no H_2O groupings appear in the structure of the compound, but the compound may undergo reaction, usually reversible, in which water is one of the products. Magnesium hydroxide and sulfuric acid could thus be said to have "water of constitution," even though it appears in their structure as hydroxyl groups, or hydroxyl groups and hydrogen atoms (protons).

The term "cationic water" may be used to describe the situation in which water appears in coordination compounds apparently joined to cations by covalent bonds. However, the fact that a number of such compounds exhibit "hydrate isomerism" is evidence for cationic bonding, as well as it is for the existence of other forms of these compounds in which the presence of water is due to electrostatic attractions or crystal stability requirements.

The term "anionic water" describes the situation in which water is joined to anions through covalent bonds, or more frequently, through hydrogen bonds. The type case is copper(II) sulfate pentahydrate, where the cation has a coordination number of four and presumably the fifth molecule of H_2O is bound to the sulfate ion (as well as to other H_2O molecules) by hydrogen bonds.

The term "lattice water" is commonly applied to cases in which the water molecules are occupying definite positions in the crystal lattice but are apparently not coordinated with either cations or anions. Again, clear-cut cases are those in which the compound is so highly hydrated that both lattice water and "ion water" are present.

The water in crystals may, however, be present in other than definite lattice positions. For example, the water molecules may be found in holes in the lattices, or they may occupy random positions in the lattices. The latter situation is often found in ion exchange resins where loss of water, up to a certain point, does not materially change the lattice structure.

Finally, in essentially noncrystalline materials, such as hydrous precipitates and colloidal gels, the water present is at the limiting case of being a hydrate, in which virtually no bonding, in the chemical sense, exists.

HYDRAULIC FLUID. A liquid or mixture of liquids designed to transfer pressure from one point to another in a system on the basis of Pascal's law, i.e., pressure on a confined liquid transmitted equally in all directions. For industrial use, such fluids are based on paraffinic and cycloparaffinic petroleum fractions, usually with added antioxidant and viscosity index improvers. Flame-resistant types include additives such as phosphate esters or emulsions of water and ethylene glycol. The brake fluids used in auto are composed of (1) a lubricant (polypropylene glycol of 1000–2000 mw, a castor oil derivative or a synthetic polymeric mixture of monobutyl ethers of oxyethylene and oxypropylene glycols); (2) a solvent blend (mixture of glycol ethers); and (3) additives for corrosive resistance buffering, etc., bp 375–550°F. The composition and performance characteristics are specified by the Society of Automotive Engineers: http://www.sae.org/.

HYDRAZINE. [CAS: 302-01-2]. $H_2N \cdot NH_2$, formula weight 32.04, colorless, fuming liquid, mp 1°C, bp 113°C, sp gr 1.011, decomposes when heated above 350°C at atmospheric pressure into N_2 and NH_3, also decomposes in presence of a catalyst (e.g., platinum) into N_2 and NH_3. Hydrazine burns when ignited in air with a violet-colored flame. The compound is soluble in all proportions with H_2O and is soluble in alcohol. Hydrazine forms a hydrate with one molecule of H_2O. Upon moderate heating or in a vacuum, the hydrate yields hydrazine and H_2O. Hydrazine is a base slightly weaker than NH_4OH.

Hydrazine is a tonnage chemical with numerous uses, including that of a propellant for rockets, yielding exhaust products at a high temperature and of a low molecular weight; use as a strong reducing agent in the manufacture of various chemicals; and as a blowing agent for foamed rubber. The compound reacts with citric acid to form *Continazin*, an antituberculan drug.

Although the earlier processes for the commercial production of hydrazine used urea as a raw material, modern processes employ direct ammonia oxidation. In one such process, reactions occur in two steps:

$$NH_3 + NaOCl \longrightarrow NH_2Cl + NaOH \qquad (1)$$

$$NH_3 + NH_2Cl + NaOH \longrightarrow H_2N \cdot NH_2 + NaCl + H_2O. \qquad (2)$$

High-grade hypochlorite is required for Step 1. Special agents, such as gelatin, ethylenediamine tetracetic acid, glue, high alcohols, and formaldehyde, are required to inhibit undesirable side reactions that would reduce the hydrazine yield through formation of ammonium chloride and N_2. In another hydrazine process, chlorine, NH_3, and H_2SO_4, along with methylethyl ketone, are used as the charge. The products of this process include hydrazine hydrate, hydrazine sulfate, ketazine, and dialkyldiazacyclopropane. Hydrazine also is used as a start-up ingredient in the preparation of cooling water for nuclear reactors where it is desired to keep the oxygen content of the water to an absolute minimum and thus decrease corrosion. Oxygen reacts with hydrazine. $H_2N \cdot NH_2 + O_2 \longrightarrow N_2 + 2H_2O$. When no oxygen is present in the water, the hydrazine acts as a sink for dissolved oxygen that may enter later, by maintaining metal oxides at their lower oxidation states.

Hydrazine forms two series of salts: (1) hydrazinium (1+) chloride, $H_2NNH_3^+\ Cl^-$, nitrate, $H_2NNH_3^+\ NO_3^-$, hemisulfate, $(H_2NNH_3^+)_2SO_4^{2-}$, (2) hydrazinium (2+) chloride, $H_3NNH_3^{2+}\ (Cl^-)_2$, dinitrate, $H_3NNH_3^{2+}\ (NO_3^-)_2$, hydrogen sulfate, $H_3NNH_3^{2+}\ (HSO_4^-)_2$, all soluble in H_2O. This last is produced when hydrogen azide reacts with concentrated H_2SO_4. It is very hygroscopic and decomposes in aqueous solution to give the slightly soluble monosulfate and H_2SO_4. The monosulfate and difluoride, which have been thought to have the structures $N_2H_5^+\ HSO_4^-$ and $N_2H_5^+\ HF_2^-$ in the solids, have been shown in fact to be $N_2H_6^{2+}\ SO_4^{2-}$ and $N_2H_6^{2+}\ (F^-)_2$. Hydrazinium azide, $N_2H_5^+\ N_3^-$, is a soluble solid.

In the laboratory, hydrazine can be prepared by converting one-half of a given amount of NH_3 into chloramine, NH_2Cl, by sodium hypochlorite solution in the presence of a colloid and heating. The remaining one-half of the NH_3 reacts with chloramine to form hydrazine. The product is then cooled to 0°C and H_2SO_4 added in amount to react with the hydrazine to form hydrazine sulfate, $N_2H_6SO_4$, insoluble solid. Hydrazine hemisulfate, $(N_2H_5)_2SO_4$, is soluble in H_2O. It can also be made by the reaction of NH_3 and hydroxylamine-*O*-sulfonic acid.

Phenylhydrazine is a colorless liquid, slightly soluble in H_2O, miscible in all proportions with alcohol or ether, forms salts with acids, e.g., phenylhydrazine hydrochloride or phenylhydrazinium chloride, $C_6H_5NHNH_3Cl$, is a powerful reducing agent, with alkaline copper(II) salt solution (Fehling's solution) yields copper(I) oxide precipitate, reacts with carbonyl group of aldehydes or ketones yielding phenylhydrazones, white solids, of definite

melting point and utilized in identification of aldehydes and ketones, e.g., acetaldehyde phenylhydrazone, $CH_3CH{:}NNHC_6H_5$.

Phenylhydrazine, as hydrochloride solution plus sodium acetate, reacts with polyhydroxy aldehydes or ketones yielding *osazones* or diphenylhydrazones, yellow solids, of definite melting point and utilized in identification of sugars, e.g., phenyl-d-glucosazone, $CH_2OH\ (CHOH)_3C{:}(NNHC_6H_5)CH{:}(NNHC_6H_5)$ plus aniline $C_6H_5NH_2$ plus NH_3.

Attention should be given to the difference between osazones and osones. An *osone* is formed by reaction of an osazone with HCl, e.g., glucosone, $CH_2OH(CHOH)_3CO \cdot CHO$.

1,1-Diphenylhydrazine is made by reduction of diphenylnitrosamine,, by zinc plus acetic acid, the nitrosamine being formed by reaction of diphenylamine,, and nitrous acid.

Tetraphenylhydrazine is a white solid, soluble in chloroform, acetone, benzene, or toluene, and upon standing is changed into triphenylamine plus azobenzene. In solution, tetraphenylhydrazine dissociates into nitrogen diphenyl, $(C_6H_5)_2N\cdot$, free radical, which in toluene at 90°C reacts with nitric oxide, NO. Tetraphenylhydrazine is formed by oxidation of diphenylamine,, by lead dioxide.

Hydrazine reacts with ketones to form *azines*.

Toxicology

Hydrazine is toxic and readily absorbed by oral, dermal, or inhalation routes of exposure. Contact with hydrazine irritates the skin, eyes, and respiratory tract. Liquid splashed into the eyes may cause permanent damage to the cornea. At high doses it can cause convulsions, but even low doses may result in central nervous system depression. Death from acute exposure results from convulsions, respiratory arrest, and cardiovascular collapse. Repeated exposure may affect the lungs, liver, and kidneys. Evidence is limited as to the effect of hydrazine on reproduction and/or development; however, animal studies demonstrate that only doses that produce toxicity in pregnant rats result in embryotoxicity.

The TLV is set at 0.1 ppm (hydrazine); 0.2 ppm (MMH); and 0.5 ppm (UDMH). The International Agency for Research on Cancer (IARC) classifies hydrazine as a 2B or possible human carcinogen. The American Conference of Governmental Industrial Hygienists (ACGIH) classifies hydrazine as an A2 or suspect human carcinogen.

HYDRAZOIC ACID. [CAS: 7782-79-8]. HN_3, formula weight 43.03, colorless, odorous, poisonous liquid, mp −80°C, bp 37°C, explodes with marked violence. Also known as azoimide and hydronitric acid, the compound is miscible in all proportions with H_2O, alcohol, and ether. Hydrazoic acid reacts (1) with metals, e.g., magnesium, aluminum, zinc, iron, to form azides or hydrazoates (or trinitrides), (2) with heavy metal salt solutions to form insoluble azides, e.g., silver azide AgN_3, mercury(I) azide HgN_3, lead azide PbN_6. Silver, mercury(I), and copper(I) azides decompose in the light to form nitrogen plus the metal. (3) It reacts with NH_4OH to form ammonium azide $NH_4 \cdot N_3$, (4) with hydrazine to form hydrazine azide $N_2H_4 \cdot HN_3$, (5) with sodium hypochlorite plus acetic acid to form chlorazide ClN_3, explosive, (6) with sodium amalgam to form NH_3 with some hydrazine, (7) with potassium permanganate to form nitrogen and H_2O.

Hydrazoic acid is formed (1) by reaction of sodium nitrate with molten sodamide, (2) by reaction of nitrous oxide with molten sodamide, (3) by reaction of nitrous acid and hydrazinium ion ($N_2H_5^+$), (4) by oxidation of hydrazinium salts, (5) by reaction of ethyl nitrite with NaOH solution and acidifying. See also **Azides**.

HYDRAZONES. The products of the reaction between an aldehyde or a ketone with phenylhydrazine are termed *hydrazones*. Sometimes the compounds are referred to as phenylhydrazones.

$$\underset{\text{(acetaldehyde)}}{CH_3{\cdot}CHO} + \underset{\text{(phenylhydrazine)}}{C_6H_5{\cdot}NH{\cdot}NH_2} \longrightarrow \underset{\text{(acetaldehyde hydrazone)}}{CH_3{\cdot}CH{:}N{\cdot}NH{\cdot}C_6H_5} + H_2O$$

$$\underset{\text{(benzaldehyde)}}{C_6H_5CHO} + C_6H_5{\cdot}NH{\cdot}NH_2 \longrightarrow \underset{\text{(benzylidenehydrazone)}}{C_6H_5{\cdot}CH{:}N{\cdot}NH{\cdot}C_6H_5} + H_2O$$

$$\underset{\text{(acetone)}}{(CH_3)_2CO} + C_6H_5{\cdot}NH{\cdot}NH_2 \longrightarrow \underset{\text{(acetonehydrazone)}}{(CH_3)_2C{:}N{\cdot}NH{\cdot}C_6H_5} + H_2O$$

$$\underset{\text{(acetophenone)}}{C_6H_5{\cdot}CO{\cdot}CH_3} + C_6H_5{\cdot}NH{\cdot}NH_2 \longrightarrow \underset{\text{(acetophenonehydrazone)}}{(C_6H_5)(CH_3)C{:}N{\cdot}NH{\cdot}C_6H_5} + H_2O$$

Several of the hydrazones may be decomposed by strong acids whereupon the original aldehyde or ketone is regenerated, along with the formation of a phenylhydrazine salt. When reduced, hydrazones yield primary amines.

HYDRIDES. Hydrides are compounds that contain hydrogen in a reduced or electron-rich state. Hydrides may be either simple binary compounds or complex ones. In the former, the negative hydrogen is bonded ionically or covalently to a metal, or is present as a solid solution in the metal lattice. In the latter, which comprise a large group of chemical compounds, complex hydridic anions such as BH_4^-, AlH_4^-, and derivatives of these, exist.

Commercial applications of hydrides have become important and some of these compounds have become industrial chemicals manufactured and used on a large scale.

Simple (Binary) Hydrides

Ionic Hydrides. The ionic or saline hydrides contain metal cations and negatively charged hydrogen ions. They crystallize in the cubic lattice similar to the corresponding metal halide, and when pure, are white solids. When dissolved in molten salts or hydroxides and electrolyzed, hydrogen gas is liberated at the anode. Their densities are greater than those of the parent metal, and their formation is exothermic. All are strong bases.

Physical properties of the alkali metal hydrides are given in Table 1. Sodium hydride finds commercial usage in organic synthesis in condensation and alkylation reactions.

Table 2 gives thermochemical data of alkaline-earth metal hydrides. All form orthorhombic crystals. Calcium hydride is a convenient portable source of hydrogen gas, which results from its reaction with water.

TABLE 1. PHYSICAL PROPERTIES OF ALKALI METAL HYDRIDES

Hydride	Mp, °C	$\Delta H_{(298)}$, kJ/mol[a]	$\Delta F_{(298)}$, kJ/mol[a]	S, J/(mol · K)[a]	Lattice energy, kJ/mol[a]	Density, g/cm³

vanadium hydride	VH	5.4
niobium hydride	NbH	6.6
niobium dihydride[a]	NbH_2	
tantalum hydride	TaH	15.1

[a] Decomposes slowly.

Covalent Hydrides. Table 3 gives some properties of these compounds. Transition-metal hydrides, i.e., interstitial metal hydrides, have metallic properties, conduct electricity, and are less dense than the parent metal. These hydrides are much harder and more brittle than the parent metal, and most have catalytic activity. They include titanium hydride, TiH_2, zirconium hydride, ZrH_2, rare earth hydrides (lanthanum dihydride, lanthanum trihydride, cerium hydride, CeH_2), group 5 (VB) hydrides (Table 4), and hydrogen storage alloys (FeTi, $LaNi_5$, Mg_2TiH_6, and $MgTi_2H_6$).

Complex Hydrides

The complex hydrides are a large group of compounds in which hydrogen is combined in fixed proportions with two other constituents, generally metallic elements. These compounds have the general formula $M(M'H_4)_n$, where n is the valence of M, and M′ is a trivalent Group 3 (IIIA) element such as boron, aluminum, or gallium. The most important complex hydrides are listed in Table 5.

Borohydrides. The alkali metal borohydrides are the most important complex hydrides. They are ionic, white, crystalline, high melting solids that are sensitive to moisture but not to oxygen. They include lithium borohydride, $LiBH_4$, and sodium borohydride, $NaBH_4$.

Complete hydrolysis of $NaBH_4$ produces 2.37 L hydrogen (STP) per gram of borohydride; similarly, addition of acid to a cold aqueous solution liberates the theoretical amount of hydrogen. The inorganic reductions of $NaBH_4$ are numerous and varied. Sodium borohydride reacts with boron halides to form diborane, B_2H_6, which is more conveniently handled as the monomer BH_3 complexed with an ether, sulfide, or amine. Sodium borohydride is used extensively for the reduction of organic compounds. Sodium borohydride is manufactured from sodium hydride and trimethyl borate in a mineral oil medium at about 275°C. Sodium borohydride is classified as a flammable solid. It is available as powder, caplets, and granules and as a 12% solution in caustic soda. The principal uses of $NaBH_4$ are in synthesis of pharmaceuticals and fine organic chemicals; removal of trace impurities from bulk organic chemicals; wood-pulp bleaching, clay leaching, and vat-dye reductions; and removal and recovery of trace metals from plant effluents.

TABLE 5. COMPLEX HYDRIDES

Formula	Density, g/cm^3	Mp, °C
$LiBH_4$	0.66	278
$NaBH_4$	1.074	505

[a] Bp, 44.5°C.

Potassium borohydride was formerly used in color reversal development of photographic film and was preferred over sodium borohydride because of its much lower hygroscopicity. Because other borohydrides are made from sodium borohydride, they are correspondingly more expensive. Generally their reducing properties are not sufficiently different to warrant the added cost Zinc borohydride, $Zn(BH_4)_2$, however, has found many applications in stereoselective reductions.

Borohydride Derivatives. Modification of the BH_4^- anion has provided derivatives of widely differing reducing properties. Alkoxyborohydrides, such as sodium trimethyoxyborohydride, $NaBH(OCH_3)_3$, exhibit enhanced reducing power but are less selective and more sensitive to decomposition by water. Sodium cyanoborohydride, $NaBH_3CN$, on the other hand, shows weakened reducing properties and is unique among the complex hydrides because it is stable in acidic aqueous solutions to a pH of about 3.

Sodium or tetramethylammonium triacetoxyborohydride has become the reagent of choice for diastereoselective reduction of β-hydroxyketones to antidiols. Trialkylborohydrides, e.g., alkali metal tri-*sec*-butylborohydrides, show outstanding stereoselectivity in ketone reductions.

Aluminohydrides. In general, the aluminohydrides are more active and powerful reducing agents than the corresponding borohydrides. They decompose vigorously with water. Reaction also occurs with alcohols, although more moderately, providing a route to substituted derivatives.

Freshly prepared lithium aluminum hydride is a white crystalline solid that tends to become gray during storage, although very little loss in purity occurs. Although lithium aluminum hydride is best known as a nucleophilic reagent for organic reductions, it converts many metal halides to the corresponding hydride, e.g., Ge, As, Sn, Sb, and Si. Commercial manufacture of $LiAlH_4$ uses the original synthetic method, i.e., addition of a diethyl ether solution of aluminum chloride to a slurry of lithium hydride.

Sodium aluminum hydride can be prepared from NaH, but direct synthesis from the elements is more economical.

Aluminohydride Derivatives. The few known derivatives of the aluminohydrides are principally alkoxy substitutions, including the trimethoxy, $LiAlH(OCH_3)_3$, triethoxy, $LiAlH(OC_2H_5)_3$, and tri-*t*-butoxy aluminohydrides, $LiAlH(O\text{-}t\text{-}C_4H_9)_3$.

Health and Safety Factors

In general, hydrides react exothermically with water, resulting in the generation of hydrogen. This hydrolysis reaction is accelerated by acids or heat and, in some instances, by catalysts. Because the flammable gas hydrogen is formed, a potential fire hazard may result unless adequate ventilation is provided. Ingestion of hydrides must be avoided because hydrolysis to form hydrogen could result in gas embolism.

Another aspect of the hydrolysis of hydrides is the alkalinity that results, especially from alkali metal and alkaline-earth hydrides. This alkalinity can cause chemical burns in skin and other tissues. Hydrolysis considerations obviously demand that hydrides be kept away from contact with acids.

Although there is little toxicity information published on hydrides, a threshold limit value (TLV) for lithium hydride in air of 25 $\mu g/m^3$ has been established. More extensive data are available for sodium borohydride in the powder and solution forms. The acute oral LD_{50} of $NaBH_4$ is 50–100 mg/kg for $NaBH_4$ and 500–1000 mg/kg for the solution. The acute dermal LD_{50} (on dry skin) is 4–8 g/kg for $NaBH_4$ and 100–500 mg/kg for the solution. The reaction or decomposition by-product sodium metaborate is slightly toxic orally (LD_{50} is 2000–4000 mg/kg) and nontoxic dermally.

HYDROBORATION. The reaction of diboranes either with alkenes (olefins) to form trialkylboron compounds or with acetylene to yield alkenylboranes. Much research has been devoted to developing these reactions, the products of which are called organoboranes. They are useful in many complex organic syntheses, including prostaglandins and insect pheeromones.

HYDROCARBONS. See **Organic Chemistry**.

HYDROCHLORIC ACID. [CAS: 7647-01-0]. HCl (hydrogen chloride gas) in aqueous solution, colorless when pure. Commercial grades of HCl (also known as muriatic acid) generally are marketed in three concentrations: (1) 18° Bé (sp gr 1.1417 at 15.6°C, 27.92% HCl); (2) 20° Bé (sp gr 1.160, 31.45% HCl); and (3) 22° Bé (sp gr 1.1789, 35.21% HCl). Frequently the commercial grades are slightly yellow because of impurities, notably dissolved iron. Fuming hydrochloric acid contains about 37% HCl, with a sp gr 1.194. Reagent grade hydrochloric acid usually is of this latter high strength, and is perfectly clear and colorless. The maximum limits set on impurities commonly are: NH_4 0.003%; arsenic 0.000001%; free chlorine 0.0001%; heavy metals, such as lead 0.001%; iron 0.00002%; sulfates 0.0001%; sulfites 0.0001%; and residue after ignition 0.0005%. A mixture of three parts HCl and one part is HNO_3 known as *aqua regia*, a powerful solvent and oxidizing agent which will dissolve materials that may be unaffected by either acid alone. Gold and platinum are soluble in aqua regia.

Hydrochloric acid is a very-high-tonnage chemical, finding major uses in (1) the cleaning and preparation of metals prior to application of coatings, (2) the recovery of zinc from galvanized iron scrap, (3) the production of numerous chlorides, and (4) production of chlorine. At one time, HCl was extensively used as a source of both hydrogen and chlorine by way of electrolysis. This process was made obsolete many years ago when the chlor-alkali process (electrolysis of sodium chloride brines) was introduced for the production of chlorine. In recent years, however, the production of byproduct HCl, resulting from chlorination of numerous organic compounds, has increased. In some of these instances, the installation of a HCl electrolysis plant may be economically feasible. For industrial consumption anhydrous HCl gas also is available in steel cylinders under a pressure of 1,000 psi (68 atmospheres). Hydrochloric acid forms a constant-boiling solution with H_2O (20.22% HCl) which has a bp 108.58°C (760 mm Hg).

Dilute HCl reacts (1) with many hydroxides, e.g., NaOH, to yield the corresponding chloride, e.g., sodium chloride, solution, (2) with many ordinary oxides, e.g., magnesium oxide, to yield the corresponding chloride, e.g., magnesium chloride, solution, (3) with many carbonates, e.g., calcium carbonate, to yield the corresponding chloride, e.g., calcium chloride solution plus CO_2, (4) with many sulfides, e.g., ferrous sulfide, to yield the corresponding chloride, e.g., ferrous chloride, solution plus H_2S, (5) with many metals, e.g., zinc (but not copper) to yield the corresponding chloride, e.g., zinc chloride, solution plus hydrogen gas, (6) with some special oxides, e.g., lead or manganese dioxide, to yield lead or manganese chloride plus chlorine gas, (7) with solution of some salts, e.g., silver nitrate, to yield the corresponding chloride, silver chloride, precipitate. Higher strengths of hydrochloric acid usually react similarly to the dilute. Hydrochloric acid sometimes reacts as a reducing acid, e.g., (6) above.

All metallic chlorides, except silver chloride and mercurous chloride, are soluble in H_2O, but lead chloride, cuprous chloride and thallium chloride are only slightly soluble. Metallic chlorides when heated melt, and volatilize or decompose, e.g., sodium chloride, mp 804°C; calcium, strontium, barium chloride volatilize at red heat; magnesium chloride crystals yield magnesium oxide residue and hydrogen chloride; cupric chloride yields cuprous chloride and chlorine. See also **Chlorine**; **Chlorinated Organics**; **Halides**; **Hypochlorites**; and **Sodium Chloride**.

Hydrogen Chloride

This is a colorless gas, heavier than air, density 1.639 g/l at standard conditions. The gas is poisonous and quickly causes suffocation. Formula weight 36.47, mp −111°C, bp −85°C, critical pressure 83 atm, critical temperature 51.3°C. The gas is very soluble in H_2O, accounting for the high concentrations of hydrochloric acid obtainable. Although hydrogen chloride gas may be used directly in some industrial operations, normally it is generated for the purpose of dissolving in H_2O to form hydrochloric acid. The most common route to HCl is by reacting sodium chloride with H_2SO_4. This is a two-step, exothermic reaction: (1) $NaCl + H_2SO_4 \longrightarrow NaHSO_4 + HCl$, and (2) $NaCl + NaHSO_4 \longrightarrow Na_2SO_4 + HCl$. Preparation of hydrochloric acid from the gas involves an absorption tower where the gas meets a fine spray of H_2O. Ratio controllers are used to assure maximum yield of the acid of desired concentration. These controls are easily adjusted for obtaining different concentrations. In most chlorinations of organic compounds, only half of the chlorine is used to substitute for hydrogen atoms, the remaining chlorine forming HCl. Frequently, this byproduct HCl is recycled or recovered.

HYDROCOLLOID. A hydrophilic colloidal material used largely in food products as emulsifying, thickening, and gelling agents. They readily absorb water, thus increasing viscosity and imparting smoothness and body texture to the product, even in concentrations of less than 1%. Natural types are plant exudates (gum arabic), seaweed extracts (agar), plant seed gums or mucilages (guar gum), cereal gums (starches), fermentation gums (dextran), and animal products (gelatin). Semisynthetic types are modified celluloses and modified starches. Completely synthetic types are also available, e.g., polyvinylpyrolidone. Most are carbohydrate polymers, but a few such as gelatin and casein are proteins.

HYDRODEALKYLATION (HDA). A type of hydrogenation used in petroleum refining in which heat and pressure in the presence of hydrogen are used to remove methyl or larger alkyl groups from hydrocarbon molecules, or to change the position of such groups. The process is used to upgrade products of low value, such as heavy reformate fractions, naphthenic crudes, or recycle stocks from catalytic cracking. Also toluene and pyrolysis gasoline are converted to benzene, and methyl naphthalenes to naphthalene, by this process.

See also **Hydrogenation**.

HYDROFORMING. The use of hydrogen in the presence of heat, pressure, and catalysts (usually platinum) to convert olefinic hydrocarbons to branched chain paraffins (isomerization) to yield high-octane gasoline. Catforming and similar terms are often used in the same sense.

HYDROGEN. [CAS: 1333-74-0]. Chemical element symbol H, at. no. 1, at. wt. 1.008, periodic table group 1, mp −259.14°C, bp −252.87°C, density 0.089 (solid at 4.2 K), 0.071 (liquid at 20.4 K), sp gr 0.0696 (air = 10,000). Solid hydrogen has a hexagonal crystal structure. Hydrogen at standard conditions is a colorless, odorless, tasteless gas, suffocating, but not toxic. Hydrogen occurs chiefly combined with oxygen in H_2O, with carbon in hydrocarbons, with carbon and oxygen, and with carbon and several other elements, including oxygen, nitrogen, sulfur, phosphorus, and most metals in a vast variety of hundreds of thousands of organic compounds. See also **Organic Chemistry**. Hydrogen is considered by some scientists as the primordial substance from which all other elements in the universe were developed. In terms of cosmic abundance, with a rating of silicon = 10,000, it has been estimated that the figure for hydrogen

is about 3.5×10^8, this figure compared with that of carbon = 80,000, nitrogen = 160,000, and oxygen = 220,000. For further comparison, the figure for gold is 0.0015 and for uranium it is 0.0002. In terms of abundance of the chemical elements in seawater, hydrogen ranks second (behind oxygen) with an estimated 510 million tons per cubic mile (~109 million metric tons per cubic kilometer). Hydrogen ranks eleventh in terms of content in igneous rocks in the earth's crust, the estimate of average content being 0.13%. Although free hydrogen escaped from the earth's lower atmosphere, some of the planets appear to have significant amounts, including the atmospheres of Jupiter, Saturn, and Uranus. At an altitude of 1,000 miles (1609 kilometers) above the surface of the earth, there is a greater abundance of hydrogen atoms than of nitrogen or oxygen atoms.

Hydrogen was first identified by Cavendish in 1766. The element was named by Lavoisier in 1783. However, it was not until 1931 that a second isotope of hydrogen (deuterium) with a mass number 2 was discovered by Urey. In 1934, Rutherford, Oliphant, and Harteck prepared a third isotope (tritium) with a mass number 3. Normal hydrogen (protium) and deuterium are stable, whereas tritium is radioactive, with a half-life of 12.26 years. Tritium emits a negative electron to form ^{3}H. It is estimated that the isotopic abundance of ^{1}H (protium) in natural occurring hydrogen is 99.9851% and on the basis of carbon = 12 (atomic weight scale), protium has a mass of 1.007825 amu. The isotopic abundance of ^{2}H (deuterium) is estimated at 0.0149% with a mass of 2.014101 amu. The artificially prepared ^{3}H (tritium), $^{9}Be + {}^{2}H \rightarrow 2\ {}^{4}He + {}^{3}H$, has a mass of 3.01605 amu. Heavy water is deuterium oxide, $^{2}H_2O$, usually written D_2O. Deuterium and deuterium oxide gained prominence largely because of their excellent properties as moderators in nuclear reactors. The ionization potential of hydrogen is 13.59765 ± 0.00022 eV. Other physical properties of hydrogen are given under **Chemical Elements**. See also **Deuteron**; and **Deuterium**.

When ignited, hydrogen burns in air with a pale blue to colorless, nonluminous flame, yielding H_2O. When mixed with air, the flammability limit is 4–74% hydrogen. When mixed with oxygen, the flammability limit is 4–94% hydrogen. Care always must be exercised where there may be hydrogen mixtures with air or oxygen because violent explosions may occur. In sunlight or magnesium light, hydrogen combines with chlorine with violent release of energy, forming hydrogen chloride HCl. When hydrogen is heated with sodium, calcium, and several other metals, the corresponding hydride is formed. In the presence of a catalyst, hydrogen reacts with nitrogen to form ammonia NH_3. Upon heating sulfur in the presence of hydrogen, hydrogen sulfide, H_2S, is formed. At elevated temperatures, hydrogen will reduce many of the metal oxides to the metal, notably copper, iron, nickel, tin, and lead. The oxides of zinc, aluminum, and magnesium are not so reduced. Hydrogen reacts with unsaturated organic compounds in most cases to form saturated compounds. For example, in the presence of a catalyst, hydrogen will add to oleic acid $C_{17}H_{33}COOH$ to form stearic acid $C_{17}H_{35}COOH$. See also **Hydrogenation**.

Production of Hydrogen

For chemical and petroleum processes, hydrogen is an extremely high-tonnage and one of the most fundamental raw materials. Sources of hydrogen and processes for producing it are described in entry on **Hydrogen (Fuel)**.

Uses

In terms of consumption, NH_3 is by far the largest user of hydrogen. Petroleum refining processes and methanol synthesis are the next largest consumers. Hydrogen needs for these uses are almost always fulfilled by hydrogen-generation capacity on the premises. What might be termed commodity hydrogen is shipped from hydrogen plants to various users. Some of the more important uses include the hydrogenation of numerous organic compounds, such as vegetable and animal oils, the oxyhydrogen and atomic-hydrogen welding applications, the reduction of several metallic oxides, such as iron, copper, nickel, cobalt, tungsten, and molybdenum, and the use of liquid hydrogen as a rocket fuel. See also **Ammonia**; **Hydrogenation**; **Methyl Alcohol**; **Petrochemicals**; and **Synthesis Gas**. For the potential role as a fuel. See also **Hydrogen (Fuel)**.

Ortho- and Para-Hydrogen

On the basis of nuclear spin, two forms of hydrogen are known: *ortho-hydrogen*, in which the two nuclei in the H_2 molecule have parallel spins, and *para-hydrogen*, in which the nuclear spins are antiparallel. At ordinary temperatures (and above) ortho-hydrogen is present to the extent of about 75%; at lower temperatures, the ortho changes to para-hydrogen, until at very low temperatures, as that of liquid hydrogen, the para form is present to the extent of 99.7%. There is some difference in properties between the two, notably in thermal conductivity.

The transition from ortho- to para-hydrogen releases heat in amount of 168 cal/g. The heat of vaporization of liquid hydrogen is 107 cal/g. Thus, more than ample heat is released to revaporize liquid hydrogen. Knowledge of the existence of the ortho-para transition and the development of catalysts to equilibrate the liquid during liquefaction essentially have made possible the very large-scale manufacture, use, and storage of liquid hydrogen.

Below −220°C the specific heat of hydrogen is that of a monoatomic gas like helium (He). Practically pure para-hydrogen may be obtained by adsorption of ordinary hydrogen, which is three-fourths ortho and one-fourth para, on charcoal at about −225°C. The mp of para-hydrogen is 0.13°C lower (ortho-hydrogen 0.04°C higher) than ordinary hydrogen, and the bp at 60 mm pressure is 0.13°C lower (ortho-hydrogen 0.04°C higher) than ordinary hydrogen. Para-hydrogen reverts slowly to ordinary hydrogen, but immediately in the presence of platinized asbestos.

Atomic Hydrogen

At high temperatures, the loss of heat from a glowing wire in hydrogen is larger than expected on regular assumptions. This is believed to be due to dissociation of ordinary hydrogen into atomic hydrogen (H). See Table 1.

When hydrogen is passed through an electric arc between tungsten poles, a considerable transformation into atomic hydrogen occurs, and when a stream of this gas strikes a surface a large evolution of heat takes place through recombination to ordinary hydrogen. This atomic hydrogen flame is of temperature sufficiently high to melt tungsten (mp 3, 370°C). The half-life of the hydrogen atom is one-third second at 0.5 mm pressure. This reaction is endothermic, values of 98–105 kcal per mole having been reported for it. It is an active reducing agent, reducing many metallic oxides and halides to the free metals, and forming hydrides with many nonmetals. The energy of its exothermic recombination is utilized, in combination with the energy released by the oxidation of the H_2 formed, by atmospheric oxygen, in the oxyhydrogen welding process.

Ionization

The ionization potential of hydrogen is 13.59765 ± .00022 eV, and the ionization process (in the case of protium) yields an electron and a free proton. The electric field of the proton is strong, due to its small radius, so that it readily combines with polarizable atoms. Thus, in aqueous solution, it shares an unshared pair of electrons of the oxygen atom of H_2O to form H_3O^+, the hydronium ion; with NH_3 it forms NH_4^+, the ammonium ion; with phosphine it forms the phosphonium ion, PH_4^+, etc. The hydrogen atom can also add an electron, to form the hydride anion, H^-, this potential (electron affinity) being only about 0.7 eV. Hydride ions have been shown (by electrolysis, crystal structure, etc.) to exist in the hydrides which hydrogen forms with the alkali metals and some of the other metals on the left side of the periodic table. While most other hydrogen compounds are essentially covalent, the binary compounds with the halogens and some of the other elements on the right side of the periodic table exhibit a considerable degree of ionicity, varying considerably in the same group.

The hydrogen atoms in many compounds tend to be shared between the electronegative atom or group to which they are attached and similar groups on other molecules. These hydrogen bonds increase the intermolecular forces and boiling points of hydrogen fluoride, water, organic acids and alcohols, etc. A descriptive explanation of the process is the positive polarity of the H atom that is attached to the electronegative atom or group, which gives it an effective coordination number of 2, so that it can attract an unshared electron pair of a fluorine, oxygen, nitrogen, atom of

TABLE 1. DISSOCIATION OF HYDROGEN

	Pressure	
Temperature, °C	At 760 mm	At 1 mm
1730	0.33%	8.7%
2230	3.1	57.5
2730	34	99.3

another molecule. The atom having the unshared pair must be negatively polarized or easily polarizable. For example, tertiary arsines form stronger hydrogen bonds with phenols than do tertiary phosphines.

A number of hydrogen compounds ionize to yield solvated protons, i.e., $2H_2O \rightleftharpoons OH_3^+ + OH^-$, and $2NH_3(\text{liq.}) \rightleftharpoons NH_4^+ + NH_2^-$. Moreover, many hydrogen compounds, when dissolved in such solvents, ionize more or less completely to give solvated protons and anions. In the case of polybasic acids, ionization constants are reported for each step in this dissociation.

Hydrides

See section on hydrides in entry on **Hydrogen (Fuel)**; and separate entry on **Hydrides**.

Water and Acids

The properties of the most prevailing hydrogen-bearing compound, water, are given under **Water**. The characteristics of acids are attributed essentially to the presence of hydrogen ions. These topics are treated under **Acids and Bases**; and **pH (Hydrogen Ion Concentration)**.

Hydrogen Under Extreme Pressure

Interest in the possible existence of hydrogen as a metal is spurred by the prospect that hydrogen may be able to conduct electricity with zero resistance near room temperature and that, because of the tremendous concentration of energy, as contrasted with liquid hydrogen, it could serve as a rocket fuel and high explosive.

In 1989, Mao and Hemley (Geophysical Laboratory, Carnegie Institution of Washington) reported on an investigation of the insulator-metal transformation in solid hydrogen at high pressure. Much earlier, theoretical calculations made by Wigner and Huntington (1935) revealed that the transition may occur in the 250-to-400 GPa (2.5-to-40 megabar) range. With the high-pressure research tools (diamond anvil cell) available today, this transition point of hydrogen has become a primary target for some researchers.

Mao and Hemley (see reference listed) reported that direct optical observations of solid hydrogen at the aforementioned pressure range and at 77 K indicated that the hydrogen sample appeared nearly opaque and that optical data were consistent with a band-overlap mechanism of metallization. These findings were later challenged by Silvera (reference listed) to the effect that "Visual darkening of a sample is not sufficient evidence of metallization, just as a lustery metallic reflection is not. Good examples are the semiconductors germanium and silicon, which as thin films, are metallic in appearance. Darkening of a sample can arise from any number of physical mechanisms that cause absorption throughout the visible spectrum." Further justification, however, was given by Mao and Hemley.

In mid-1991, Badding, Hemley, and Mao reported on studies of the high-pressure chemistry of hydrogen in metals and made specific studies of the reaction between iron and hydrogen at sudden pressure-induced expansion at 3.5 gigapascals of iron samples immersed in fluid hydrogen. The investigators mention numerous specific areas of interest that may be addressed with a better understanding of the behavior of hydrogen with metallic environments, including the hydrogen degradation of ferrous metals.

HYDROGENATION. In its simplest interpretation, to hydrogenate is to add hydrogen. There are scores of examples where hydrogenation is used as a unit process throughout the chemical and process industries. Generally, the process is associated with relatively high pressure, elevated temperature, and the presence of a catalyst.

Nickel, prepared in finely divided form by reduction of nickel oxide in a stream of hydrogen gas at about 300°C, was introduced by Sabatier (1897) as a catalyst for the reaction of hydrogen with unsaturated organic substances to be conducted at about 175°C. Nickel proved to be one of the most successful catalysts for such reactions. The unsaturated organic substances that are hydrogenated are usually those containing a double bond, but those containing a triple bond also may be hydrogenated. Platinum black, palladium black, copper metal, copper oxide (Adkin catalyst), nickel oxide, aluminum, and other materials have subsequently been developed as hydrogenation catalysts. Temperatures and pressures have been increased in many instances to improve yields of desired product. The hydrogenation of methyl ester to fatty alcohol and methanol for example, occurs at about 3,000 psig (204 atmospheres) and 290–315°C. In the hydrotreating of liquid hydrocarbon fuels to improve quality, the reaction may take place in fixed-bed reactors at pressures ranging from 100 to 3,000 (7 to 204 atmospheres) psig. Many hydrogenation processes are of a proprietary nature, with numerous combinations of catalysts, temperature, and pressure possible.

Among the better known products of hydrogenation are hydrogenated vegetable and fish oils, which may be hardened or solidified by catalytic hydrogenation. Some of these oils can be partially hydrogenated to clarify and deodorize them. Fatty oils, such as oleic acid, may be converted into stearic acid by hydrogenation. Through hydrogenation, peanut oil, cottonseed oil, and coconut oil can be converted to materials that taste, appear, and smell like lard; or by varying the process, they can be made to resemble tallow. Most synthetic shortenings are comprised of hydrogenated oils. Usually, hydrogenated oils will have higher melting points and lower iodine values than the natural untreated oils.

Hydrogenation of Coal and Crudes

The interest in hydrogenation has been greatly intensified since the early- and mid-1970s in connection with the synthesis of new types of fuels to augment the world energy supplies. Basically, however, the hydrogenation of coal is not a new concept, but dates back at least a half-century to the time when manufactured gas (artificial, illuminating, producer, water gas, etc.) was used prior to the more general availability of low-cost, cleaner natural gas. In 1927, a White Paper was published discussing the processes then available for production of oil from coal. One of the first large-scale applications of the Fischer-Tropsch process for the production of oil from coal was that of the South African Coal, Oil and Gas Corporation's plant in Sasolburg, Republic of South Africa, constructed in the mid-1950s and expanded and improved several times during the interim.

Similarly, sour crudes, heavy residuums, and other petroleum-base starting materials can be hydrogenated, sometimes coupled with other processes, to sweeten, reduce viscosity, and otherwise improve the materials for better use as fuels. See also **Coal**; **Hydrotreating**; and **Petroleum**.

HYDROGEN FLUROIDE. See **Fluorine**.

HYDROGEN (Fuel). Because of the wide use of hydrogen in the processing industries and for the hydrogenation of various oils and fats in the food and related industries, hydrogen has become much better understood during the past several decades. For many years, hydrogen has served as a specialized fuel for certain applications, such as oxyhydrogen cutting and welding torches. But generally, until the late 1960s, the possible role of hydrogen as a major energy source fuel was rarely discussed. The word *hydrogen* took on a negative connotation with the development of

the hydrogen bomb, as it also did some years ago when the hydrogen-filled dirigible Hindenburg exploded as it moved toward its mooring mast in Lakewood, New Jersey in 1937.

The probable future of hydrogen in the world's energy system was the subject of prophecy over one hundred years ago. In 1874, Jules Verne wrote: "I believe that water will one day be employed as a fuel; that hydrogen or oxygen, which constitute it, used singly or together, will furnish an inexhaustible source of heat and light." And, in the early 1900s, Britain's Lord Haldane said: "It is axiomatic that the exhaustion of our coal and oil fields is a matter of centuries only. . . . As it has often been assumed that their exhaustion would lead to the collapse of industrial civilization, I may perhaps be pardoned if I give some of the reasons which led me to doubt this proposition." Haldane envisioned networks of windmills generating the electricity needed to separate hydrogen from water. The hydrogen would then be liquefied and stored underground.

Some readily apparent advantages of hydrogen, both as a direct and an indirect fuel (discussed later) have been extrapolated into terms of a future hydrogen economy. As the result of continuing and concentrated research and development in the energy field, many experts see a hydrogen energy economy gradually emerging.

Like other energy proposals (and there have been many in the past decade or so) three factors will likely determine the pace of hydrogen energy technology: (1) the manner in which, step-by-step, hydrogen-oriented systems and subsystems will compete economically and environmentally with other energy source, conservation, and utilization proposals; (2) the pace of technological advancement in related fields, such as nuclear engineering, upon which hydrogen systems may depend; and (3) the pace of unilateral efforts on behalf of hydrogen-oriented systems, including the refinement of current planning-purpose data and opinions into actual operating information relating to hydrogen generation, transportation, conversion and/or end-utilization, and safety. Without the funding of a series of "crash programs," unilateral developments probably will be relatively slow. Most likely, the information bank for hydrogen systems will stem from an increasing awareness of the energy characteristics of hydrogen and the progressive use of hydrogen subsystems in situations where they are eminently superior.

The present concept of a hydrogen fuel economy includes a primary energy source, such as a nuclear fission or fusion reactor, a geothermal source, or a solar-powered source, with hydrogen being produced as the portable energy carrier. See Fig. 1. Thermal energy from nuclear sources would be used to generate electricity that would then be used to electrolyze water for the production of hydrogen and oxygen. The hydrogen would be distributed by pipeline to distant points of use, with storage provided by underground gas storage, or by liquefaction and refrigerated storage.

Fuel-related Background of Hydrogen. Although the abundant hydrogen isotope *protium* is the simplest known atom, it forms two diatomic molecules, namely, *ortho-hydrogen*, in which the two atomic nuclei spin in the same direction; and *para-hydrogen*, in which the nuclei spin in opposite directions. While the equilibrium composition of hydrogen gas is 75% ortho at ambient temperature, it changes to 99.8% para in the liquid state. The transition from ortho- to para-hydrogen is exothermic (168 cal/gram), so that the heat released is more than enough to revaporize liquid hydrogen (heat of vaporization 107 cal/gram). Recognition of the existence of the ortho-para transition and the development of catalysts to equilibrate the liquid during liquefaction have made possible the large-scale production, use, and storage of liquid hydrogen.

Hydrogen molecules dissociate to atoms endothermally at high temperatures (heat of dissociation about 103 cal/gram mole), in an electric arc, or by irradiation. This property is used to effect atomic-hydrogen arc welding, in which hydrogen gas is dissociated by an electric arc between two tungsten electrodes, the hydrogen atoms recombining at the metal surface to provide the heat required for welding.

Pertinent properties of hydrogen are given in Table 1.

Actual and potential uses for hydrogen can be predicted by inspection of its properties. Its low density, 7% that of air, plus its high thermal conductivity, 6.7 times that of air, have led to its use as a coolant in large rotating electrical equipment. The low density reduces windage friction losses to less than 10% those with air, while its high thermal conductivity and heat capacity permit more efficient heat transfer, the result being an overall increase in generator efficiency of as much as 1%.

The high heats of reaction of hydrogen with oxygen or fluorine, plus the low molecular weights of the product gases, have made hydrogen a prime fuel for rocket propulsion, since rocket thrust increases directly with the temperature and inversely with the molecular weight of the exhaust gases. Liquid hydrogen and oxygen were used in the second- and third-stage Saturn engines in the Apollo moon flights. The low atomic weight of hydrogen has made it the preferred propellant for nuclear rockets, in which nuclear emission provides heat for exhausting hydrogen gas at high temperatures.

Some studies have indicated that the cost of transporting and distributing hydrogen by pipeline may be less than the cost of transporting and distributing electric power. Presumably existing natural gas pipelines and distribution systems can be adapted to the use of hydrogen. Although hydrogen has a net heating value of only 275 Btus per cubic foot (2448 Calories per cubic meter) as compared with 913 Btus per cubic foot (8126 Calories per cubic meter) for methane, the lower density and viscosity of hydrogen make it possible for a pipeline to deliver about the same amount of thermal energy as with methane, at a somewhat greater compression cost. The thermal energy in hydrogen can be utilized more efficiently in home

In air	4 to 74

heating than natural gas, because hydrogen can be burned in nonvented heaters, with no loss of heat, since its only primary combustion product is water. By using flameless catalytic heaters, nitrogen oxide formation can be eliminated. However, oxygen depletion of closed spaces will still present a hazard.

One advantage of hydrogen as a source of thermal energy, as compared with electricity, is that it can be stored for later use—it is a commodity with weight and volume. Electricity, although it can be converted into chemical energy in batteries, essentially is a form of energy that must be used as it is generated. Hydrogen, like natural gas or substitute natural gases, may be stored and transported as a refrigerated liquid, or stored as a gas under pressure in underground systems. Hydrogen also may be stored as a metallic hydride.

Categories of Energy-related Hydrogen Uses. The probable functions of hydrogen in future energy technology may be put into two major categories: (1) *direct functions*, in which hydrogen serves as a fuel, that is, as the source of heat, power, and light without prior conversion to some other energy form; and (2) *indirect functions*, in which hydrogen is an important component of the total energy system, but before the end-use of that energy, the hydrogen is involved in some conversion, possibly chemically, used in the creation of a synthetic fuel, such as substitute natural gas, or possibly converted into electrical energy which becomes the final end-energy used. One of the major indirect or secondary roles proposed for hydrogen is that of an energy transporter, wherein in one scheme, other forms of energy would be consumed to generate hydrogen which then would be pipelined and stored at distant points available for another conversion step—for example, converted into electrical energy as needed.

Hydrogen as Energy Source for Motive Power

Aside from their relatively low costs until the mid-1970s and continuing into the 1980s, the hydrocarbon fuels, notably gasoline and kerosene, have offered convenience in handling and transportability for use in connection with powered vehicles. And, during the past decade, the political factors that arise from the striking geographic imbalance between petroleum resources and petroleum consumption in most regions of the world have provided ample incentives to strike out for alternative sources of vehicular power.

Hydrogen, when cost competitive, can provide many of the advantages of petroleum liquids and offer the additional attraction of decreasing air pollution. Because of its low density, the net storage volume required would be at least as much as for gasoline. The storage tank must be maintained at a temperature of −423°F (−253°C), which is the boiling point of hydrogen at atmospheric pressure. This would require insulation that would increase the overall size of the storage container. Vaporization losses from the storage tank, amounting to perhaps 2% or more per day, must be vented so that no ignition of the vented hydrogen gas can occur, and no accumulation of explosive hydrogen-air mixtures are possible. The lower explosive limit of hydrogen in air is 4%, so adequate ventilation must be provided. Fortunately, hydrogen gas, being the lightest gas with a specific gravity of 0.07 referred to air, will rise and diffuse rapidly and thus can be easily dispersed. Service stations for dispensing liquid hydrogen will require more expensive storage and pumping facilities than required for gasoline.

The estimated weights and volumes expressed in Table 2 are relative to the same energy content of gasoline. Relative weight includes that of containers. The data indicate that magnesium hydride would be at a 4.6 weight disadvantage and thus require four times the tankage in comparison with the use of gasoline in a conventional automobile. New hydrides, as described later, may change this. This would be equivalent to 450 pounds (204 kilograms) of added vehicle weight and 60 more gallons (227 liters) (2 × 2 × 2 feet storage; 0.2 cubic meter) over that required for a vehicle with a 20-gallon (76 liters) gasoline tank. Bursting upon collision for liquid storage can be overcome by using containers capable of withstanding 30 Gs, which are presently available.

If a designer were to elect the option of using hydrogen in the gaseous phase at 2000 psi (136 atmospheres), this would require a metal container weighing some 30 times and requiring a volume of some 24 times that required for an energy equivalent volume of a hydrocarbon fuel. Also important in the total energy equation is the additional energy required to compress hydrogen (gaseous phase) or to liquefy it.

It is most likely that the first major use of liquid hydrogen as an energy source for motive power will be jet aircraft, largely because of the excellent weight advantage and the less serious nature of the boil-off loss and distribution problems as compared with other forms of transportation. City buses and long-haul motor trucks, already equipped mainly with hydride hydrogen power, have been tested in the United States and Germany, among other countries. These may follow as candidates wherein refueling may be effected through replacement of entire storage tanks (dewars). Because the private motorcar presents the most crucial logistics problems, including the small-capacity fuel system, concern with safety, boil-off loss of fuel even when vehicle is not in use, and the education and acceptance involving millions of users, it probably will follow rather than lead the use of hydrogen in other modes of transportation. However, during the last few years, a few firms have offered hydrogen-powered private motor vehicles, set up to switch from hydrocarbon fuel to hydrogen and vice versa, but at a cost that is not competitive with mass-marketed vehicles.

Metal Hydrides. For a number of years many scientists and advanced planners have considered the possible use of metal hydrides to store hydrogen at atmospheric or reasonable pressures and at relatively low temperatures (comparable to current metal temperatures in some conventional engines). The fact that hydrogen will form hydrides with most metals has been known for many years, during which time, a number of these hydrides have been formed and tested. Until comparatively recently, magnesium hydride and a hydride of a rare-earth metal plus nickel, such as $LaNi_5$, appeared to be best suited as hydrogen storage media.

TABLE 2. SOME HYDROGEN STORAGE OPTIONS FOR VEHICLES

Storage system	Relative system weight[a]	Relative contained volume[a]
Gaseous phase, 2,000 psi (136 atmospheres)	~30.0	~24.0
Solid (as magnesium hydride with 40% porosity)	4.6	4.0
Liquid phase at 37°R	2.4	3.8

[a] Relative to gasoline, as unity for same energy content.

The hydride-forming reaction is exothermic and reversible: Metal + Hydrogen ⇌ Metal Hydride + Heat. Thus, when it is desired to call for the separation of hydrogen from the hydride, heat (of decomposition) is required. As may be expected, the heat of decomposition is roughly proportional to the stability of the particular hydride. It is thus evident that for a metal hydride to serve as an efficient and viable means for storing hydrogen, it should be capable of decomposition at a relatively low temperature—say 300°C or lower. At the same time, the hydride must be reasonably stable and, of course, not require a high hydrogen pressure to manufacture it. It is further evident that the metal portion of the hydride must be comparatively inexpensive and thus common and readily available in the quantities that may be required. Metal hydride storage, operating as it does in terms of hydrogen as a battery operates in terms of electricity, must be capable of easy and efficient replenishing or "recharging" cycles. In every respect, the hydride storage element must be as safe as current vehicular fuel systems.

Researchers have investigated a large number of known binary hydrides, i.e., compounds that contain one metal and hydrogen. Investigators now regard magnesium hydride (MgH_2) as a borderline possibility. This binary hydride evolves hydrogen at a pressure of one atmosphere and requires a decomposition temperature of 289°C.

In comparatively recent research, much has been learned concerning the manner in which hydride compounds hold hydrogen. It has been known for a long time, of course, that the metal portion of the hydride should be comprised of tiny particles so that there is a large surface area available for reaction. In searching for reasons why hydrides permit such a high density of hydrogen, Reilly/Sandrock (1980) have observed that it is possible to pack more hydrogen into a metal hydride than into the same volume of liquid hydrogen. When the subject metal is first exposed to diatomic hydrogen (H_2), the hydrogen atoms are adsorbed onto the surface of the metal. Immediately, some of the hydrogen is dissociated into monoatomic hydrogen (H). This permits the monoatomic hydrogen to penetrate deeply into the crystal lattice of the metal and to occupy what are known as *interstitial sites*. Investigators have found that these sites must have a critical minimum volume if they are to easily receive the hydrogen atom. Upon increasing the pressure of the hydrogen applied, the metal reaches a saturated phase—the metal hydride phase. It has been found that under certain conditions and with certain metals, the number of hydrogen atoms contained in the crystal will range from 2 to 3 times the number of metal atoms.

The most recent experimentation with metal hydrides has involved multiple-metal hydrides. It has been known for some time that hydrogen reacts with alloy metal combinations. Considerable research has gone forth in connection with ternary hydrides (2 metals + hydrogen), and one of the most promising of these compounds as of the early 1980s is iron-titanium hydride ($FeTiH_x$), where x may range from 1 to 2. Reilly/Sandrock report that the hydrogen storage capacity by weight percent of this ternary hydride is 1.75 and by volume (grams per milliliter) is 0.096. The energy density by weight is 593 calories per gram; and the energy density by volume is 3254 calories per milliliter. Thus, this ternary hydride has a higher hydrogen-storage capacity than an equal volume of liquid or gaseous hydrogen (at 100 atmospheres). Another promising intermetallic hydride is lanthanum-pentanickel hydride ($LaNi_5H_x$), although it is more costly to produce. In this hydride, x may range from 1 to 6. Both the iron-titanium hydride and the lanthanum-pentanickel hydride have low temperatures of formation and decomposition, contributing to easy charging and discharging at ambient temperature.

In connection with hydrogen engine design, it is assumed that the heat of decomposition required by the hydride can be furnished from the inevitable waste heat generated by any engine. See also **Hydrides**.

Hydrogen as a Heating Fuel

The routine use of hydrogen as a heating fuel for industry and commercial-residential installations entails even greater complications and would appear to be much more dependent upon the overall economic and technical aspects of a so-called hydrogen fuel economy. From many standpoints, assuming availability, hydrogen can be an excellent fuel for almost any heating application. Hydrogen can be used in the home for cooking and heating (and even lighting) and likewise in commerce and industry. Compared with natural gas, hydrogen burns with a faster, hotter flame. Hydrogen-air mixtures are flammable over wider limits of mixtures. Hydrogen burns without producing noxious exhaust products, allowing unvented appliances except where water vapor and resulting increased humidity may be objectionable. In winter, the additional humidity can, in fact, be highly desirable. But, in humid locations in summer, the water vapor produced could be objectionable. Adequate ventilation must be provided to prevent depletion of oxygen in closed spaces.

But, generally because of the absence of hazards from carbon monoxide and other fumes, large savings could be achieved from the elimination or at least simplification of flues. Some experts suggest that not only construction costs could be lowered as the result of clean burning, but that an increase of some 30% in the efficiency of a gas-fired home heating system could be achieved. The concept of peripherally placed unflued devices, particularly through the use of catalytic "flameless" heaters, could ultimately lead to a serious revision of the widely accepted central heating concept. By maintaining the temperature of a catalytic bed as low as 100°C, the production of nitrogen oxides would be virtually eliminated.

Because hydrogen burns with a hotter flame, some design features of heating apparatus would require change. The energy content per unit mass of liquid hydrogen is about 2.75 times greater than that of hydrocarbon fuels. On the other hand, there are only 325 Btus per standard cubic foot (2893 Calories per cubic meter) of hydrogen as compared with about 1,000 Btus per standard cubic foot (8900 Calories per cubic meter) of natural gas, thus dictating further design changes. The ignition energy of hydrogen is about 0.02 millijoules, which is less than 7% that of natural gas, a major factor in making low-temperature catalytic burners possible; also a major factor in designing for safe operation.

Despite the numerous advantages of hydrogen as a direct heating fuel, particularly in the home, the application of hydrogen must be viewed in terms of the total energy concept of an exclusively hydrogen-supplied (all-hydrogen home) installation. Where the direct use of hydrogen for heating is large, the economy will be most favorable. If a substantial amount of the hydrogen must be converted into electrical energy, as by a fuel cell, then economic justification becomes more difficult.

Lighting in the all-hydrogen home may be accomplished by condoluminescence, a cold process. A phosphor is spread on the inside of a tube similar to the conventional fluorescent lamp. Upon coming in contact with the phosphor, small amounts of hydrogen combine with the oxygen in the air to excite bright luminescence in the phosphor.

Conversion of burners and other design aspects of heating systems and appliances to pure hydrogen, or to a hydrogen-enriched natural or substitute natural gas supply, while costly and inconvenient, is certainly not in the economically insurmountable category. Similar alterations over the years were made in the United States when communities switched from manufactured gas (about 50% hydrogen) to natural gas. Such switchovers are even more recent in European communities.

As more hydrogen becomes available for transportation use and as more hydrogen is pipelined regionally or transcontinentally (depending largely on the demand placed upon the supply of hydrogen for industrial uses), it may be that the hydrogen content of community gas supplies will be progressively enriched (in a periodic, stepwise manner because of switchover problems) and thus contribute in a gradual manner to less pollution and to the conservation of natural gas.

Hydrogen as an Energy Transporter

With the possible use of hydrogen as a source of motive power in the transportation field, the *non*chemical interest in hydrogen in the total energy picture is directed to the use of hydrogen as a means or mode of storing and transporting energy. It is in this area that hydrogen directly confronts the past ever-increasing trend toward a fully electrical energy economy. Undeniably, hydrogen energy has a major starting advantage over electrical energy, namely, hydrogen is a storable energy form. Investigations are showing that hydrogen in pipelines may cost less to transport than electricity flowing over long power lines. Thus, hydrogen may play an important future role simply as a mode of storage and transport, even though source and terminal energy conversions may be required.

Electrical power plants are most efficient when operated at constant output at full-rate load. Because of wide fluctuations in consumer load (daily and seasonally), generating rates require constant adjustment. Communication systems and some emergency systems employ batteries for interim storage of electrical energy, but these applications are minuscule when compared with the total electrical generating and distribution system. The principal means of large-scale storage is the use of pumped storage,

i.e., in essence a reversible hydroelectric station wherein electrical energy is temporarily converted to a hydraulic head by pumping water to an elevated reservoir. Unfortunately, the topography has to be suitable for such an installation and thus this approach is limited to comparatively few power-generating sites.

The high-voltage cables required to transmit electricity from generating stations to load centers are costly. The cost of going to underground cables for transmitting bulk current ranges from 9 to 20 times that of overhead configurations. The effective use of cryogenic superconducting cables may lower underground costs considerably, but much research remains to be completed before this is possible.

Because of the tremendous volumes of fuel that can be moved in pipelines, the construction, maintenance, and operating costs of a buried pipeline are much less in terms of a percentage of the total product moved. Pipeline operations have been profitable even at the relatively low price ranges for liquid and gaseous fuels prevailing prior to the price rises of the 1970s and 1980s. Pipeline technology, of course, is well established—with several hundred thousand miles of trunklines installed and operating in the United States. These lines transport nearly 23 trillion cubic feet (0.65 trillion cubic meters) of gas. Typical pipelines range from 600 to 1,000 miles (965–1609 kilometers) in length and are up to 48 inches (1.2 meters) in diameter. Line pressures may range from 600 to 800 psi (41–54 atmospheres) but go up to 1,000 psi (68 atmospheres). A representative 36-inch (0.9 meter) pipeline will carry a gaseous fuel with the equivalent of 37,500 billion Btus (9450 billion Calories) per hour. The electrical energy equivalent would be 11,000 megawatts. By comparison, this is ten times the energy-carrying capacity of a single-circuit 500-kilovolt overhead transmission line.

The figures for pipeline transportation of pure hydrogen are not quite so attractive, but nevertheless the comparison with electric transmission costs remains highly significant.

One study shows that the pipeline transmission costs for hydrogen will range from 30% to 50% more than for natural gas. Conversion of an existing natural gas line to hydrogen service is estimated to require a rise of compressor capacity by a factor of 3.8 and compressor horsepower by 5.5.

Obviously, hydrogen transmission costs represent but one part of a total system. Should the costs of generating hydrogen in the first place, and the subsequent conversion of hydrogen into electricity at the terminal end of the system remain excessively high, then the savings in energy transportation costs, of course, become academic.

Sources of Hydrogen

The major source of chemical hydrogen over the past several decades has been natural gas. In strictly terms of chemical needs, where economic factors are favorable, natural gas has served this need well. Obviously, in terms of total energy conservation, where hydrogen is looked to as a means of conserving fossil-fuel sources, a much less costly and much more abundant hydrogen-containing raw material must be sought. The logical candidate is water. Particularly in areas of the world where hydrocarbons are not readily available, reasonably large water electrolysis installations have been made, notably in locations with low electricity costs.

In addition to electrolysis, the principal means under consideration for deriving hydrogen from water is that of thermochemical splitting. The waste heat and high temperature available from certain types of nuclear reactors would effect a series of chemical reactions, still much in the research phase, to free hydrogen and oxygen from water. Additional proposals have included the use of ultraviolet radiation from the plasma of a fusion reactor for the direct photolysis of water vapor (Department of Energy) and the use of some forms of algae, under the stimulation of light, to convert hydrogen ions to hydrogen gas by a complex chain of biochemical reactions (Case Western Reserve University).

Electrolysis. Because of years of operating experience, electrolysis is possibly an order of magnitude ahead of other proposals from a technological standpoint. Although simple in concept, electrolysis is costly—hence the research efforts to find other ways of splitting water carry a high incentive. Nevertheless, this side of one or more breakthroughs in other areas, most likely electrolysis operations will continue to serve as the basis for costs in extending the use of hydrogen in the relatively near term.

As of the early 1980s, industrial electrolyzers ranged in size from 500 standard cubic feet (14.2 cubic meters) of hydrogen production per day, consuming 3 kilowatts of electricity, to more than 40 million standard cubic feet (~1.1 million cubic meters) of hydrogen per day, consuming 240,000 kilowatts. Most common installations are from 10,000 to 500,000 standard cubic feet (283–14,160 cubic meters) of hydrogen per day. Two factors generally characterize an electrolyzer installation: (1) access to comparatively low-cost electricity, as found in some areas served by hydroelectric installations; and (2) need for the oxygen which accompanies the production of the hydrogen. Industrial electrolyzers usually operate at efficiencies of about 60% to 70%. Some high-pressure prototype models have reached 85%. It has been pointed out (D.P. Gregory, Institute of Gas Technology) that, in theory, electrolyzers can approach a maximum electrical efficiency of nearly 120% as the result of the ideal unit absorbing ambient heat and also converting this energy into hydrogen. A reasonable, practical target for an improved electrolyzer appears to be around 100%. Thus, the production of electrolytic hydrogen would be limited only by the efficiency of electric current generation, namely, between 35% and 45%. An estimate has been made (E.C. Tanner, Princeton University; R. Huse, Public Service Electric & Gas Co.) that the overall conversion efficiency of electricity-to-hydrogen-to-electricity will approximate 38%. The theoretical power required to produce hydrogen from water is 79 kilowatts per 1,000 cubic feet (~28 cubic meters) of hydrogen gas. One of the largest electrolyzers operating commercially is that of Cominco, Limited (British Columbia). This is a 90-megawatt installation that produces approximately 36 tons (32.4 metric tons) of hydrogen gas per day for use in ammonia synthesis. Other large plants are located in Norway and Egypt.

Two main types of electrolyzers are in commercial use: (1) Tank cells with monopolar electrodes. Porous diaphragms separate the alternate cathodes and anodes to prevent gas mixing. The anodes and cathodes are connected in parallel to keep the required voltage at approximately 2 volts and to permit high current densities. This arrangement requires a large floor area; (2) bipolar electrodes, connected in series and suitably insulated. The electrodes are cathodic on one side; anodic on the other side. This arrangement requires less floor space, is more complex, and requires high voltages.

High pressure can increase efficiency and this concept has been under development for many years. A commercial electrolyzer (Lurgi) is available which operates at a pressure of 30 atmospheres and 90°C, requiring 300 amperes of electric current at 217 volts. In the mid-1960s, bipolar cells of porous nickel electrodes were developed which operate at current densities of 800 and 1600 amperes per square foot (0.09 square meter).

In the mid-1960s, electric-high-temperature, vapor-phase electrolysis (General Electric Co.) was developed. In this process, the electrolyte is solid, porous zirconia, which contains dopants. Operating temperature ranges from 500° to 800°C. A modification of the process is under development which will produce only hydrogen by consuming byproduct oxygen.

Among electrolyzer design improvements that may occur are better electrodes which may result as a spinoff from fuel-cell work. There are indications that electrode improvement could cut the costs of electrolytic hydrogen by about 20% to 25%. Electrolysis looms high in consideration of utilization of ocean thermal gradients and thus these two technologies are closely interacting.

Thermochemical Splitting. The major objective is to find one or more series of chemical reactions that will result in the satisfactory separation of hydrogen (and oxygen) from water. Considerable work has been going forth at the Nuclear Research Center, Julich, Federal Republic of Germany, where much attention has been given to sulfur- and chlorine-base thermochemical cycles. Other researchers (Institute of Gas Technology; General Electric Co.; European Atomic Energy Community) have been probing various combinations of at least 56 chemical elements, including over 700 different compounds that may show promise in various schemes for a closed-water-splitting cycle. It is understood that approximately 20 promising schemes have emerged, mainly centered in chlorine compounds. The most frequent flaw encountered among prospective reactions is the large amount of free energy required to force one or possibly two of the series of reactions; and the appearance of reactions that produce stable compounds incapable of regeneration.

Some of these reactions would rely upon a nuclear reactor as a heat source and would not have to await the emergence of a practical, operating fusion reactor. One sequence of reactions, in particular, is of interest:

$$CaBr_2 + 2H_2O \longrightarrow Ca(OH)_2 + 2HBr$$

$$Hg + 2HBr \longrightarrow HgBr_2 + H_2$$

$$HgBr_2 + Ca(OH)_2 \longrightarrow CaBr_2 + HgO + H_2O$$

$$HgO \longrightarrow Hg + \frac{1}{2}O_2$$

A drawback of this sequence is its use of highly corrosive hydrogen bromide. The scheme also requires a large inventory of mercury.

Of major concern to investigators in the thermochemical splitting schemes is the availability of appropriate materials of construction. Heat exchangers between the nuclear side and the chemical side must withstand both corrosion and radioactive contamination. The conventional nickel-chromium alloys are capable up to about 1050 K; exotic, but available alloys, up to about 1400 K. Above these temperatures, ceramics and new alloys may have to be used. Considerable materials research along these lines is going forth at the Los Alamos Scientific Laboratory.

Conventional Hydrogen Uses. Even before its serious consideration in the fuel economy, the demand for hydrogen grew at a rate of about 15% annually since World War II. About 3 trillion standard cubic feet (~85 million cubic meters) of hydrogen (8 million tons; 7.2 million metric tons) were produced in the United States in 1970. Not including energy applications, the chemical requirements for hydrogen are expected to increase by about 7% per year through the year 2000. Among demands for hydrogen include petroleum refining, plastics, elastomers, increased desulfurization of fuel oils, increased use in iron ore reduction, aerospace uses, and hydrogen/air fuel cells. About 42% of the hydrogen produced now is consumed in ammonia production; about 38% is used in petroleum refining. The other large consumers are metallurgical and food processing.

In terms of presently nonconventional fuels that will require increasing quantities of hydrogen as new processes develop, it is estimated that (1) synthetic crude oil from coal will require 6,500 standard cubic feet (184 cubic meters) of hydrogen per barrel of oil; (2) 1,300 standard cubic feet (37 cubic meters) of hydrogen will be required per barrel of oil from shale; and (3) 1,500 standard cubic feet (42 cubic meters) of hydrogen will be required for every 1,000 standard cubic feet (~28 cubic meters) of synthetic pipeline gas produced from the gasification of coal. Petroleum refining use of hydrogen is expected to increase to 610 standard cubic feet (~17.3 cubic meters) per barrel of crude refined. Direct iron ore reduction use of hydrogen is expected to increase to 20,000 standard cubic feet (566 cubic meters) per ton (0.9 metric ton) of iron. If there were not other hydrogen sources available, the hydrogen needs could be met by using approximately 10% of the natural gas production.

HYDROGEN CYANIDE. [CAS: 74-90-8]. HCN, formula weight 27.03, colorless gas with characteristic odor, very poisonous, mp −14°C, bp 26°C, critical temperature 183.5°C, critical pressure 50 atmospheres, density 0.20 g/cm^3, sp gr 0.697 (18°C). There are two isomeric forms: (1) HCN which forms cyanides, (2) HNC (inferred from its derivatives) which forms isocyanides. Hydrogen cyanide is soluble in H_2O, or alcohol, or ether in all proportions. The compound usually is marketed as an aqueous solution containing 2–10% (weight) HCN. For many process uses, it is frequently more convenient to generate HCN as needed and thus avoid storage and handling problems. HCN burns with a red-blue flame, yielding CO_2, nitrogen, and H_2O. Aqueous solutions of HCN decompose slowly, yielding ammonium formate: $HCN + 2H_2O \longrightarrow HCOONH_4$. Decomposition is slowed by storage in dark locations. Peaches, apricots, bitter almonds, cherries, and plums contain some HCN derivatives in their kernels, frequently in combination with glucose and benzaldehyde as a glucoside (amygdalin). The bitter almond fragrance of HCN and its derivatives sometimes can be detected in such kernels.

Production

Hydrogen cyanide can be prepared from a mixture of NH_3, methane, and air by partial combustion in the presence of a platinum catalyst:

$$HN_3 + CH_4 + 1.5\ O_2 + 6\ N_2 \longrightarrow HCN + 3\ H_2O + 6N_2$$

The process is carried out at about 900–1,000°C; yield ranges from 55–60%. In another process, methane (contained in natural gas) is reacted with NH3 over a platinum catalyst at from 1,200–1,300°C, the reaction requiring considerable heat input. In still another process, a mixture of methane and propane is reacted with NH_3 : $C_3H_8 + 3NH_3 \longrightarrow 3HCN + 7H_2$; or $CH_4 + NH_3 \longrightarrow HCN + 3H_2$. An electrically heated fluidized bed reactor is used. Reaction temperature is approximately 1,510°C.

The high-tonnage uses of HCN are in the preparation of numerous chemical products and intermediates for organic syntheses. As a gas, HCN sometimes is applied as a disinfectant; or cellulosic disks impregnated with HCN may be used. In ore processing and metal treating, cyanides are widely used.

Hydrogen cyanide reacts with hydrogen at 140°C in the presence of a catalyst, e.g., platinum black, to form methyl amine CH_3NH_2. When burned in air, it produces a pale violet flame; when heated with dilute sulfuric acid, it forms formamide $HCONH_2$ and ammonium formate $HCOONH_4$; when exposed to sunlight with chlorine it forms cyanogen chloride CNCl, plus hydrogen chloride. An important reaction of hydrogen cyanide is that with aldehydes or ketones, whereby cyanhydrins are formed, e.g., acetaldehyde cyanhydrin $CH_3CHOH \cdot CH$, and the resulting cyanhydrins are readily converted into alpha-hydroxy acids, e.g., alpha-hydroxypropionic acid $CH_3 \cdot CHOH \cdot COOH$.

Metallic cyanides are (1) soluble, e.g., sodium cyanide NaCN, potassium cyanide KCN, calcium cyanide $Ca(CN)_2$, mercuric cyanide $Hg(CN)_2$, aurous cyanide AuCN, (2) insoluble, e.g., silver cyanide AgCN, cuprous cyanide CuCN, (3) complex, (a) decomposed by dilute H_2SO_4 and not affected by dilute NaOH, e.g., sodium silver cyanide $NaAg(CN)_2$ solution, sodium cuprous cyanide $NaCu(CN)_2$ colorless solution, (b) changed only to acid by dilute H_2SO_4 and reactive with dilute NaOH, e.g., potassium hexacyanoferrate(II) $K_4Fe(CN)_6$ yields, with dilute H_2SO_4, hexacyanoferric(II) acid, cupric hexacyanoferrate(II) $Cu_2Fe(CN)_6$ yields, with dilute NaOH, cupric hydroxide.

Sodium cyanide solution dissolves certain metals (1) with absorption of oxygen, e.g., gold, silver, mercury, lead, and (2) with evolution of hydrogen, e.g., copper, nickel, iron, zinc, aluminum, magnesium; and solid sodium cyanide, when heated with certain oxides, e.g., lead monoxide PbO, stannic oxide SnO_2, yields the metal of the oxide, e.g., lead, tin, respectively, and sodium cyanate NaCNO. Two classes of esters are known, cyanides or nitriles, and isocyanides, isonitriles or carbylamines, the latter being very poisonous and of marked nauseating odor.

Methyl cyanide CH_3CN, bp 82°C, formed by reaction of (1) methyl iodide and potassium cyanide, (2) acetamide and phosphorus pentoxide. Methyl isocyanide CH_3NC, bp 60°C, formed by reaction (1) of methyl iodide and silver cyanide, (2) of methylamine, chloroform and NaOH solution warmed. Ethyl isocyanide C_2H_5NC, bp 78°C. Phenyl isocyanide C_6H_5NC, bp 78°C at 40 torr pressure.

Oxidation of cyanide ion (e.g., by copper(II) gives cyanogen or oxalonitrile NCCN, poisonous colorless gas, bp −21°C. This reacts with organic compounds and bases like a halogen, for example, disproportionating in aqueous alkali to cyanide and cyanate. In aqueous acid, hydrolysis to oxalamide and ultimately oxalic acid takes place. Oxidation of cyanides by oxygen donors (e.g., lead monoxide or dioxide, manganese dioxide or dichromate) a little below red heat produces cyanates.

HYDROGEN-ION ACTIVITY. Hydrogen ions are involved in a wide variety of natural and industrial reactions, and the equilibrium positions as well as the rates of these reactions are therefore dependent on hydrogen-ion concentration. The hydrogen ion is more correctly termed hydronium ion. The unhydrated proton does not exist in aqueous solution but rather is bound to several molecules of water. This ion, sometimes represented as $H(H_2O)_n^+$, is usually written simply as H^+. More important is the distinction between the hydrogen ion concentration and its activity. The hydrogen ion concentration, or total acidity, is obtained by titration and corresponds to the total concentration of hydrogen ions available in a solution, i.e., free, unbound hydrogen ions as well as hydrogen ions associated with weak acids. The hydrogen ion activity refers to the effective concentration of unbound hydrogen ions, i.e., the form which affects

physicochemical reaction rates and equilibria. The effective concentration of hydrogen ion in solution is expressed in terms of pH, which is the negative logarithm of the hydrogen-ion activity, a_H.

$$\mathrm{pH} = -\log_{10} a_H \qquad (1)$$

The relationship between activity, a, and concentration, c, is

$$a = \gamma c \qquad (2)$$

where the activity coefficient γ is a function of the ionic strength of the solution and approaches unity as the ionic strength decreases; i.e., the difference between the activity and the concentration of free hydrogen ions diminishes as the solution becomes more dilute. The pH of a solution may have little relationship to the titratable acidity of a solution that contains weak acids or buffering substances; the pH of a solution indicates only the free hydrogen-ion activity. If total acid concentration is to be determined, an acid–base titration must be performed.

pH Determination

Two methods are used to measure pH: electrometric and chemical indicator. The most common is electrometric and uses the commercial pH meter with a glass electrode. This procedure is based on the measurement of the difference between the pH of an unknown or test solution and that of a standard solution.

More recently, two different types of nonglass pH electrodes have been described which have shown excellent pH-response behavior. In the neutral-carrier, ion-selective electrode type of potentiometric sensor, synthetic organic ionophores, selective for hydrogen ions, are immobilized in polymeric membranes. Another type of pH sensor is based on an integrated ion-selective electrode and insulated-gate field-effect transistor. These sensors, usually termed ion-selective field-effect transistors (ISFETs), are based on the modulation of the transistor source-drain current by a potential (or charge) applied to the transistor gate region.

The second method for measuring pH, the optical indicator method, has more limited applications. The success of this procedure depends on matching the color that is produced by the addition of a suitable indicator dye to a portion of the unknown solution with the color produced by adding the same quantity of the same dye to a series of standard solutions of known pH. The indicator dyes can also be immobilized onto paper strips (e.g., litmus paper) or, more recently, have been placed onto the distal end of fiber-optic probes which, when combined with photometric readout, provide more quantitative indicator-dye pH determinations.

Accuracy and Interpretation of Measured pH Values. To define the pH scale and permit the calibration of pH measurement systems, a series of reference buffer solutions have been certified by the U.S. National Institute of Standards and Technology (NIST). The acidity function which is the experimental basis for the assignment of pH, is reproducible within about 0.003 pH unit from 10 to 40°C. However, errors in the standard potential of the cell, in the composition of the buffer materials, and in the preparation of the solutions may raise the uncertainty to 0.005 pH unit. The accuracy of the practical scale may be further reduced to 0.008–0.01 pH unit as a result of variations in the liquid-junction potential.

Sources of Error. Several common causes of measurement problems are electrode interferences and/or fouling of the pH sensor, sample matrix effects, reference electrode instability, and improper calibration of the measurement system.

pH Measurement Systems

Glass Electrodes. The glass electrode is the hydrogen-ion sensor in most pH-measurement systems. The pH-responsive surface of the glass electrode consists of a thin membrane formed from a special glass that, after suitable conditioning, develops a surface potential that is an accurate index of the acidity of the solution in which the electrode is immersed. To permit changes in the potential of the active surface of the glass membrane to be measured, an inner reference electrode of constant potential is placed in the internal compartment of the glass membrane. The inner cell commonly consists of a silver–silver chloride electrode or calomel electrode in a buffered chloride solution. Immersion electrodes are the most common glass electrodes. Miniature and microelectrodes are also used widely, particularly in physiological studies. Capillary electrodes permit the use of small samples and provide protection from exposure to air during the measurements. The composition of the glass has a profound effect on the electrical resistance, the chemical durability of the pH-sensitive surface, and the accuracy of the pH response in alkaline solutions.

Reference Electrodes and Liquid Junctions. The electrical circuit of the pH cell is completed through a salt bridge that usually consists of a concentrated solution of potassium chloride. The solution makes contact at one end with the test solution and at the other with a reference electrode of constant potential. The liquid junction is formed at the area of contact between the salt bridge and the test solution.

The commercially used reference electrode–salt bridge combination usually is of the immersion type. Some provision is made to allow a slow leakage of the bridge solution out of the tip of the electrode to establish the liquid junction with the test solution.

Combination electrodes have increased in use and are a consolidation of the glass and reference electrodes in a single probe, usually in a concentric arrangement, with the reference electrode compartment surrounding the pH sensor. The advantages of combination electrodes include the convenience of using a single probe and the ability to measure small volumes of sample solution or in restricted-access containers.

Theoretical considerations favor liquid junctions by which cylindrical symmetry and a steady state of ionic diffusion are achieved.

Samples that contain suspended matter are among the most difficult types from which to obtain accurate pH readings because of the so-called suspension effect, i.e., the suspended particles produce abnormal liquid-junction potentials at the reference electrode. Internal consistency is achieved by pH measurement using carefully prescribed measurement protocols, as has been used in the determination of soil pH.

Another effect that may result in spurious pH readings is caused by streaming potentials. Presumably, these are attributable to changes in the reference electrode liquid junction that are caused by variations in the flow rate of the sample solution. This problem may be avoided by maintaining constant flow and geometry characteristics and calibrating the system under operating conditions that are identical to those of the sample measurement.

pH Instrumentation. The pH meter is an electronic voltmeter that provides a direct conversion of voltage differences to differences of pH at the measurement temperature.

Because of the very large resistance of the glass membrane in a conventional pH electrode, an input amplifier of high impedance (usually $10^{12}-10^{14}$ Ω) is required to avoid errors in the pH (or mV) readings.

In addition, most devices provide operator control of settings for temperature and/or response slope, isopotential point, zero or standardization, and function (pH, mV, or monovalent–bivalent cation–anion). Microprocessors are incorporated in advanced-design meters to facilitate calibration, calculation of measurement parameters, and automatic temperature compensation.

Temperature Effects. The emf, E, of a pH cell may be written

$$E = E_g'' - k\mathrm{pH} \qquad (3)$$

where k is the Nernst factor (2.303 RT)/F, and E_g'' includes the liquid-junction potential and the half-cell emf on the reference side of the glass membrane. Changes of temperature alter the scale slope because k is proportional to T. The scale position also is changed because the standard potential is temperature dependent: E_g'' is usually a quadratic function of the temperature.

The objective of temperature compensation in a pH meter is to nullify changes in emf from any source except changes in the true pH of the test solution. Nearly all pH meters provide automatic or manual adjustment for the change of k with T.

Nonaqueous Solvents

The activity of the hydrogen ion is affected by the properties of the solvent in which it is measured. Scales of pH only apply to the medium, i.e., the solvent or mixed solvents, e.g., water–alcohol, for which the scales are developed. The comparison of the pH values of a buffer in aqueous solution to one in a nonaqueous solvent has neither direct quantitative nor thermodynamic significance. Consequently, operational pH scales must be developed for the individual solvent systems.

Other difficulties of measuring pH in nonaqueous solvents are the complications that result from dehydration of the glass pH membrane, increased sample resistance, and large liquid-junction potentials. These effects are complex and highly dependent on the type of solvent or mixture used.

Indicator pH Measurements

The indicator method is especially convenient when the pH of a well-buffered colorless solution must be measured at room temperature with an accuracy no greater than 0.5 pH unit. Under optimum conditions an accuracy of 0.2 pH unit is obtainable.

Because they are weak acids or bases, the indicators may affect the pH of the sample, especially in the case of a poorly buffered solution. Variations in the ionic strength or solvent composition, or both, also can produce large uncertainties in pH measurements, presumably caused by changes in the equilibria of the indicator species. Specific chemical reactions also may occur between solutes in the sample and the indicator species to produce appreciable pH errors.

Industrial Process Control

The pH meters and electrodes for process control do not differ materially from those used for measurements in the laboratory, but the emphasis in industrial applications is on rugged construction to withstand mechanical stresses and extremes in ambient conditions.

The pH meter usually is coupled to a data recording device and often to a pneumatic or electric controller. The controller governs the addition of reagent so that the pH of the process stream is maintained at the desired level.

HYDROGEN PEROXIDE. [CAS: 7722-84-1]. H_2O_2, formula weight 34.02, in pure, anhydrous form is a viscous, colorless liquid, sp gr 1.44, mp −0.89°C, bp 151.4°C. Hydrogen peroxide is soluble in H_2O in all proportions, soluble in alcohol, or ether, but not in hydrocarbons. Reagent, chemically pure (CP) grade H_2O_2 is a solution of 90% H_2O_2 and 10% H_2O, sp gr 1.39. This concentration contains 42% active oxygen by weight. One volume yields 410 volumes of oxygen. Hydrogen peroxide solutions are high-tonnage chemicals and are supplied commercially in several strengths, ranging from 3–35% H_2O_2 by weight. Commercial grades for oxidation and bleaching normally contain 27.5–35% H_2O_2.

To reduce the tendency of H_2O_2 solutions to decompose, storage must be at comparatively low temperatures and in light-tight containers. Often, an organic material, such as acetanalide, will retard degradation. H_2O_2 has been used as an oxidizer in liquid bipropellant systems, or as a monopropellant through controlled catalytic decomposition, in supplying oxygen to various fuel mixtures for rockets and torpedoes. Low-concentration (normally 3% H_2O_2) solutions have been used for many years as antiseptics in medical applications. Bleaching is a primary outlet for H_2O_2, particularly in connection with cotton, wool, groundwood pulp—as well as hair-bleaching formulations. The compound is used as a source of gas in foaming rubber plastics. The highly reactive H_2O_2 molecule readily participates in oxidation, epoxidation, and hydroxylation reactions and is frequently used in an intermediate capacity in chemical syntheses. In restoring old paintings, H_2O_2 has been used to convert black PbS tarnish into the original white lead sulfate.

Use in Food Processing

Within recent years, there has been increased interest in the use of H_2O_2 as a bactericidal and sporicidal agent in aseptic systems used for sterilizing food processing equipment and packaging materials. Several factors affect the success of such use. At low concentration, H_2O_2 may be regarded as bactericidal, but not highly sporicidal. The latter requires concentrations of up to 35% H_2O_2. Elevated solution temperature also increases effectiveness. Hydrogen peroxide solutions can be applied at a temperature up to 95°C because of their excellent thermal stability. Such treatment must be followed by hot-air heating at about 125°C in order to dissipate H_2O_2 residuals, which must be ≤0.1 ppm H_2O_2. Some inorganic salts, notably cupric salts, increase bactericidal activity. Treatment with H_2O_2 and ultrasonic radiation has been shown to produce a synergistic effect on the destruction of bacterial spores. Similarly, the combination of ultraviolet radiation and H_2O_2 appears to be synergistic. In one system, a UV-irradiated solution of H_2O_2 is used. The resistance of spores varies with species. In general, the resistance of clostridial spores to H_2O_2 is lower than that of spores of bacilli. Further details are given in the Stevenson/Shafer reference listed.

Researchers have found that alkaline hydrogen peroxide renders plant fibers more digestible by ruminants and thus suggests that a number of alternative feed sources, including crop residues and other cellulosic plant biomass, may be used in animal production. Researchers at the University of Illinois and the U.S. Department of Agriculture have treated lignocellulosic residues (wheat straw, corncobs, and cornstalks) with dilute alkaline H_2O_2 solutions and have found that the fermentability of such substances increases and that the byproducts produced may be considered an acceptable energy source for the ruminant animal. Details are given in the Kerley, et al. reference listed.

Industrial Production of Hydrogen Peroxide

The traditional process for manufacturing H_2O_2 has been the electrolysis of aqueous solutions of $KHSO_4$, H_2SO_4, or NH_4HSO_4. In recent years, chemical auto-oxidation processes have grown in favor, largely because of energy costs. In these processes, the feedstock may be an alkylated quinone, alkylated anthraquinone, and hydroquinone solvents, together with hydrogen, air or oxygen, H_2O, and a nickel, palladium, or platinum catalyst. The process yields a 15–75% solution of H_2O_2 in H_2O, depending upon adjustment of process concentrations and conditions to provide desired concentration. The yield for this type of process is about 90% of theoretical. The process proceeds essentially in two steps. In the first step, anthraquinone contained in a solvent is hydrogenated at a temperature of about 40°C and a pressure of 1–3 atmospheres. The anthraquinone is reduced to hydroquinone (*p*-dihydroxybenzene):

$$C_6H_4:(CO)_2:C_6H_2 \longrightarrow C_6H_4:(COH)_2:C_6H_3R$$

R is a radical such as ethyl or tertiary butyl. In the second step, the hydroquinone solution is oxidized with air or oxygen: $C_6H_4:(COH)_2:C_6H_3R + O_2 \longrightarrow C_6H_4:(CO)_2:C_6H_3R + H_2O_2$. In theory, the process consumes only hydrogen, atmospheric oxygen, and H_2O. A solvent must be used that will minimize side reactions during hydrogenation while also dissolving both the hydrogenated and oxidized forms of the organic compound. Solvents referred to in this connection are benzene-methyl-cyclohexanol mixtures and primary and secondary nonyl alcohols. Very tight purity precautions are required because any impurities in the H_2O_2 cause spontaneous catalytic decomposition of the product. As the result of these necessary precautions, the resulting H_2O_2 is one of the purest of commercial chemicals.

The process is highly corrosive. At one time, enameled steel vessels were standard for H_2O_2 processing. Aluminum, once properly passified through pickling and treatment after fabrication, has been found satisfactory.

Hydrogen peroxide reacts (1) with alkalis to form peroxides, (2) with potassium iodide solution, in presence of ferrous sulfate, to liberate iodine. This reaction serves to indicate the presence of as small an amount as 1 part by weight of hydrogen peroxide in 25,000,000 parts of H_2O. (3) with lead sulfide PbS, brown solid, to form lead sulfate $PbSO_4$, white solid, and sometimes used to brighten the lead pigment of darkened oil paintings, (4) with lead dioxide to form lead oxide, (5) with sulfites, especially in alkaline solution, to form sulfates, (6) with nitrites to form nitrates, (7) with arsenites for form arsenates, (8) with ferrous compounds to form ferric, (9) with chromic compounds to form chromates (See also **Chromium**), (10) with permanganates in acid solution to form manganous compounds plus oxygen of twice the volume available from the hydrogen peroxide, (11) with dichromates in acid solution cold to form perchromic acid, blue solution, more soluble in ether than in acid, (12) with titanic salt solutions to form pertitanic acid, yellow solution, (13) with colored organic materials, e.g., litmus, indigo, to destroy the color, and thus used for bleaching hair, silk, feathers, straw, ivory, teeth, bones, gelatin, flour. When hydrogen peroxide solution is treated with finely divided platinum or other

substances, or comes in contact with rough surfaces, e.g., ground glass, oxygen is evolved (water also formed).

In the laboratory, hydrogen peroxide is prepared from barium peroxide by treatment with ice-cold dilute acid; when H_2SO_4 is used barium sulfate insoluble may be separated by filtration. Other peroxides, e.g., sodium peroxide, react similarly with acids to form hydrogen peroxide plus the salt corresponding to the peroxide and acid used. Hydrogen peroxide is formed when ether is exposed to sunlight, when a hydrogen-oxygen flame impinges on ice, and when H_2O in a quartz vessel is exposed to ultraviolet light.

HYDROGEN SCALE. 1. A thermometric scale. (See also **Temperature Scales and Standards.**)

2. Since there is no reliable method for determining the absolute potential of a single electrode, electrode potentials are measured against a reference electrode whose potential is arbitrarily taken as zero. The arbitrary zero in general use is the potential of a reversible hydrogen electrode, with gas at 1 atmosphere pressure, in a solution of hydrogen ions of unit activity, or other electrodes calibrated against the hydrogen electrode.

HYDROGEN SULFIDE. [CAS: 7783-06-4]. H_2S, formula weight 34.08, colorless, odorous gas, mp −82.9°C, bp −59.6°C, sp gr 1.1895 (air = 1). The gas must be handled carefully because of (1) its toxic properties (particularly dangerous because it may paralyze the olfactory nerves), and (2) its explosive tendencies (low ignition temperature of 260°C and wide flammability range from 4.3 to 44% by volume in air). Hydrogen sulfide liberates considerable heat upon burning (6,230 calories/liter at 15.6°C). The gas is produced by acid hydrolysis of many sulfides and by water hydrolysis of those elements higher in the hydrogen scale.

An aqueous solution of hydrogen sulfide is termed hydrosulfuric acid, which undergoes slow atmospheric oxidation to sulfur. The acid is a strong reducing agent, usually with the separation of sulfur, e.g., with nitric acid (nitric oxide formed), with concentrated H_2SO_4(SO_2 is formed), with permanganate (manganous ion formed in the presence of acid), dichromate (chromic ion formed in the presence of acid).

Fluorine, chlorine, bromine, and iodine react with H_2S to form the corresponding halogen acid. Metal sulfides are formed when H_2S is passed into solutions of the heavy metals, such as Ag, Pb, Cu, and Mn. This reaction is responsible for the tarnishing of Ag and is the basis for the separation of these metals in classical wet qualitative analytical methods. Hydrogen sulfide reacts with many organic compounds.

The gas results from the decomposition of metal sulfides and albuminous matter and is found in the areas of mineral springs, sewers, and in some mines where it is referred to as "stink damp." H_2S also is a byproduct of several industrial processes, including synthetic rubber, viscose rayon, petroleum refining, dyeing, and leather-treating operations. In the laboratory, H_2S usually is prepared by treating a sulfide with an acid, such as iron pyrites and HCl, or by heating thioacetamide $CH_3C(:S)NH_2$. Three processes are used industrially to produce H_2S in large quantities: (1) treating a sulfide with an acid, $2NaHS + H_2SO_4 \longrightarrow 2H_2S + Na_2SO_4$, (2) reacting sulfur with an alkali, $4S + 2NaOH + 2H_2O \longrightarrow 2H_2S + Na_2S_2O_3$, and (3) directly reacting sulfur with hydrogen, $S + H_2 \longrightarrow H_2S$. Large quantities of byproduct H_2S usually are converted into elemental sulfur or H_2SO_4.

Industrial uses for H_2S include: (1) the preparation of sulfides, such as sodium sulfide and sodium hydrosulfide; (2) the production of sulfur-bearing organic compounds, such as thiophenes, mercaptans, and organic sulfides; (3) the removal of Cu, Cd, and Ti from spent catalysts where the gas acts as a precipitant; (4) the formulation of extreme-pressure lubricants; and (5) the preparation of rare-earth phosphors used in color TV tubes.

See also **Coal**.

HYDROLYSIS. A chemical reaction in which water reacts with another substance to form two or more substances. This involves ionization of the water molecules as well as splitting of the compound hydrolyzed, e.g., $CH_3COOC_2H_5 + H \cdot OH \longrightarrow CH_3COOH + C_2H_5OH$. Examples are: conversion of starch to glucose by water in the presence of suitable catalysts; or the conversion of sucrose (cane sugar) to glucose and fructose by reaction with water in the presence of an enzyme or acid catalyst; or conversion of natural fats into fatty acids and glycerin by reaction with water, as occurs in one stage of soap manufacturing; or the reaction of the ions of a dissolved salt to form various products, such as acids, complex ions, etc. See also **Cellulose Ester Plastics (Organic)**; **Organic Chemistry**; and **Starch**.

HYDRONIUM ION. An ion found in water and all its solutions, which has the formula H_3O^+ and which consists of a proton combined with a water molecule. It has been established that hydrogen ions do not exist free in aqueous solution, but are present as hydronium ions. Formation of such ions is statistically rare, resulting from the interaction of water molecules in a ratio of 1 to 556 million.

HYDROPHILIC. Having a strong tendency to bind or absorb water, which results in swelling and formation of reversible gels. This property is characteristic of carbohydrates, such as algin, vegetable gums, pectins, starches, and of complex proteins, such as gelatin and collagen. See also **Colloid Systems**; and **Detergents**.

HYDROPHOBIC. Antagonistic to water; incapable of dissolving in water. This property is characteristic of oils, fats, waxes, and many resins, as well as of finely divided powders, such as carbon black and magnesium carbonate. Some interesting concepts are explored in "The Hydrophobic Effect and the Organization of Living Matter," by C. Tanford, *Science*, **200**, 1012–1018 (1978). See also **Colloid Systems**.

HYDROQUINONES. These are dihydroxy aromatic compounds with the two groups in positions corresponding to *ortho* or *para* substitution in the benzene ring. They are closely related to the quinones from which they can be obtained by reduction. Thus *o*-dihydroxybenzene (catechol) can be obtained from *o*-benzoquinone, and hydroquinone (*p*-dihydroxybenzene or quinol) from *p*-benzoquinone. Resorcinol (*m*-*d*ihydroxybenzene) is not properly a hydroquinone since the corresponding *meta* quinone is not known to exist. Homologs of hydroquinone are usually named after the parent hydrocarbon. Thus toluhydroquinone is 2,5-dihydroxy-1-methylbenzene and naphthohydroquinone is 1,4-dihydroxy-naphthalene. Unlike many of the quinones, the ring systems are fully aromatic and undergo substitution reactions common to phenols and other benzene derivatives. However they are easily oxidized by some reagents to the less stable quinones and degradation products frequently result. Thus treatment of hydroquinone with nitric acid yields oxalic acid while halogenation with sulfuryl chloride results in a mixture of chlorohydroquinones, quinone, quinone chlorides, and tetrachloro-*p*-benzoquinone. The formation of side and degradation products can be minimized if the molecule is protected against oxidation by acetylating or benzoylating at least one of the hydroxyl groups. For example 2-nitro-hydroquinone can be prepared in good yield by the nitration of monobenzoyl hydroquinone followed by hydrolysis. Concentrated sulfuric acid gives hydroquinone-2,5-disulfonic acid directly, and tertiary amyl groups can be introduced into the ring in the 2 and 5 positions by treatment with amylene in the presence of sulfuric acid. The hydroxyl groups are weakly acidic and can readily be converted to ethers by treatment with alkyl halides or sulfates in the presence of alkali. A diacetate is formed on treatment with acetic anhydride. The most characteristic reaction of hydroquinones is their reversible oxidation to quinones.

Catechol, or 1,2-dihydroxybenzene, was first prepared by the dry distillation of catechin obtained from *Mimosa catechu*. It can also be formed by the hydrolysis of its methyl ether, guaiacol, which is a constituent of beechwood tar. It is prepared synthetically by fusing phenol-*o*-sulfonic acid with sodium hydroxide, or treating *o*-chlorophenol with aqueous alkali in the presence of copper at a high temperature and pressure. It crystallizes from benzene in colorless monoclinic plates which melt at 105°C. The lead salt can be oxidized to *o*-benzoquinone by a solution of iodine in chloroform. The ethers of catechol are of considerable importance and can be derived from a number of naturally occurring substances. The methylene ether of protocatechualdehyde is known as piperonal, and is closely related to various natural products including piperine, safrole, and isosafrole, from which it can be derived. These compounds have been used

for the synthesis of pyrethrin synergists. *Vanillin*, the principal flavoring constituent of vanilla, is the 3-methyl ether of protocatechualdehyde.

Hydroquinone is found in nature combined in the glycoside arbutin, from which it can be released by hydrolysis with emulsin or dilute sulfuric acid. It is prepared commercially from *p*-benzoquinone by reduction with sulfur dioxide. It is a dimorphic solid with the stable form melting at 170.5°C. Hydroquinone is one of a number of compounds that possess the property of forming molecular compounds with gases such as hydrogen sulfide, sulfur dioxide, krypton, xenon, etc. These are known as clathrate compounds, and their existence is due to the entrapment of atoms or molecules of the gas in the crystal lattice of the hydroquinone. Three moles of hydroquinone can entrap one mole of gas, which is firmly held but which is liberated when the clathrate is dissolved in water. The most important commercial use of hydroquinone is for the development of photographic film. Its effectiveness is dependent on its ability to reduce the silver subhalide formed on exposure of the film to light to metallic silver. It gives films of high density and it is often necessary to reduce the harshness of contrast by using it in combination with other developers such as metol or paramidophenol. Hydroquinone and its derivatives are effective antioxidants for the preservation of fats, oils, and rubber. It has also been used as a short-stopping agent for controlling polymerization in the production of synthetic rubber of the butadienestyrene type.

Gulf South Research Institute
New Iberia, Louisiana

HYDROTREATING. A specialized kind of hydrogenation in which the quality of liquid hydrocarbon streams is improved by subjecting them to mild or severe conditions of hydrogen pressure in the presence of a catalyst. The objective is to convert undesirable material in the feedstock to either desired materials or easily disposed byproducts, on a highly selective basis. As of the early 1980s about 45% of the crude oil refined in the United States is hydrotreated. Some applications of hydrotreating include: (1) improvement of the burning quality of jet fuels, kerosines, and diesel fuels; (2) purification of light aromatic byproducts from pyrolysis operations; (3) pretreatment of naphtha feeds for catalytic reforming units; (4) reduction in sulfur content of residual fuel oils; (5) pretreatment of catalytic cracking feeds and cycle oils by removal of metals, sulfur, nitrogen, and reduction of polycyclic aromatics; (6) desulfurization of distillate fuels; (7) upgrading of lubricating oil quality; and (8) improvement of color, odor, and storage stability of various fuels.

Some of the specific reactions involved include: (1) hydrogenation of monoaromatics to naphthenes to improve burning quality of certain fuels; (2) removal of nitrogen as ammonia from its organic combinations; (3) removal of oxygen from its organic combinations as water; (4) hydrogenation of polycyclic aromatics so that only one aromatic ring remains in the molecule; (5) hydrogenation of diolefins and olefins to paraffins or naphthenes; (6) removal of sulfur from its organic combinations in various types of sulfur compounds by hydrodesulfurization to form hydrogen sulfide; and (7) decomposition and removal of organometals, such as arsenic compounds in naphthas, by retention of these metals on the catalyst. Vanadium and nickel also can be removed.

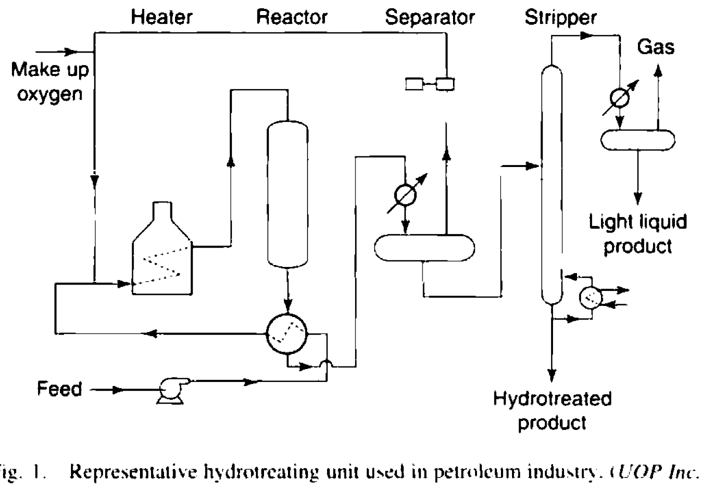

Fig. 1. Representative hydrotreating unit used in petroleum industry. (*UOP Inc.*)

In the hydrotreating process shown by the Fig. 1, the liquid feed is preheated by exchange with the reactor effluent. It is then heated to the desired reactor-inlet temperature in a fired heater. At this point, recycle hydrogen joins the feedstock. An excess of hydrogen is used to suppress accumulation of deactivating carbonaceous deposits on the catalyst. Fresh makeup hydrogen enters the process to maintain a sufficient supply and also pressure on the system. Cooled effluent from the reactor goes to a separator vessel at which point the recycle or net hydrogen is removed. The liquid then goes to a stripper or stabilizer where hydrogen, hydrogen sulfide, ammonia, water, and light hydrocarbons dissolved in the separator liquid are removed. The stabilized hydro-treated liquid, free of dissolved, unwanted contaminants, is routed to subsequent processing or to product fuel blending.

It is interesting to note that there are over 25 proprietary versions of this basic process. Numerous modifications are required, depending upon the nature of the feedstock and desired end products.

HYDROXPROLINE. See **Amino Acids**.

HYDROXYCARBOXYLIC ACIDS

Lactic Acid

Lactic acid (2-hydroxypropanoic acid), $CH_3CHOHCOOH$, is the most widely occurring hydroxycarboxylic acid and thus is the principal topic of this article. Lactic acid is a naturally occurring organic acid that can be produced by fermentation or chemical synthesis. It is present in many foods both naturally or as a product of *in situ* microbial fermentation, as in sauerkraut, yogurt, buttermilk, sourdough breads, and many other fermented foods. Lactic acid is also a principal metabolic intermediate in most living organisms, from anaerobic prokaryotes to humans.

Two significant producers of lactic acids are CCA Biochem by of the Netherlands, with subsidiaries in Brazil and Spain, and Sterling Chemicals, Inc. in Texas City, Tex. CCA uses carbohydrate feedstocks and fermentation technology, and Sterling uses a chemical technology. Lactic acid has been considered a relatively mature fine chemical in that only its use in new applications, e.g., as a monomer in plastics or as an intermediate in the synthesis of high volume oxygenated chemicals, would cause a significant increase in its anticipated demand.

Physical Properties. Pure, anhydrous lactic acid is a white, crystalline solid with a low melting point. However, it is difficult to prepare the pure anhydrous form of lactic acid; generally, it is available as a dilute or concentrated aqueous solution. The properties of lactic acid and its derivatives have been reviewed. A few important physical and thermodynamic properties from this reference are summarized in Table 1.

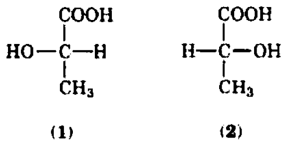
Lactic acid is also the simplest hydroxy acid that is optically active. $L(+)$-Lactic acid (**1**) occurs naturally in blood and in many fermentation products. The chemically produced lactic acid is a racemic mixture and

TABLE 1. PHYSICAL AND THERMODYNAMIC PROPERTIES OF LACTIC ACID

Property	Value
density, g/mL at 20°C	1.2243
viscosity,[a] mPa·s(= cP)	36.9
heat of solution, $L(+)$ at 25°C, kJ/mol[b]	7.79
heat of fusion, kJ/mol[b]	
racemic	11.33
$L(+)$	16.86
heat of combustion, MJ/mol[b]	
racemic	−1.355
$L(+)$	−1.343

[a] 88.6 wt% solution at 25°C.
[b] To convert J to cal, divide by 4.184.

some fermentations also produce the racemic mixture or an enantiomeric excess of $D(-)$-lactic acid (**2**).



(**1**) (**2**)

Many of the physical properties are not affected by the optical composition, with the important exception of the melting point of the crystalline acid, which is estimated to be 52.7–52.8°C for either optically pure isomer, whereas the reported melting point of the racemic mixture ranges from 17 to 33°C.

Chemical Properties. Its two functional groups permit a wide variety of chemical reactions for lactic acid. The primary classes of these reactions are oxidation, reduction, condensation, and substitution at the alcohol group.

Economic Aspects. The incentive for economical production of lactic acid is coming from the development of new, large-volume uses of lactic acid, particularly as feedstocks for biodegradable polymers and oxygenated chemicals. The advent and deployment of highly efficient, membrane-based separation processes and chemical and catalytic conversion technologies, together with commercial interest by several agriprocessing and chemical companies, will lead to the production of low cost lactic acid, which in turn will result in new opportunities for large-scale use of lactic acid.

Specifications, Quality Control, and Analytical Methods. Lactic acid is generally sold under four general product categories: synthetic, fermentation, heat-stable fermentation, and technical.

Lactic acid is generally recognized as safe (GRAS) for multipurpose food use. Lactate salts such as calcium and sodium lactates and esters such as ethyl lactate used in pharmaceutical preparations are also considered safe and nontoxic.

Uses. Currently, the principal use of lactic acid is in food and food-related applications, which in the United States accounts for approximately 85% of the demand. The rest (~15%) of the uses are for nonfood industrial applications.

Hydroxyacetic Acid

Hydroxyacetic acid (glycolic acid), $HOCH_2COOH$, is the first and simplest member of the family of hydroxycarboxylic acids. It occurs naturally as the chief acidic constituent of sugar-cane juice and also occurs in sugar beets and unripe grape juice. It is widely used as a cleaning agent for a variety of industrial applications, and also as a specialty chemical and biodegradable copolymer feedstock.

Properties. Glycolic acid is a colorless, translucent solid; mp = 10°C; bp = 112°C; d at 25°C = 1.26 g/mL; K_a at 25°C = 1.5×10^{-4} pH at 25°C = 0.5; heat of combustion = 697.1 kJ/mol (166.6 kcal/mol); heat of solution = −11.55 kJ/mol; and flash point >300°C.

Glycolic acid is soluble in water, methanol, ethanol, acetone, acetic acid, and ethyl acetate. It is slightly soluble in ethyl ether and sparingly soluble in hydrocarbon solvents.

Reactions. Because it contains both a carboxyl and a primary hydroxyl group, glycolic acid can react as an acid or an alcohol or both. Thus some of the important reactions it can undergo are esterification, amidation, salt formation, and complexation with metal ions, which lead to many of its uses. As a fairly strong acid it can liberate gases (often toxic) when it reacts with the corresponding salts.

Manufacture, Processing, and Economic Aspects. Hydroxyacetic acid is produced commercially in the U.S. by the reaction of formaldehyde with carbon monoxide and water.

Other Hydroxy Acids

Apart from lactic and hydroxyacetic acids, other α- and β-hydroxy acids have been small-volume specialty products produced in a variety of methods for specialized uses.

Preparation. The general preparation of α-hydroxy acids is by the hydrolysis of an α-halo acid or by the acid hydrolysis of the cyanohydrins of an aldehyde or a ketone. β-Hydroxy acids may be made by catalytic reduction of β-keto esters followed by hydrolysis. β-Hydroxy acids can also be prepared by the Reformatsky reaction. γ-Hydroxy acids are seldom obtained in the free state because of the ease with which they form monomeric inner esters, which form stable five-membered rings. Thus the lactones of these acids are the common chemical forms and among these lactones γ-butyrolactone is one of the larger volume specialty chemicals derived from dehydrogenation of 1,4-butanediol.

Reactions and Uses. The common reactions that α-hydroxy acids undergo such as self- or bimolecular esterification to oligomers or cyclic esters, hydrogenation, oxidation, etc. have been discussed in connection with lactic and hydroxyacetic acid. A reaction that is of value for the synthesis of higher aldehydes is decarbonylation under boiling sulfuric acid with loss of water.

β-Hydroxy acids lose water, especially in the presence of an acid catalyst, to give α,β-unsaturated acids, and frequently β,γ-unsaturated acids. γ-Hydroxybutyric acid and its derivatives, particularly its sodium salt, have been studied and used as anesthetics, tranquilizers, sedatives, and hypnotics in surgery and general obstetrics.

Certain bacterial species produce polymers of γ-hydroxybutyric acid and other hydroxyalkanoic acids as storage polymers. These are biodegradable polymers with some desirable properties for manufacture of biodegradable packaging materials, and considerable effort is being devoted by ICI Ltd. and others to the development of bacterial fermentation processes to produce these polymers at a high molecular weight.

γ-Butyrolactone undergoes amination reactions with methylamine or ammonia to produce N-methyl-2-pyrrolidinone (NMP) or 2-pyrrolidinone (PDO) respectively, both of which are commercially important derivatives.

Other multifunctional hydroxycarboxylic acids are mevalonic and aldonic acids which can be prepared for specialized uses as aldol reaction products (mevalonic acid) and mild oxidation of aldoses (aldonic acids).

HYDROXYLAMINE. [CAS: 7803-49-8]. H_2NOH, formula weight 33.02, white, odorless solid, mp 33°C, bp 56°C (22 mm pressure), explosive, soluble in all proportions in H_2O or alcohol. Hydroxylamine is: (1) A weak base forming with acids soluble salts that decompose more or less violently when heated, e.g., hydroxylamine hydrochloride (hydroxylammonium chloride, $H_2NOH \cdot HCl$), mp 151°C, nitrate $H_2NOH \cdot HNO_3$, hemisulfate $H_2NOH \cdot \frac{1}{2}H_2SO_4$. Dihydroxylamine oxalate and trihydroxylamine phosphate are insoluble in H_2O. Hydroxylamine hydrochloride is soluble in alcohol. (2) A weak acid forming with bases soluble salts, e.g., sodium hydroxylamite H_2NONa. Hydroxylamine salt solution is a powerful reducing agent, more especially in alkaline than in acid solution, for example, cupric salt solutions changed to cuprous oxide, silver salt solutions to silver, mercuric chloride solution to mercurous chloride, ferric salt solutions (in acid) to ferrous. Ferrous hydroxide in sodium hydroxide is, however, oxidized by hydroxylamine to ferric hydroxide plus NH_3.

Hydroxylamine reacts with carbonyl group =CO of aldehydes, ketones or quinones, yielding *oximes*, white solids, of definite melting point and used in identification of aldehydes and ketones, e.g., acetaldehyde oxime $CH_3CH{:}NOH$.

Beta-phenylhydroxylamine, N-phenylhydroxylamine, is a white solid, slightly soluble in water, very soluble in alcohol or ether, forms salts with acids, e.g., beta-phenylhydroxylamine hydrochloride $C_6H_5\ NHOH \cdot HCl$, upon exposure to air the water solution forms azobenzene $C_6H_5N{:}NC_6H_5$. Beta-phenylhydroxylamine reacts (1) with oxidizing agents, such as chromic acid or ferric chloride, to form nitrosobenzene C_6H_5NO, (2) with reducing agents, such as tin plus hydrochloric acid, to form aniline $C_6H_5NH_2$, (3) with alkaline cupric salt solution (Fehling's solution) at room temperature to form cuprous oxide, (4) with ammonio-silver salt solution (Tollen's solution) at room temperature to form silver, (5) in the presence of hydrochloric acid to form paraminophenol $HO \cdot C_6H_4 \cdot NH_2(1,4)$.

Beta-phenylhydroxylamine is formed by reduction of nitrobenzene (1) by zinc and calcium chloride or ammonium chloride solution, (2) by electrolysis in acetic acid plus sodium acetate solution.

Diphenylhydroxylamine is prepared by reaction of nitrosobenzene and phenylmagnesium bromide in anhydrous ether, followed by treatment with H_2O (magnesium hydroxybromide also formed).

When hydroxylamine reacts with aldehydes, the resulting compounds are termed *aldoximes* as, for example, acetaldoxime, $CH_3 \cdot CHO + H_2NOH \longrightarrow CH_3 \cdot CH{:}N \cdot OH$(acetaldoxime) $+ H_2O$. Hydroxylamine reactions with ketones produce *ketoximes*, $(CH_3)_2CO + H_2NOH \longrightarrow (CH_3)_2C{:}N \cdot OH$(dimethylketoxime) $+ H_2O$.

The lower aldoximes are essentially odorless, volatile liquids, and miscible with H_2O in all proportions. The higher members are only slightly soluble. Ketoximes have similar properties.

HYDROXY DICARBOXYLIC ACIDS

HYDROXY DICARBOXYLIC ACIDS. Many natural and synthetic organic compounds are hydroxy dicarboxylic acids. This article discusses mainly malic and tartaric acids; thiomalic acid is included because of its structural similarity to malic acid.

Malic Acid

Malic acid (hydroxysuccinic acid, hydroxybutanedioic acid, or 1-hydroxy-1,2-ethanedicarboxylic acid), $C_4H_6O_5$, is a white, crystalline material. The levorotatory isomer, *S*(−)-malic acid (L-malic acid), is a natural constituent and common metabolite of plants and animals. The racemic compound, *R,S*-malic acid (DL-malic acid), is a widely used food acidulant. This material is also used in some industrial applications as a sequestrant and as a buffer for pH control. *R*(+)-Malic acid (D-malic acid) is available only as a laboratory chemical. Following the introduction of a modern, continuous manufacturing process in the early 1960s, malic acid gradually became a large-volume industrial organic acid.

Physical Properties. Malic acid crystallizes from aqueous solutions as white, translucent, anhydrous crystals. The S(−) isomer melts at 100–103°C and the R(+) isomer at 98–99°C. On heating, DL-malic acid decomposes at ca 180°C, by forming fumaric acid and maleic anhydride. Under normal conditions, malic acid is stable; under conditions of high humidity, it is hygroscopic. Malic acid is a relatively strong acid. Its dissociation constants are given in Table 1.

Chemical Properties. Because of its chiral center, malic acid is optically active.

Reactions. Malic acid undergoes many of the characteristic reactions of dibasic acids, monohydric alcohols, and α-hydroxycarboxylic acids.

Manufacture. In the United States, Canada, and Europe, only the synthetic *R,S*-malic acid is produced commercially, whereas both the S and R,S forms are produced in Japan.

Aqueous fumaric acid is converted to levorotatory malic acid by the intracellular enzyme, fumarase, which is produced by various microorganisms.

The commercial synthesis of *R,S*-malic acid involves hydration of maleic acid or fumaric acid at elevated temperature and pressure.

Energy And Environmental Considerations. The energy requirements to produce malic acid via conventional processes are fairly moderate. Malic acid production generates low levels of solid, airborne, and liquid waste. Solid waste is primarily nontoxic malic acid salts resulting form regenerating carbon cells and ion-exchange resins. Airborne emissions are primarily particulates. A 1% malic acid solution is readily biodegradable, with BOD of 5300 mg/L.

TABLE 1. PHYSICAL PROPERTIES OF *R,S*-MALIC ACID

Property	Value
mol wt	134.09
melting point, °C	ca 130
d_4^{20}	1.601
dissociation constant	
K_1	4×10^{-4}
K_2	9×10^{-6}
viscosity (50% aqueous solution at 25°C), mPa · s(s = cP)	6.5
solubility in nonaqueous solvents, % wt/wt	
ethanol	45.5
acetone	17.8
methanol	82.7

Shipping and Storage. Malic acid is shipped in 50-lb, 100-lb, and 25-kg, multiwall paper bags or 100-lb (45.5 kg) fiber drums. Malic acid can be stored in dry form without difficulty, although conditions of high humidity and elevated temperatures should be avoided to prevent caking.

Economic Aspects. Malic acid is manufactured in over 10 countries. The production is primarily used for food (26.6%) and beverages (54.7%); however, some industrial applications (18.7%) exist, e.g., coatings, polymers, and resins. (Historical patterns of use in the United States have been stable and are as noted in parentheses).

Health and Safety. The U.S. FDA has affirmed *R,S*- and *S*(−)-malic acid as substances that are generally recognized as safe (GRAS) as flavor enhancers, flavoring agents and adjuvants, and as pH control agents. *R,S*- and *S*(−)-malic acid may not be used in baby foods. Malic acid is also cleared to correct natural acid deficiencies in juice or wine.

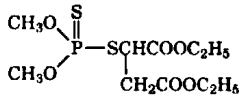
Uses. *R,S*-Malic acid is utilized in a variety of food and beverage and some industrial applications because of its unique combination of properties. These include having unusual taste-blending characteristics, flavor-fixing qualities, the ability to retain sour taste longer, high water solubility, and chelating and buffering properties. Malic acid is also a reactive intermediate in chemical synthesis.

Thiomalic Acid

Thiomalic acid (mercaptosuccinic acid), $C_4H_6O_4S$, mol wt = 150.2, is a sulfur analogue of malic acid. The properties of the crystalline, solid thiomalic acids are given in Table 2. The racemic acid has the following acid dissociation constants at 25°C : $pK_{a1} = 3.30$; $pK_{a2} = 4.94$.

R,S-Thiomalic acid can be prepared from bromosuccinic acid by reaction with K_2S. The two enantiomers can be obtained from the corresponding optically active potassium bromosuccinates.

Thiomalic acid is a skin sensitizer and an antidote in heavy-metal poisoning. Traditionally, it was a component of cold permanent hair-waving solutions and of rust-removing and corrosion-inhibiting compositions. Sodium aurothiomalate (Myochrisin) and other gold thiomalate complexes have antiarthritic properties. The well-known insecticide, malathion, is the thiomalate *S*-ethyl ester of *O,O*-dimethylphosphonodithioic acid.



Tartaric Acid

Tartaric acid (2,3-dihydroxybutanedioic acid, 2,3-dihydroxysuccinic acid), $C_4H_6O_6$, is a dihydroxy dicarboxylic acid with two chiral centers. It exists as the dextro- and levorotatory acid; the meso form (which is inactive owing to internal compensation), and the racemic mixture (which is commonly known as racemic acid). The commercial product in the United States is the natural, dextrorotatory form, (*R-R**, *R**)-tartaric acid (L(+)-tartaric acid). This enantiomer occurs in grapes as its acid potassium salt (cream of tartar). In the fermentation of wine, this salt forms deposits in the vats.

Physical Properties. When crystallized from aqueous solutions above 5°C, natural (R−R*,*R**;)-tartaric acid is obtained in the anhydrous form. Below 5°C, tartaric acid forms a monohydrate which is unstable at room temperature. Some of the physical properties of (*R-R**,*R**;)-tartaric acid are listed in Table 3.

The solubility of (*R-R**,*R**;)-tartaric acid in water varies from 115 g/100 g H_2O at 0°C to 343 g/100 g H_2O at 100°C. One hundred grams of absolute ethanol dissolves 20.4 g of tartaric acid at 18°C, and 100 g of ethyl ether dissolves 0.3 g at 18°C.

TABLE 2. PROPERTIES OF THIOMALIC ACIDS

Acid	Mp, °C	Solubility: Water	Solubility: Ethanol	$[\alpha]_D^{17-17^a}$
R,S-	151	very sol	very sol	
R	154	sol	sol	+64.4°
S	152–153	sol	slightly sol	−64.8°

[a] 5% acid in ethanol.

TABLE 3. PHYSICAL PROPERTIES OF (*R*-*R**,*R**;)-TARTARIC ACID

Property	Value
mol wt	150.086
mp,°C (anhydrous)	169–170
d^{20}, g/cm^3	1.76
heat of solution, kJ/mol[a]	−13.8

[a] To convert kJ to kcal, divide by 4.184.

Chemical Properties. The notation used by *Chemical Abstracts* to reflect the configuration of tartaric acid is as follows: (*R*-*R**,*R**;)-tartaric acid, (*S*-*R**,*R**;)-tartaric acid, and *meso*-tartaric acid. Racemic acid is an equimolar mixture of the two optically active enantiomers and, hence, like the meso acid, is optically inactive.

When free (*R*-*R**,*R**;)-tartaric acid is heated above its melting point, amorphous anhydrides are formed which, on boiling with water, regenerate the acid. Further heating causes simultaneous formation of pyruvic acid, $CH_3COCOOH$; pyrotartaric acid, $HOOCCH_2CH(CH_3)COOH$; and, finally, a black, charred residue. In common with other hydroxy organic acids, tartaric acid complexes many metal ions.

Occurrence. (*R*-*R**,*R**;)-Tartaric acid occurs in the juice of the grape and in a few other fruits and plants. It is not as widely distributed as citric acid or *S*(−)-malic acid. The only commercial source is the residues from the wine industry. The racemic acid is not a primary product of plant processes but is formed readily from the dextrorotatory acid by heating alone or with strong alkali or strong acid. *meso*-Tartaric acid is not found in nature. It is obtained from the other isomers by prolonged boiling with caustic alkali.

Manufacture. The chemical reactions involved in tartaric acid production are formation of calcium tartrate from crude potassium acid tartrate, formation of tartaric acid from calcium tartrate, formation of Rochelle salt from argols, and formation of cream of tartar from tartaric acid and Rochelle salt (RS) liquors.

Economic Aspects. The estimated total worldwide market for tartaric acid is 58,000 t and potassium bitartrate (acid basis) is 20,000 t.

Health and Safety. The FDA affirmed (*R*-*R**,*R**;)-tartaric acid as a generally-recognized-as-safe (GRAS) food substance.

Uses. Tartaric acid is used in carbonated beverages, wine making, and other foods. It is also used to produce emulsifiers, in the manufacture of pharmaceuticals, and in many industrial uses.

Salts. Rochelle salt is used in the silvering of mirrors. Its properties of piezoelectricity make it valuable in electric oscillators. Medicinally, it is an ingredient of mild saline cathartic preparations, e.g., compound effervescing powder. In food, it can be used as an emulsifying agent in the manufacture of process cheese. Cream of tartar is used in baking powder and in prepared baking mixes.

HYGROMETRY AND PSYCHROMETRY. These are instrumental methods for measuring humidity. Humidity can be expressed in a variety of different forms: wet bulb temperature; percent relative humidity (% RH); vapor pressure; mixing ratio; dew/frost point; grains per pound; grams per kilogram; and parts per million, among others. These parameters can be measured by a number of different instruments, each capable of accurate measurement under certain conditions and within specific limitations.

Definition of Humidity

Unless one is routinely working with humidity measurements, there is a tendency to overlook the fact that humidity is water gas, behaving in accordance with the ideal gas laws. One of the easiest ways to put humidity in its proper perspective is through application of Dalton's law of partial pressures to the most commonly encountered gas—*air*.

Dalton's law states that the total pressure P_m exerted by a mixture of gases or vapors is the sum of the pressure of each gas if it were to occupy the same volume by itself. The pressure of each individual gas is called its *partial pressure*. The total pressure of an air-water gas mixture, containing oxygen, nitrogen, and water, is equal to the sum of the partial pressures of each gas:

$$P_m = P_{N_2} + P_{O_2} + P_{H_2O} + \cdots$$

Therefore, the partial pressure of water vapor in air is directly related to the measurement of humidity. This vapor pressure varies from 1.22×10^{-3} mb (millibar) of mercury (0.122 Pascal) at the −75°C frost point of "bone dry" arctic or industrial dry air—to 1.013×10^3 mb of mercury (0.1013×10^6 Pascal) at the 100°C dew point of saturated hot air in a product drier. This is a change of almost a million to one over the span of interest in industrial humidity measurement.

The ideal humidity instrument would be a linear, wide-range pressure gage, specific to water vapor and employing a primary or fundamental measuring method. Such an instrument, although physically possible, would be cumbersome. Most humidity measurements are made by some secondary instrument which is responsive to humidity-related phenomena.

Humidity Parameters

The humidity parameters most often encountered in scientific and industrial applications are given in Table 1. In addition to these common parameters, numerous other formats exist for use in narrow applications or specific technologies. However, most of these are variations of the parameters listed.

The psychrometric chart provides a quick means for converting from one humidity format to another because dew point, relative humidity, ambient temperature, and wet bulb temperature can be conveniently related to each other on a single sheet of paper. The psychrometric chart has

TABLE 1. HUMIDITY MEASUREMENT METHODS

Parameter	Description	Units	Typical applications
Wet bulb temperature	Minimum temperature reached by a wetted thermometer in an airstream	°F or °C	High temperature driers, air conditioning, meteorology, test chambers
Percent relative humidity	The ratio of the actual vapor pressure to the saturation vapor pressure, with respect to water, at the prevailing dry bulb temperature	0–100%	Monitoring conditioning rooms, test chambers, pharmaceutical and foodpackaging
Dew/frost point	Dew point is the temperature to which the air must be cooled to achieve saturation. If the temperature is below 32°F, it is called the frost point	°F or °C	Heat treating, annealing atmospheres, drier control, instrument air monitoring, meteorological/environmental measurements
Volume or mass ratio	Parts per million (ppm) by volume is the ratio of the partial pressure of the water vapor to the partial pressure of the dry carrier gas. PPM by weight is identical to ppm by volume, but the ratio changes according to the molecular weight of the carrier gas.	ppm_v, ppm_w,	Used primarily to insure dryness of industrial process gases such as air, nitrogen, oxygen, methane, hydrogen, etc.

long been the basic tool of air conditioning engineers. A chart of this type is given in the entry entitled **Psychrometric Chart.** Psychrometric charts are available for higher temperatures and humidities and are quite useful in drier and condensation system design. Charts are also available for lower temperatures, but these tend to be less useful because wet bulb measurements are difficult to make with any accuracy at temperatures below −7°C.

Wet Bulb/Dry Bulb Measurements

Psychrometry has long been a popular method for monitoring humidity, primarily due to its simplicity and inherent low cost. A typical industrial psychrometer consists of a pair of matched electrical thermometers, one of which is maintained in a wetted condition. Water evaporation cools the wetted thermometer, resulting in a measurable difference between it and the ambient, or dry bulb measurement. When the wet bulb reaches its maximum temperature depression, the humidity is determined by comparing the wet bulb/dry bulb temperatures on a psychrometric chart. In a properly designed psychrometer, both sensors are aspirated at an airstream rate between 4 and 10 meters per second for proper cooling of the wet bulb, and both are thermally shielded to minimize errors from radiation.

A properly designed and utilized psychrometer, such as the Assman laboratory type, is capable of providing accurate data. However, very few industrial psychrometers meet these criteria and are limited to applications where low cost and moderate accuracy are the underlying requirements. The psychrometer does have certain inherent advantages: (1) The psychrometer is capable of highest accuracy near 100% RH. From an accuracy standpoint, it is superior to most other humidity sensors near saturation. Since the dry bulb and wet bulb sensors can be connected differentially, this allows the wet bulb depression (which approaches zero as the relative humidity approaches 100%) to be measured with a minimum of error. (2) Although large errors can occur if the wet bulb becomes contaminated or improperly fitted, the simplicity of the device affords easy repair at minimum cost. (3) The psychrometer can be used at ambient temperature above 100°C, and the wet bulb measurement is usable up to 100°C.

Major limitations of the psychrometer include: (1) As relative humidity drops below about 20% RH, the problem of cooling the wet bulb to its full depression becomes difficult. The result is impaired accuracy below 20% RH, and few psychrometers work at all below 10% RH. (2) Wet bulb measurement at temperatures below 0°C are difficult to obtain with any high degree of confidence. Automatic water feeds are not feasible, because of freezing. (3) Because a wet bulb psychrometer is a source of moisture, it can only be used in environments where added water vapor from the psychrometer exhaust is not a significant component of the total volume. (4) Generally speaking, psychrometers cannot be used in small, closed volumes.

Percent Relative Humidity

Percent relative humidity is the best known and perhaps the most widely used method for expressing the water vapor content of air. Percent relative humidity is defined as the ratio of the prevailing water vapor pressure e_a to the water vapor pressure if the air were saturated, e_s, multiplied by 100:

$$\% \text{ RH} = (e_a/e_s) \times 100$$

The term "percent relative humidity" appears to be derived from the invention of the hair hygrometer in the 17th Century. The hair hygrometer operates on the principle that many organic filaments, such as hair, goldbeater's skin, and even nylon, change length as a nearly linear function of the *ratio* of *prevailing water vapor pressure* to the *saturation vapor pressure*.

Basically, percent relative humidity is an indicator of the water vapor saturation deficit of the gas mixture, rather than an indicator of sorption, desorption, comfort, or evaporation. A measurement of % RH without a corresponding measurement of dry bulb temperature is not of particular value, since the water vapor content cannot be determined from % RH alone.

Sensors for Measuring % RH. Over the years, devices other than the simple hair hygrometer have evolved which permit a direct measurement of % RH. These devices are, for the most part, electrochemical sensors that offer a degree of ruggedness, compactness, and remote electronic readout ability not afforded by hair devices.

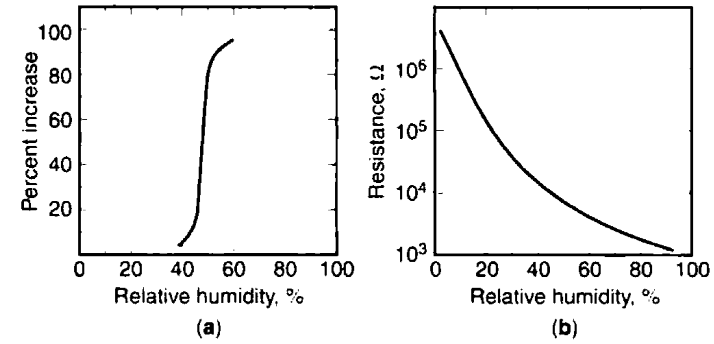

Fig. 1. Resistance characteristics of typical Dunmore and Pope sensors. (**a**) Dunmore sensors are limited to a narrow range of humidity. This sensor operates between 40 and 60% RH. (**b**) Pope sensors operate over a wide humidity range, but output impedance of the sensor varies from 1000 ohms (100% RH) to several megohms (10% RH), which complicates readout circuitry

Two widely used electronic % RH sensors are the Dunmore element and the Pope cell. The Dunmore sensor employees a bifilar-wound inert wire grid on an insulative substrate which is coated with a lithium chloride solution of a controlled concentration. The hygroscopic nature of this salt causes it to take up water vapor from the surrounding atmosphere. The ac resistance of the sensor is an indication of the prevailing % RH. Dunmore cells are excellent RH sensors, but, because of the characteristics of lithium chloride, are usually designed to cover a narrow range of interest. For example, a single sensor may cover from 40 to 60% RH and the sensor output is usable only in that range. See Fig. 1(a).

Wide-range Dunmore sensors can be made with a cluster of narrow range sensors in a common housing, mated with an electrical matching network. This arrangement, however, usually results in a rather bulky sensor.

The Pope cell employs a similar bifilar conductive grid on an insulative substrate. In this sensor, the substrate is made from polystyrene, which has been treated in a prescribed fashion with sulfuric acid. This results in sulfonation of the longer-chain polystyrene molecules. Because the sulfate radical (SO_4) is highly mobile in the presence of hydrogen ions (available from the water molecule in vapor form), the $(SO_4)^{2-}$ ions can detach and take on H^+ ions, thereby altering the surface resistivity of the sensor as a function of humidity.

In both the Dunmore and Pope sensors, the element is arranged in an ac-excited Wheatstone bridge so that only alternating current flows through the grid. Direct current excitation of either the Dunmore or Pope elements polarizes the sensor, eventually causing loss of calibration.

The Pope sensor has one significant advantage over the Dunmore sensor in that the Pope unit is a wide-range sensor, typically covering 15% RH to 99% RH in a single element. See Fig. 1(b). Considerable attention must be given to readout circuitry for the Pope sensor because the resistance varies in a nonlinear fashion from 1000 ohms to several megohms.

Dew Point Hygrometry

Dew point measurements are widely used in scientific and industrial applications when precise measurement of water vapor pressure is needed. Dew point, the temperature at which water condensate begins to form on a surface, can be accurately measured from −75°C to +100°C across the entire range of humidity with a condensation (chilled mirror) hygrometer.

Three types of instruments have received wide acceptance in dew point measurements: (1) the saturated salt dew point sensor; (2) the condensation-type hygrometer; and (3) the aluminum oxide sensor. Many other instruments are used in specialized applications, including pressure ratio devices, dewcups, and fog chambers. The latter are manually operated.

Saturated Salt Dew Point Sensors. The saturated salt (lithium chloride) dew point sensor is widely used because of its inherent simplicity, ruggedness, and low cost. Both the United States and Canadian government weather services use this type of sensor for most official groundbased humidity measurements. However, some of these are being converted to the more accurate condensation hygrometers.

The principle of the saturated salt dew point sensor is based on the relationship that the vapor pressure of water is reduced in the presence of a salt. When water vapor in the air condenses on a soluble salt, it forms a saturated layer on the surface of the salt. This saturated layer has a lower

vapor pressure than water vapor in the surrounding air. If the salt is heated, its vapor pressure increases to a point where it matches the water vapor pressure in the surrounding air and the evaporation/condensation process reaches equilibrium. The temperature at which equilibrium is reached is directly related to the dew point.

A saturated salt sensor is constructed with an absorbent fabric bobbin covered with a bifilar winding of inert electrodes and coated with a dilute solution of lithium chloride. Lithium chloride (LiCl) is often used as the saturating salt because of its hygroscopic nature, which permits application in relative humidities between 11 and 100%.

An alternating current is passed through the winding and salt solution, causing resistive heating. As the bobbin heats, water evaporates into the surrounding air from the diluted LiCl solution. The rate of evaporation is determined by the vapor pressure of water in the surrounding air. When the bobbin begins to dry out, due to evaporation of water, resistance of the salt solution increases. With less current through the winding, because of increased resistance, the bobbin cools and water begins to condense, forming a saturated solution on the bobbin surface. Eventually, equilibrium is reached and the bobbin neither takes on nor loses any water.

Properly used, a saturated salt sensor is accurate to ±1°C between dew point temperatures of −12 and +38°C. Outside these limits, small errors may occur as a result of the multiple hydration characteristics of lithium chloride, which may produce ambiguous results at 41°C, −12°C, and −34°C dew points. Maximum errors at these ambiguity points are 1.4, 1.6, and 3.4°C, respectively, but actual errors encountered in typical applications are usually less.

Applications. The saturated salt sensor has certain advantages over other electrical humidity sensors, such as % RH instruments. Because the salt sensor operates as a current carrier saturated with Li and Cl ions, addition of contaminating ions has little effect on its behavior compared to a typical RH sensor, which operates "starved" of ions and is easily contaminated. A properly designed saturated salt sensor is not easily contaminated since, from an ionic standpoint, it can be considered precontaminated.

If a saturated salt sensor does become contaminated, it can be washed with an ordinary sudsy ammonia solution, rinsed and recharged with lithium chloride. It is seldom necessary to discard a saturated salt sensor if proper maintenance procedures are observed.

Limitations of saturated salt sensors include: (1) relatively slow response time; and (2) a lower limit to the measurement range imposed by the nature of lithium chloride. The sensor cannot be used to measure dew points when the vapor pressure of water is below the saturation vapor pressure of lithium chloride, which occurs at about 11% RH. In certain gases, ambient temperatures can be reduced, increasing the RH to above 11%; but the extra effort needed to cool the gas usually warrants selection of a different type of sensor. Fortunately, a large number of scientific and industrial measurements fall above this limitation and are readily handled by the sensor.

Condensation-Type Hygrometers. The condensation-type dew point hygrometer is one of the most accurate and reliable of sensors for humidity measurements, and has the widest range. These features are achieved, however, through increased complexity and cost. In the condensation-type hygrometer, a surface is cooled (either thermoelectrically, mechanically, or chemically) until dew or frost begins to condense out. The condensate surface is maintained electronically in vapor pressure equilibrium with the surrounding gas, while surface condensation is detected by optical, electrical, or nuclear techniques. See Fig. 2. The surface temperature is then the dew point temperature, by definition.

The largest source of error in a condensation hygrometer stems from the difficulty in measuring condensate surface temperature accurately. Typical industrial versions of the instrument are accurate to ±0.2°C over very wide temperature spans. Laboratory models offer accuracies up to ±0.1°C.

Wide span and minimal errors are two main features. A properly designed condensation hygrometer can measure dew points from 100°C down to frost points of −75°C.

Response time of a condensation dew point hygrometer is usually specified in terms of its cooling/heating rate, typically 1.5°/second, making it considerably faster than a saturated salt dew point sensor and nearly as fast as most electrical % RH sensors. Perhaps the most significant feature of the condensation hygrometer is its fundamental measuring technique, which essentially renders the instrument self-calibrating. For calibration, it is only necessary to manually override the surface-cooling control loop, causing the surface to heat, and witness that the instrument recools to the same dew point when the loop is closed. Assuming that the surface temperature measuring system is calibrated, this is a reasonable and valid check on the instrument's performance.

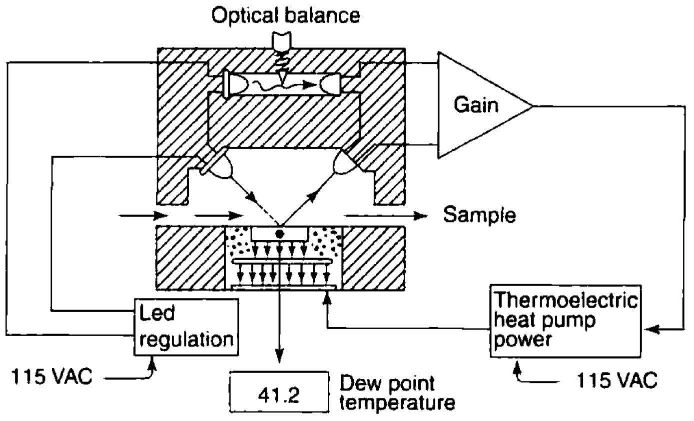

Fig. 2. Dew is detected in a condensation hygrometer by cooling a surface until water begins to condense. Condensation is detected optically or electronically. The signal is fed into a control circuit which maintains the surface temperature at the precise dew point

Because of its fundamental nature and superior accuracy and repeatability, this kind of instrument is widely used as a secondary standard (National Bureau of Standards) for calibrating other lower level humidity instruments.

The inert construction of the condensation hygrometer makes it virtually indestructible. Although the instrument can become contaminated, it is easy to wash and return to service without impairment of performance or calibration.

The condensation (chilled mirror) hygrometer measures dew/frost temperature. Unfortunately, many applications require measurement of % RH, water vapor in parts per million, or some other humidity parameter. In such cases, the user must decide whether to employ the fundamental, high accuracy condensation hygrometer and convert the dew/frost point measurement to the desired parameter, or use lower level instrumentation to measure these parameters directly. In recent years, microprocessors have been developed which can be incorporated in the design of a condensation hygrometer, resulting in instrumentation that can offer accurate measurements of humidity in terms of almost any humidity parameter.

Electrolytic Hygrometer. A typical electrolytic hygrometer utilizes a cell coated with a thin film of phosphorous pentoxide (P_2O_5), which absorbs water from the sample gas. See Fig. 3. The cell has a bifilar winding of inert electrodes on a fluorinated hydrocarbon capillary. Direct current applied to the electrodes dissociates the water, which is absorbed by the P_2O_5, into hydrogen and oxygen. Two electrons are required to electrolyze each water molecule and thus the current in the cell represents the number of molecules dissociated. A further calculation, based on flow rate, temperature and current, yields the parts per million concentration of water vapor.

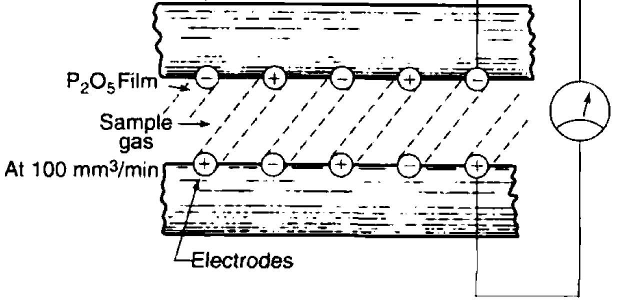

Fig. 3. An electrolytic hygrometer dissociates water, absorbed by P_2O_5, into hydrogen and oxygen by electrolysis. Since two electrons are required to electrolyze a molecule of water, the amount of current used by the hygrometer relates to parts per million of water vapor

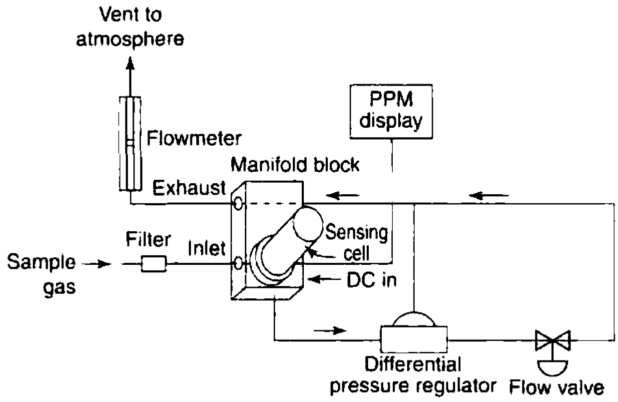

Fig. 4. Calculation of the water vapor content in an electrolytic hygrometer is dependent on precise control of the flow rate. This arrangement controls the sample pressure across the cell, ensuring correct flow regardless of input pressure fluctuations

In order to obtain accurate data, the flow rate of the sample gas through the cell must be known and constant. Since the ppm calculation is partially based on flow, an error in the flow rate causes a direct error in measurement.

A typical sampling system for insuring constant flow is shown in Fig. 4. Constant pressure is maintained within the cell. Sample gas enters the inlet, passes through a stainless steel filter, and enters a stainless steel manifold block. It is very important that all components prior to the sensor be made of an inert material, such as stainless steel, to minimize contamination. After passing through the sensor, the sample gas pressure is controlled by a differential pressure regulator which compares pressure of the gas leaving the sensor with the pressure of the gas venting to atmosphere through a preset valve and flowmeter. In this way, constant flow is maintained even though there may be nominal pressure fluctuations at the inlet port.

A typical electrolytic hygrometer can cover a span from 0 to 2000 ppm with an accuracy of ±5% of the reading, more than adequate for most industrial applications. The sensor is suitable for most inert elemental gases and organic and inorganic gas compounds that do not react with P_2O_5.

Electrolytic hygrometers cannot be exposed to high water vapor levels for any long period of time because this results in a high usage rate for the P_2O_5 and high cell currents.

Aluminum Oxide Moisture Sensor. This type of sensor is a capacitor, formed by depositing a layer of porous aluminum oxide onto a conductive substrate, and then coating the oxide with a thin film of gold. The conductive base and the gold layer become the capacitor's electrodes. Water vapor penetrates the gold layer and is absorbed by the porous oxidation layer. The number of water molecules absorbed determines the electrical impedance of the capacity, which is, in turn, a measure of water vapor pressure.

Advantages of the aluminum oxide sensor are: (1) small size and suitability for *in situ* use; (2) it can be used very economically in multiple sensor arrangements; (3) suitability for very low dew point levels without the need for sensor cooling () as required in condensation-type sensors—(typically, dew points down to −100°C can be measured without serious difficulty); (4) the unit covers a wide span.

Limitations of the aluminum oxide sensor include: (1) the sensor is a secondary measurement device and must periodically be calibrated to accommodate aging effects, hysteresis, and contamination; and (2) sensors require separate calibration curves, which are typically nonlinear.

Aluminum oxide humidity instruments are available in a variety of types, ranging from a low-cost, single-point system, including portable battery operated models, to multipoint microprocessor based systems with capability to compute and display humidity information in different parameters, such as dew point, % RH, etc.

The aluminum oxide sensor is also used for moisture measurements in liquids (hydrocarbons). Because of its low power usage, it is suitable for use in explosion proof installations. These sensors are frequently used in petrochemical applications where low dew points are to be monitored on line and where the reduced accuracies and other limitations are acceptable. The advantages of the sensor must be weighted against the fact that accuracy is lower than with any of the fundamental measurement sensor types. As a secondary measurement device, it can provide reliable data only if kept in calibration and if damage due to incompatible contaminants is avoided.

HYGROSCOPIC. 1. Pertaining to a marked ability to accelerate the condensation of water vapor. In meteorology, this term is applied principally to those condensation nuclei composed of salts that yield aqueous solutions of a very low equilibrium vapor pressure compared with that of pure water at the same temperature. Condensation on hygroscopic nuclei may begin at a relative humidity much lower than 100% (about 75% for sodium chloride); while on so-called nonhygroscopic nuclei, which merely furnish sufficiently large (by molecular standards) wettable surfaces, relative humidities of nearly 100% are required.

2. Descriptive of a substance, the physical characteristics of which are appreciably altered by effects of water vapor. The hygroscopicity of certain materials has been advantageously utilized in humidity measurement and control devices; for example, the hair element of a hair hygrometer.

HYPERCONJUGATION. The description of the properties of a molecule in terms of resonance structures in which an atom or group is not joined by any sort of bond to the atom to which it is ordinarily considered linked. Also called no-bond resonance. The hypothesis of hyperconjugation has been advanced to interpret some properties of substances containing but 1 double bond by analogy with those of substances containing conjugated double bonds. Consider a substance with a terminal structure $H_3C{-}CH{=}CH\ldots$ One of the possible resonating structures of this group is

$$H_3{\equiv}C{-}CH{=}CH \text{ —— } H_3{=}C{=}CH{-}CH{-}$$

the dotted line indicating two unpaired electrons with opposite spins.

HYPEREUTECTIC ALLOY. An alloy with a composition falling on the right of the eutectic point of a binary phase diagram that freezes with a structure containing some eutectic.

HYPERFINE STRUCTURE. In general, a set of very closely spaced lines in atomic spectra or other kinds of spectra. There may be many causes of hyperfine structure: (1) for a single atomic species or nuclide, the occurrence of spectral lines as doublets, triplets, etc., due to the interaction, or coupling, of the total angular momentum of the orbital electrons with the nuclear spin and associated magnetic moment; (2) for an element consisting of several isotopes, the occurrence of components for each spectral line that is observable under high resolution, each isotope contributing one or more components. This type of hyperfine structure is often called isotope structure to differentiate it from the first type of hyperfine structure discussed above. See also **Atomic Spectra**.

HYPERONS. These are subatomic particles that are more massive than nucleons (protons and neutrons). *Strangeness* is a property of elementary particles found useful in classifying hyperons. Each particle is assigned a strangeness quantum number S which is related to the electric charge Q, the isospin number T, and the baryon number B by the formula $Q = T + (S + B)/2$. ($T = \frac{1}{2}$ for a proton and $-\frac{1}{2}$ for a neutron; other particles may have $T = 0$ or $T = 1$, depending on the type.) Strangeness is conserved in reactions involving the strong interaction. The selection rules resulting from strangeness conservation are important in understanding why some reactions take place much more slowly than others. See also **Particles (Subatomic)**.

HYPERSORPTION. Process in which activated carbon selectively absorbs the less-volatile components from a gaseous mix, while the more-volatile components pass on unaffected. Particularly applicable to separations of low-boiling mixtures such as hydrogen and methane, ethane from natural gas, ethylene from refinery gas, etc.

HYPERSTHENE. The mineral hypersthene is an orthorhombic pyroxene, chemically a ferromagnesian silicate, differing from enstatite in that

the iron content is considerable (FeO being greater than 15%). A general formula is (Mg, Fe)SiO_3. It is usually found as a massive mineral, whose crystals tend to be prismatic or tabular in habit. It has a distinct prismatic cleavage; fracture, uneven; brittle; hardness, 5–6; specific gravity, 3.42–3.84; luster, pearly to somewhat metallic; color, brownish-green, brown, greenish-black to grayish-black; streak, grayish-brown; translucent to opaque. Hypersthene is often associated with labradorite in gabbro and norite and in extrusive rocks like andesite. It is occasionally encountered in meteorites. Hypersthene is associated with pyrrhotite in Bavaria, with labradorite on the Isle St. Paul, Labrador. It is also found in Montmorency County, Quebec; and in the United States in the rocks of the Cortlandt series in the Hudson River Valley, and the andesites of Colorado and northern California. Superb crystals of exceptional size and quality have been found growing into and within the almandinepyrope garnets at Gore Mountain, North River, New York. The rarity of hypersthene in crystal form makes this occurrence noteworthy. The word hypersthene comes from the Greek words meaning *strong* or *tough*.

See also **Pyroxene**.

HYPOBARIC (CONTROLLED-ATMOSPHERE) SYSTEMS. Sensitive materials, notably fresh foods, normally cannot withstand long periods of transportation and storage prior to consumption. Over the years, much of the effort extended toward offering produce in marketplaces far distant from the source was concentrated on reducing the time for delivery. Thus, the extensive use of air express and air freight. Conventional refrigeration systems for trucks and railway cars also were especially adapted for use during transport. But even with all of these improvements in technology, certain transporting feats (as, for example, shipping midwestern pork to the California and even Hawaii markets) were difficult to achieve. The controlled-atmosphere hypobaric concept has greatly extended the potential for distant shipping of delicate, perishable materials (not necessarily limited to foodstuffs).

In 1964, the Institute of Food Technologists annual award was given in recognition of the development of a controlled-atmosphere storage system. Essentially, the process was designed to reduce the rate of deterioration of certain fruits and vegetables in refrigerated storage by reducing the oxygen level, increasing the carbon dioxide level, and maintaining the relative humidity close to 100%. In an initial design, the conditions were created by using a home-furnace size catalytic generator that burned natural gas or propane gas to create the atmosphere that essentially halts the natural respiration of the stored products. Later, the gas generator was replaced by cryogenic liquefied gases, allowing additional flexibility and the creation of any desired gas mixture. Atmospheres can be tailored to particular perishables. For example, an atmosphere of 15–20% carbon dioxide and 80–85% nitrogen is optimal for strawberries. For iceberg lettuce, an atmosphere of 8–10% oxygen, less than 10% carbon dioxide, with the remainder nitrogen is used. As of the early 1980s, the system has been installed on over ten thousand rail cars and 7000 sea vans.

In 1979, another IFT award was given in recognition of a hypobaric transport and storage system for fresh meats and meat products. Hypobarics is defined as a precisely controlled combination of low pressure, low temperature, high humidity, and ventilation which, when properly applied, extends up to six times the length of time a perishable commodity remains fresh. This makes possible the shipment of perishable items by way of relatively low-cost surface transportation to distant points. In developing the concept, it was observed that refrigerated storage of fruits in closed containers will result in accumulation of gases generated by the fruit, i.e., ethylene and carbon dioxide, an atmosphere which hastens ripening and spoilage. Although ventilation of fruit containers can prevent accumulation of the gases, the gases are not removed from within the product itself—with no prevention of accumulation of gases within the cells of the fruit. The researchers made the supposition that by drawing a partial vacuum on a closed vessel containing the fruit, the low pressure would increase the diffusivity of the gases, thus promoting release and removal of the gases. At the same time, a reduction of pressure would reduce the oxygen concentration, thus retarding respiration and attendant spoilage. Combined with refrigeration, this would decelerate the metabolic processes, not only of the fruit, but also of any bacteria present. Humidification of the chamber would prevent any drying of the fruit. After testing the concept on bananas and other perishables, the system was patented.

Generally the storage temperature for meats is about −1°C, and up to 10 or 12°C for various fruits and vegetables. In all cases, the relative humidity is controlled at about 95%. Pressure ranges between 10 and 80 millimeters of mercury. Lower pressures are maintained for meats and seafoods; somewhat higher pressures for fruits and vegetables.

HYPOCHLORITES. When chlorine is reacted with an alkali, a hypochlorite is formed. These compounds are very high-tonnage chemicals for sanitizing and bleaching purposes. Commercial sodium hypochlorite NaClO, CAS: 7681-52-9, usually is available in two strengths (1) the familiar household liquid bleach which contains about 5.25% (weight) NaClO, and (2) commercial bleach which contains about 13% (weight) NaClO. The latter compound sometimes is referred to as 15% bleach because the chlorine content is approximately 150 grams/liter of available chlorine. The term "liquid chlorine" usually refers to a solution of NaClO (up to 10%) used in the swimming-pool trade. "Dry chlorine" is part of the registered trademark of a proprietary calcium hypochlorite product containing 70% available chlorine. See also **Bleaching Agents**.

Sodium hypochlorite normally is manufactured in batches by diluting caustic soda to the proper starting concentration. This is approximately 6.8% NaOH for the 5.25% bleach; and about 18.5% NaOH for the 15% bleach. After cooling the caustic soda solution, chlorine gas is added through a sparger pipe until the desired concentration is reached. This usually is determined by making a series of titration analyses. Bleaching powder $CaOCl_2$ is made by passing chlorine gas over slaked lime. This was the first type of chlorine bleaching agent made and dates back to 1799. The product usually contains about 30% available chlorine. Over the years, it was used extensively in the bleaching of textiles and for sanitizing even though the compound is unstable and difficult to use. The original bleaching powder largely has been replaced by an improved calcium hypochlorite product, which contains about 70% available chlorine. The compound essentially is a calcium hypochlorite dihydrate and, in one process, is made by chlorinating a slurry of lime and caustic soda. The crystals that precipitate out are mixed with calcium chloride and chlorinated lime. When warmed, the calcium hypochlorite dihydrate precipitates, with sodium chloride remaining in solution. After filtering, the cake is dried, granulated, sized, and packaged. In addition to use in swimming pools, products of this type are used widely for water purification, algae control, and sanitation. On a very high-tonnage basis, calcium hypochlorite $Ca(ClO)_2 \cdot 4H_2O$ is used for pulp bleaching in the paper industry. Bleach liquor containing from 20–40% available chlorine may be produced in batches or continuously. In a continuous system, the flow of chlorine is controlled by making frequent (or continuous) measurements of oxidation-reduction potential.

A common means of detecting hypochlorites is the production of a blue color (caused by free iodine) with starch iodide paper by hypochlorites in weakly alkaline solution. Silver nitrate also precipitates part of the hypochlorite in solutions as white silver chloride.

Hypochlorous Acid. [CAS: 7790-92-3]. This compound, HOCl, is prepared by the reaction of (1) chlorine monoxide Cl_2O with H_2O, (2) sodium hypochlorite and an acid, excess acid yielding chlorine and oxygen, and (3) chlorine with mercuric oxide suspended in water, mercuric chloride being formed simultaneously. Hypochlorous acid is a yellow solution of characteristic odor. It decomposes upon standing, the rate depending upon (1) concentration, (2) exposure to light, (3) presence of a catalyst (cobaltous hydroxide, for example, promotes the evolution of oxygen), and (4) acidity or alkalinity. Hypochlorous acid is a powerful oxidizing agent and sometimes used as a bleaching agent for organic colors.

Perchloric Acid. [CAS: 7601-90-3]. This compound, $HClO_4$, is a colorless, fuming, oily liquid, miscible with H_2O, volatile under diminished pressure. A maximum constant-boiling solution (203°C, 760 millimeters Hg) results when the concentration of $HClO_4$ reaches 73% in H_2O. Cold dilute perchloric acid reacts with such metals as zinc and iron, yielding hydrogen gas and the corresponding perchlorate in solution. It is stable from the point of view of oxidation and reduction (except that iodine is oxidized to periodic acid, with liberation of chlorine, ferrous salt solutions to ferric, titanous salt solutions to titanic). Concentrated hot perchloric acid, on the other hand, is a powerful oxidizing agent, exploding violently in contact with charcoal, paper, or alcohol; causes serious wounds in contact with the skin. Prepared by distilling ammonium perchlorate with HNO_3 and HCl.

Metallic perchlorates are soluble in water, except that potassium perchlorate is slightly soluble. Potassium perchlorate is, however, insoluble

in alcohol containing perchloric acid, a property made use of in the qualitative recognition and quantitative estimation of potassium in salt solutions. Perchlorates, when heated, evolve oxygen and leave the chloride as a residue. Potassium perchlorate decomposes at 400°C.

HYPOEUTECTIC ALLOY. An alloy to the left of the eutectic point in a binary phase diagram that freezes with a structure containing some eutectic.

HYPOFLUORITE. Any compound containing the group—OF. The simple anion FO^- is unknown. A number of covalent hypofluorites are known, including such compounds with carbon, oxygen, nitrogen, sulfur, chlorine and arsenic (uncertain). CF_3OF, CF_3COOF, C_2F_5COOF, NO_2OF, OF_2, O_2F_2, O_3F_2, SF_5OF, FSO_2OF, ClO_3OF and possibly AsF_4OF. These are all powerful fluorinating agents. They react violently with water yielding OF_2 as one product. The oxygen fluorides O_3F_2 and O_2F_2 decompose about −158°C and −100°C, respectively, the former into the latter and the latter into the elements. Nitryl and perchloryl hypofluorites (fluorine nitrate and fluorine perchlorate) easily detonate. The perfluoracyl hypofluorites are much more stable but may also decompose violently. The others appear to be stable.

HYPOIODOUS ACID AND HYPOIODITES. Hypoiodous acid (HOI) is a greenish-yellow solution, of characteristic odor. It is unstable, and cannot be distilled unchanged.

Prepared by reaction (1) of iodine and mercuric oxide (see also **Mercury**) suspension in water, mercuric iodide being simultaneously formed, (2) of sodium hypoiodite and an acid, excess acid yielding iodine.

Sodium hydroxide solution reacts with iodine to form iodide and hypoiodite, the latter decomposing in a few hours at ordinary temperatures to form iodide and iodate.

HYPONITROUS ACID AND HYPONITRITES. Hyponitrous acid $H_2N_2O_2$ is a white solid, explosive even at as low a temperature as 0°C, soluble in water, more soluble in ether, can thus be extracted from water solution by ether and the latter evaporated, water solution decomposes quickly into nitrous oxide plus water. Hyponitrous acid is nonreactive with hydriodic acid (a strong reducing agent), but reactive with permanganic acid (a strong oxidizing agent) to form nitrous or nitric acid.

Prepared (1) by reaction of silver hyponitrite $Ag_2N_2O_2$ and hydrogen chloride in anhydrous ether, an evaporation of the resulting solution, (2) by reaction of hydroxylamine H_2NOH plus nitrous acid HONO.

Sodium hyponitrite $Na_2N_2O_2$ is formed (1) by reaction of sodium nitrate or nitrite solution with sodium amalgam (sodium dissolved in mercury), after which acetic acid is added to neutralize the alkali. Sodium stannite ferrous hydroxide, or electrolytic reduction with mercury cathode may also be utilized, (2) by reaction of hydroxylamine sulfonic acid and sodium hydroxide. Silver hyponitrite is formed by reaction of silver nitrate solution and sodium hyponitrite.

HYPOPHOSPHORIC ACID AND HYPOPHOSPHATES. Hypo-phosphoric acid (H_2PO_3 or $H_4P_2O_6$) is a solid, melting point 55°C, decomposing in solution to form phosphorous plus phosphoric acids. Hypophosphoric acid is used in solution and is a reducing agent, but only with strong oxidizing agents, such as potassium permanganate: and the acid is unaffected by zinc and dilute sulfuric acid (distinction from phosphorous acid). Dehydration of hypophosphoric acid does not yield phosphorus tetroxide; hydration of phosphorus tetroxide does not yield hypophosphoric acid but phosphorous plus phosphoric acids.

Hypophosphoric acid is formed by reaction (1) of yellow phosphorous and potassium permanganate in sodium hydroxide medium, (2) of red phosphorus and calcium hypochlorite solution, (3) also one of the products of slow oxidation at ordinary temperatures of phosphorus in moist air.

There are recorded the following sodium hypophosphates: Na_2PO_3 (or $Na_4P_2O_6$), $NaHPO_3$ (or $Na_2H_2P_2O_6$), $Na_3H(PO_3)_2$ (or $Na_3HP_2O_6$), and $(NaH_3PO_3)_2$ (or $NaH_3P_2O_6$). There is evidence in support of each of the formulas H_2PO_3, $H_4P_2O_6$ for hypophosphoric acid.

Ester: Dimethyl hypophosphate $(CH_3)_2PO_3$ or $(CH_3O)_2PO$. See also **Phosphorus**.

HYPOPHOSPHOROUS ACID AND HYPOPHOSPHITES. Hypo phosphorous acid (H_3PO_2, or $H \cdot PO_2H_2$) is a colorless liquid, melting point 26.5°C, density 1.493.

Hypophosphorous acid is miscible with water in all proportions and a commercial strength is 30% H_3PO_2. Hypophosphites are used in medicine.

Hypophosphorous acid is a powerful reducing agent, e.g., with copper sulfate forms cuprous hydride Cu_2H_2, brown precipitate, which evolves hydrogen gas and leaves copper on warming; with silver nitrate yields finely divided silver; with sulfurous acid yields sulfur and some hydrogen sulfide; with sulfuric acid yields sulfurous acid, which reacts as above; forms manganous immediately with permanganate.

Hypophosphorous acid is formed by reaction of barium hypophosphite and sulfuric acid, and filtering off barium sulfate. By evaporation of the solution in vacuum at 80°C, and then cooling to 0°C, hypophosphorous acid crystallizes.

Sodium hypophosphite $NaPO_2H_2$, the only sodium hypophosphite, is formed (1) by reaction of yellow phosphorus and sodium hydroxide solution (phosphine simultaneously formed), (2) by reaction of hypophosphorous acid and sodium hydroxide, and evaporating. Sodium hypophosphite, upon heating, yields sodium phosphate and sodium phosphide. Common tests for the hypophosphites are as follows:

1. Zinc reduces dilute sulfuric acid solution of hypophosphites to phosphine recognizable by odor (difference from phosphates).
2. Barium chloride produces no precipitate (difference from phosphites). See also **Phosphorus**.

HYPOSULFUROUS ACID AND HYPOSULFITES. Hyposulfurous acid $H_2S_2O_4$ is a yellow solution rapidly oxidized in air to sulfurous acid and then to sulfuric acid. Commercially known as hydrosulfurous acid and its salts as hydrosulfites (but not to be confused with "hypo" which is sodium thiosulfate).

Hyposulfurous acid is a powerful reducing agent, e.g., with copper sulfate forms cuprous hydride Cu_2H_2, brown precipitate, which evolves hydrogen gas and leaves copper on warning, with silver nitrate yields finely divided silver, with permanganate yields manganous compounds. Hyposulfurous acid is formed by reaction of sodium hyposulfite and an acid.

Sodium hyposulfite, sodium hydrosulfite $Na_2S_2O_4 \cdot 2H_2O$ is formed (1) by reaction of zinc and sulfurous acid (or sodium hydrogen sulfite), yielding zinc hyposulfite and then converted by sodium chloride into sodium hyposulfite, (2) by electrolysis of sodium hydrogen sulfite and then addition of sodium chloride.

Sodium hyposulfite is used to bleach sugar, indigo, wood pulp. With moist hydrogen sulfide, sulfur is precipitated and sodium thiosulfate simultaneously formed.

HYPOTHESIS. A tentative assumption, usually based upon some reasonable concept, made in order to generate interest in obtaining proof and to consider the consequences of the assumption.

HYSTERESIS. (Derived from the Greek word meaning "to lag behind.") In general, the phenomenon exhibited by a system whose state depends

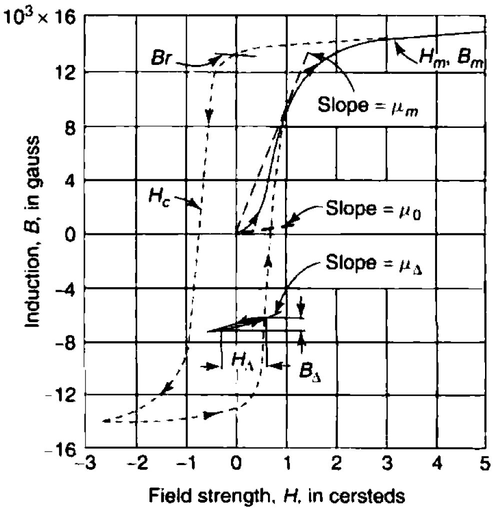

Fig. 1. Hysteresis loop (dotted). Some important magnetic quantities are shown

on its previous history. This term usually refers to magnetic hysteresis, of importance in alternating-current machinery. When a ferromagnetic material such as iron is placed in a magnetic field, a certain amount of energy is involved in bringing about its magnetization. If the field is a rapidly alternating one, the material may become noticeably warm. It appears that the repeated changes of orientation in whatever it is within the substance that responds to the reversals of field are opposed by something like viscous friction.

A quantitative study of the process indicates that, as the field intensity H increases, the magnetic induction B also increases in a manner characteristic of the substance. This is conveniently represented by a graph, which is called the magnetization curve. See Fig. 1. Its initial slope is the initial permeability (μ_0). If H is carried to some maximum value H_m and then reduced (to $-H_m$), B follows the dotted hysteresis curve. B does not fall off as it was built up (solid line); the residual induction B_r is the induction remaining when H has been reduced to zero; the reverse H needed to reduce B to zero is called the coercive force (H_c). From this point the cycle proceeds to describe the closed curve shown by the dotted lines, which is called the hysteresis loop. The initial portion (solid line) is not retraced. The amount of energy converted into heat is proportional to the area of the cycle.

Electric hysteresis is a somewhat analogous phenomenon exhibited by dielectrics in the electric field and gives rise to heating in capacitors.

Some solids exhibit what is called elastic hysteresis, in which the variables corresponding to H and B in the magnetic case are the stress and the strain or deformation. Elastic bodies such as metals operating at stresses below the proportional limit also undergo hysteresis.

Hysteresis energy is that energy used per cycle of operation to overcome the effect of hysteresis.

I

-IC. A suffix, used in naming inorganic compounds, that indicates that the central element is present in its highest oxidation state. Thus in ferric chloride ($FeCl_3$) the iron has an oxidation number of +3, equivalent to its valence: in an ionized state it would have three positive charges (Fe^{3+}). (A recommended change in this system of nomenclature is to use the common name of the element (iron) together with a Roman numeral showing the oxidation number: thus, ferric chloride would be iron (III) chloride.)

ICE. The solid form of water. All commonly occurring forms of ice are crystalline, although large single crystals are relatively rare except in glaciers. At a pressure of one atmosphere, ice melts at 0°C by definition of the centigrade temperature scale. On the other hand, ice does not invariably form in liquid water cooled to 0°C, because of supercooling and the absence of ice nuclei. Ice is found in the atmosphere in such forms as ice crystals, snow, hail, and ice pellets; and on the earth's surface in such forms as hoarfrost, rime, and glaze, and the following:

Anchor ice is ice attached to the bed of streams, lakes, and shallow seas, irrespective of its nature of formation. On clear, cold nights in relatively still water, it may form directly on submerged objects. It also develops in supercooled water of turbulence sufficient to maintain uniform temperature at all depths. When the water temperature increases to above 0°C, the ice rises to the surface, often carrying with it the object on which it had accumulated. (Cf. ground ice, defined below.)

Droxtal is a tiny ice particle, about 10 to 20 microns in diameter, formed by direct freezing of supercooled water droplets at temperatures below −30°C. The term is coined by combining the words "drop" and "crystal."

Fossil ice is ice that was formed in the geologic past, found in regions of permafrost or where present-day temperatures are not low enough to have formed it.

Frazil crystals are ice crystals that form in supercooled water too turbulent to permit coagulation into smooth sheet ice. This is most common in swiftly flowing streams, but is also found in a turbulent sea (cf. lolly ice, defined below). It may accumulate as anchor ice on submerged objects obstructing the water flow.

Glacier ice is any ice that is or was once a part of a glacier. It has been consolidated from firn (i.e., old snow that has become granular and compacted) by further melting and refreezing, and by static pressure. It may be found in the sea as icebergs.

Ground ice is a body of clear ice in frozen ground. It is most commonly found in more-or-less permanently frozen ground, and may be of sufficient age to be termed fossil ice.

Lolly ice is salt water frazil.

Pack ice is ice covering more than half the visible sea surface; no open water whatever is visible in unbroken pack ice, such as that which sometimes covers the central Arctic Ocean.

Sludge is a dense accumulation of frazil or lolly ice; an early stage in the freezing of a body of water. The sea surface becomes thick and soupy and sometimes greasy in appearance. Sludge depth seldom exceeds 1 foot (0.3 meter).

Molecular Forms of Ice

The H_2O molecules in an ice crystal are much further apart than the molecules in liquid water and thus the density of ice is less than that of liquid water, permitting ice to float atop liquid water. In the ice crystal, the molecules are joined by highly directional, obtuse-angled hydrogen bonds, forming a regular hexagonal design. As ice is warmed and passes through the freezing point, the characteristic *rigid* but open structure of the ice crystal gives way, thus allowing H_2O molecules to crowd into the former "open spaces."

Through the application of pressure (2000 atmospheres and higher), water molecules can be forced to assume various deformed patterns (as compared with ordinary ice). For many years, eight solid forms of water have been so produced, designated ice II through ice IX (water is designated ice I). These high-pressure forms of solid water exist at specific temperature-pressure domains in the extended phase diagram of water. Upon release of the applied high pressure, these ice structures revert to common ice or water depending upon the temperature.

Still another form of solid water was proposed several years ago by Holzapfel (a German physicist). This form, designated ice X, was described by Holzapfel as a very dense crystal structure that would not be made up of well-defined molecules linked by hydrogen bonds. Rather, each oxygen atom would be surrounded by a tight cubic array of nearest-neighbor oxygen atoms, and a hydrogen atom would be located halfway between each pair of oxygen atoms such that a hydrogen atom would be associated no more with one oxygen atom than with the other. It was predicted that this form of solid water would exist at a pressure greater than 350,000 atmospheres. At the time of this prediction, equipment for producing pressure that high was not available.

With the development of the diamond-anvil high-pressure cell, researchers at the Argonne National Laboratory, in a series of experiments, subjected water to high pressures ranging between 300,000 and 670,000 atmospheres. Through the use of Brillouin-scattering spectroscopy, an anomaly was noted at a pressure of 440,000 atmospheres. The researchers tentatively observe that this "is the tenth known solid phase of H_2O and ... is probably the predicted symmetric ice. As such it would be the first non-molecular structure for H_2O." (In Brillouin-scattering spectroscopy, the compressibility of a sample is ascertained indirectly by measuring the reflection of laser light from highly directional sound waves in the sample.)

ICE POINT. The temperature at which, a mixture of air-saturated pure water and pure ice may exist in equilibrium at a pressure of one standard atmosphere.

-IDE. A suffix, used in naming compounds composed of two elements; in such names the first (electropositive) element retains its name without change, while the second (electronegative) bears the suffix—*ide* as a modification of the elemental name. Examples: sodium hydroxide, magnesium chloride, hydrogen sulfide, etc. Similarly, oxygen is modified to oxide, fluorine to fluoride, phosphorus to phosphide, and carbon to carbide.

IDEAL GAS LAW. An "ideal gas" would, if kept at a constant temperature, behave as respects volume and pressure in strict accord with Boyle's law. If now the temperature is also allowed to vary, we must

combine the law of Charles (or of Gay Lussac) with Boyle's law, yielding the Boyle-Charles law:

$$pv = p_0v_0(1 + at), \tag{1}$$

in which p_0v_0 is the value of the pressure-volume product pv when the temperature t is zero, a is the coefficient of expansion of the gas, practically the same for all gases, and in the ideal case equal to the reciprocal of the absolute temperature of the scale zero. If the centigrade scale is used, the value of a is approximately 1/273.2 per degree. Substituting this, Equation (1) may be written

$$pv = \frac{p_0v_0(t + 273.2^\circ)}{273.2^\circ} \tag{2}$$

which is one expression for the ideal gas law.

The factor $t + 273.2^\circ$ will be recognized as the absolute temperature T of the gas. And since the ideal gas obeys Boyle's law, the product p_0v_0 is constant however p_0 and v_0 may vary between themselves. We may thus denote the coefficient $p_0v_0/273.2^\circ$ by a single constant symbol, say R, and the ideal gas equation then takes the usual form

$$pv = RT \tag{3}$$

The value of R depends, of course, upon the quantity of gas used, since at any pressure p_0 it is proportional to the volume v_0. For 1 gram of air, R equals about 2,868,000 gcm^2/sec^2 deg. At the zero of temperature and at any given pressure p_0, the gram molecular weights, or moles, of all pure gases have equal volumes. (This follows from Avogadro's law.) Hence if one mole of any pure gas is used, R will always have the same value, in c.g.s. units about 8.316×10^7 g cm^2/sec^2 deg; which is called the "ideal gas constant." Many physical formulas involve a quantity which may be regarded as the ideal gas constant per molecule, that is, the above molar gas constant divided by the number of molecules in a mole, 6.025×10^{23}, giving 1.3803×10^{-16} g cm^2/sec^2 deg. This is the "Boltzmann constant."

Since actual gases, even those with the smallest molecules, hydrogen and helium, do not obey the ideal gas law exactly, various empirical characteristic equations have been devised to represent their behavior.

See also **Avogadro Law**; **Boyle-Charles Law**; **Boyle's Law**; **Characteristic Equation**; and **Combustion (Fuels)**.

IDEAL SYSTEM. A thermodynamic system is called an ideal system when the chemical potentials of all the components are of the form

$$\mu_i = \mu_i(T, p) + RT \ln x_i \tag{1}$$

where $\mu_i(T, p)$ is a function only of the variables absolute temperature, T, and pressure, p. The x_i are the mole fractions of the components.

Systems for which μ_i has this form possess remarkably simple properties. Moreover, mixtures of perfect gases (i.e., gases under conditions which can be approximated with sufficient accuracy by the ideal gas law) and very dilute solutions have these properties.

According to Equation (2), a system is called ideal if the chemical potential of component i varies linearly with the logarithm of the mole fraction of i, with a slope RT. This linear relation need not necessarily extend over the whole concentration range, so that the quantity $\mu_i(T, p)$ is, in general, the value of μ_i extrapolated to $x_i = 1$ at constant T, p. If the system is ideal in a concentration range which extends to $x_i = 1$, then

$$\mu_i(T, p) = \mu_i^0(T, p) \tag{2}$$

where μ_i^0 is the chemical potential of the pure component i. They are two important cases: (1) The mixture is ideal for all values of x_i and for all i. It is then called a *perfect mixture* and Equation (2) is verified for all i. (2) The mixture is ideal when all components but one (index 1) are present in very small amount. Such systems are called *ideal dilute solutions*. Then Equation (2) is only valid for component 1.

Different kinds of ideal systems are distinguished by the form of $\mu_i(T, p)$. In a mixture of perfect gases, $\mu_i(T, p)$ varies logarithmically with pressure, while for a liquid or solid solution, one can, to a first approximation, regard μ_i as independent of pressure.

See also **Perfect Gas**.

ILMENITE. A mineral oxide of iron and titanium, $FeTiO_3$. Magnesium and manganous manganese may replace ferrous iron to form a complete isomorphous series between ilmenite, and its magnesium-manganese end members, geikielite and pyrophanite. It crystallizes in the rhombohedral division of the hexagonal system; hardness, 5–6; specific gravity, 4.72; brittle, with uneven to conchoidal fracture. Crystals tabular, rarely rhombohedral, also massive, lamellar, granular. Color, iron black; opaque, with metallic to dull luster.

Ilmenite occurs as a common accessory mineral in both igneous and metamorphic rocks, and as heavy concentrations in certain black beach sands with magnetite, rutile, and zircon. Also found in pegmatites and as vein deposits. Valuable deposits are found in Norway; Sweden; Mexico; Finland; Ilmen Mountains, former U.S.S.R.; Canada; England; Brazil; and Italy. Brazil and India are rich in beach sand deposits. United States localities include California, Idaho, Colorado, Wyoming, Arkansas, Kentucky, Pennsylvania, Massachusetts, Connecticut, Orange County and the Adirondack Mountain Deposits in New York, and as beach sands in Florida north of St. Augustine.

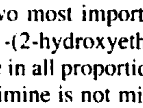
Named after the Ilmen Mountains, former U.S.S.R.

IMIDES. An imide may be defined as a compound that has the divalent radical NH combined with two acid radicals. The definition implies that the acid from which an imide is derived must be a dibasic acid, such as oxalic acid, HOOC · COOH, or succinic acid, HOOC · CH_2 · CH_2 · COOH. The derivatives of these two acids illustrate the relationship between amides and imides.

COOH | COOH	CO.NH_2 | CO.NH_2	CO.NH_2 | CO.OH	CO＼ | NH CO／
(oxalic acid)	(oxamide)	(oxamic acid)	(oximide)
CH_2CO.OH | CH_2CO.OH	CH_2CO.NH_2 | CH_2CO.NH_2	CH_2CO.NH_2 | CH_2CO.OH	CO＼ | NH CO／
(succinic acid)	(succinamic)	(succinamic acid)	(succinamide)

Phthalimide, $C_6H_4 \cdot (CO)_2 \cdot NH$, is an imide of commercial and industrial importance, forming a number of interesting derivatives. With alcoholic potash, phthalimide forms a potassium derivative, $C_6H_4 \cdot (CO)_2 \cdot NK$, which, when reacted with ethyl iodide (or other alkyl halides), yields ethylphthalimide, $C_6H_4 \cdot (CO)_2 \cdot N \cdot C_2H_5$. The latter product, when hydrolyzed with an acid or alkali, further yields ethylamine. Such reaction chains are useful in the preparation of certain primary amines and their derivatives.

IMINES, CYCLIC. Ethyleneimine (aziridine, azacyclopropane) is the smallest cyclic imine consisting of a three-membered *N*-heterocyclic ring ($n = 2$):



This article describes ethyleneimine and the most important aziridine derivatives. Unsubstituted ethyleneimine is industrially the most important representative of the aziridine class. The BASF group is by far the largest manufacturer of ethyleneimine and has production plants in Germany and the U.S. Another important producer is the Nippon Shokubai Co. Ltd. of Japan.

Physical Properties

Ethyleneimine (EI) and its two most important derivatives, 2-methylaziridine (propyleneimine), and 1-(2-hydroxyethyl)aziridine (HEA) are colorless liquids. They are miscible in all proportions with water and the majority of organic solvents. Ethyleneimine is not miscible with concentrated aqueous NaOH solutions (>17% by weight). Ethyleneimine has an odor similar to ammonia. The physical properties of ethyleneimine and the derivatives mentioned are given in Table 1.

Chemical Properties

Ethyleneimine is the only C_2H_5N isomer stable at room temperature provided CO_2 is excluded from the air. Unexpectedly, ethyleneimine has the highest calculated relative heat of formation of the C_2H_5N isomers. Ethyleneimine shows a lower basicity than noncyclic aliphatic amines such as dimethylamine.

Reactions

Depending on the experimental conditions used, the basicity or the ring strain can be the driving force in reactions involving ethyleneimine. With

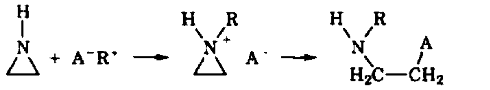
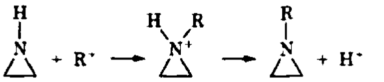
catalysis by Brönsted or Lewis acids, the aziridine ring can be opened by a large number of nucleophiles to give β-substituted ethylamines. In the absence of strong nucleophiles and at elevated temperatures, preparation of polyethyleneimines from aziridines is possible by acid-catalyzed reaction of the aziridine with itself. On the other hand, ethyleneimine and other aziridines substituted only on carbon show the typical reactions of a secondary amine, such as addition onto unsaturated systems, complex formation with metals, and reaction with halogen compounds. At low temperatures and alkaline pH the N-substituted aziridines are generally formed in these reactions. High temperatures and catalysis by acids or nucleophiles promote secondary reactions with opening of the three-membered ring, and these can be used for synthesis of heterocyclic compounds.

Nucleophilic Ring Opening. Opening of the ethyleneimine ring with acid catalysis can generally be accomplished by the formation of an intermediate aziridinium salt, with subsequent nucleophilic substitution on the carbon atom which loses the amino group. In the following, R represents a Lewis acid, usually H^+; A^- = the nucleophile.



Electrophilic Reactions on the Aziridine Nitrogen. The generalized reaction of aziridines with an electrophile (R^+) is as follows.

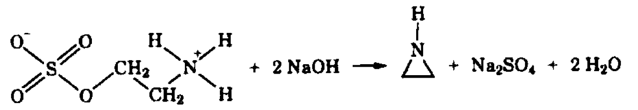


Reactions with Transition-Metal Compounds. The numerous published products of reactions of transition-metal compounds with aziridines can be divided into complexes in which the aziridine ring is intact, compounds formed by reaction of aziridine with the ligands of a complex, and complexes in which the aziridine molecule is fragmented (imido complexes).

Other reactions include reductive ring opening, oxidative ring opening, thermal and photochemical reactions, and polymerization.

Preparation

The Wenker process has been carried out by BASF and various other companies since the end of the 1960s. In this process the hemisulfate of monoethanolamine, a nonvolatile, crystalline substance, is used for the alkaline cyclization. The reaction can be carried out under pressure.



A production plant for salt-free ethyleneimine synthesis by catalytic dehydration of monoethanolamine in the gas phase has started operation at the Japanese company Nippon Shokubai.

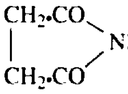
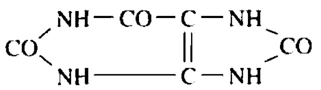
IMINO COMPOUNDS. Imino compounds are organic compounds containing the imino group >NH, e.g., dimethylamine, $(CH_3)_2NH$, dibenzamide, $(C_6H_5CO)_2NH$, succinimide,



NH, purrole (C_4H_4NH), and uric acid.



IMMUNE SYSTEM AND IMMUNOCHEMISTRY. The word *immunity* is derived from the Latin *immunis* (free of). The term originally referred to the ability of the body to resist invasion by pathogenic organisms, but has now been expanded to include specific reactions to antigens (Ags) in general, and to include reactions observed in the emerging field of tumor immunology. See also **Antigen**.

Immunity is derived from the *immune system* which, when functioning properly, protects the organism from infection. Failures of the immune system produce some of the most challenging and serious diseases that a physician can meet in the patient population.

The immune system consists of a number of lymphoid organs, including the thymus, lymph nodes, spleen, and tonsils. It also includes aggregates of lymphoid tissue in nonlymphoid organs, such as Peyer's patches in the intestines and clusters of lymphoid tissue dispersed throughout the connective and epithelial tissues of the body. The immunologically active cells of the immune system comprise the various classes of lymphocytes. A number of cells, however, including monocytes (macrophages) and polymorphonuclear leucocytes play important accessory roles. The stem cells from which the lymphocytes arise are derived from the yolk sac and the fetal liver, later some stem cells originate from the bone marrow and differentiate into lymphocytes in the primary lymphoid organs.

The function of the immune system is the preservation of the body's integrity against antigens recognized by the lymphocytes as foreign, e.g., surface structures of microorganisms, tissue transplants, or a wide variety of chemicals. Specifically, antigens include such structurally diverse substances as proteins, polysaccharides, nucleic acids, and lipids. Large, rigid proteins are the most antigenic, and the more insoluble the foreign material, the more antigenic it appears.

The various antigens are recognized by lymphocytes, which have a memory and specificity, an ability to increase the number of antigen-specific lymphocytes following the antigenic stimulus, and an ability to distinguish between self and nonself. The production of immunoglobulins (Igs—see later) by the immune response is under the control of genes which are located in the same chromosome as, and very close to, another group of genes which control the production of the histocompatibility antigens (HLA). These are antigens that identify as self the cells they are on and differentiate from cells of other individuals. These two groups of genes form the major histocompatibility complex (MHC) which plays a crucial role in the immune system. An intriguing aspect of the genetic control of immunoglobulin synthesis is the diversity of the product; plasma cells can make antibodies that react with more than a million antigens.

As previously indicated, the primary cells involved in the immune response are lymphocytes which have a centrally located round nucleus, lack specific granules, and have a basophilic cytoplasm containing free ribosomes. The (thymus-dependent) T-lymphocytes are involved in cell mediated reactions and also interact with B-lymphocytes (see later) to regulate the production of antibody. The B cells differentiate into the antibody-producing plasma cells. There is growing evidence that neither T

nor B cells constitute a homogeneous population, but actually consist of a number of subgroups which can be differentiated from each other by their surface markers and by their function.

Thymus-dependent antigens are those in which antibody production requires thymus-derived (T) cell participation, i.e., serum proteins. Thymus-independent antigens do not require this participation, i.e., polysaccharides, such as endotoxins.

Antigen is any substance capable of generating an immune response that is reacting with T and B cells to induce the formation of antibodies and sensitized lymphocytes and then reacting with those antibodies and cells once they are formed. The basis for the general immunogenicity of proteins is not known, but is probably related to their unique and stable configuration. Antigens invoke immune responses by the host which include the production of *antibodies* (Abs) possessing a specificity for the antigen which is determined by the latter's structure. See also **Antibody**. Antibodies belong to a group of *immunoglobulins* (Igs) which bind with the antigens to form complexes in which the two components are held together by weak hydrogen bonds, van der Waals forces, or ionic bonds, but not by covalent bonding. An antibody that binds a given antigen will also bind antigens having similar structural configurations. This is referred to as *cross-reactivity*. The extent to which this binding occurs indicates the measure of similarity of the two antigens. Most antigens have several antigenic determinants or Ab binding sites and the antibody response to any antigen is thus the sum of responses to each individual determinant.

In addition to antigens per se, two other types of substance are recognized by the immune system: (1) *haptens*, which are molecules capable of reacting with antibodies, but which are unable to stimulate their production unless coupled to a carrier—an immunogenic substance that is usually a protein or a synthetic polypeptide; and (2) *adjuvants*, which enhance the immune response to an antigen. These include, but are not limited to, aluminum salts, bacterial endotoxins, *Bacillus Calmette-GuÉrin* (BCG), *Bordetella pertussis*, and mycobacteria.

The immune response to antigens can proceed through several paths, the two major ones being *humoral* and *cellular*. Most immune responses involve both pathways. Humoral immunity is mediated by antigen-specific antibodies, which circulate through the body; they act at a site distant from that of their production; it can be transferred from one person to another by serum transfusion. Cell-mediated immunity is mediated by specifically sensitized cells, which release mediators in the vicinity of the antigen. This form of immunity can be transferred from one person to another by cell transfer. Cell-mediated immune responses usually take longer to develop and are responsible for resistance to many infectious agents and tumors as well as for some drug allergies, rejection of foreign organ grafts, and some autoimmune diseases.

The level of immune response to antigens varies. A *primary response* is seen to antigens the body has never before encountered. In this, the first antibody to be produced is IgM (described later), the serum concentration of which peaks after a lag of several days and then decreases. IgG production shows a longer lag time, but its concentration remains elevated for a more extended period. *Secondary responses* are more rapid and of greater intensity; they differ markedly from primary responses in having a shorter lag period, higher serum antibody levels with earlier and more pronounced emphasis upon IgG production. These secondary responses occur when the immune system faces a previously encountered antigen and illustrates the basic characteristic of immune response—*memory*. For this reason, secondary responses are also known as *anamnestic*. These memorized responses are derived from two of the major cell types which work together to produce immune responses—T and B lymphocytes. The former are thymus-dependent, are responsible for cell-mediated immune responses and for providing help for most antibody responses. B cells depend upon another central lymphoid organ (in birds, this has been identified as the Bursa of Fabricus). There does not appear to be a bursa equivalent in mammals, however, even though it was originally thought that such animals had some gut-associated primary lymphoid organ. Current evidence suggests that stem cells can differentiate into B cells in the bone marrow and in the peripheral lymphoid organs themselves. B lymphocytes have immunoglobulin on their surface and it can be shown that the cell itself has produced this. When stimulated by antigens, B cells become *plasma cells* and produce antibodies specific for that antigen. T and B cells cannot be distinguished morphologically, but may be differentiated, such as by theta antigen on T cells and surface immunoglobulin on B cells. Unlike T cells, B cells tend to migrate.

The spleen, lymph nodes, tonsils, and gut-associated lymphoid tissue comprise the secondary or peripheral system wherein T and B lymphocytes undergo terminal differentiation in response to antigen stimulation.

The third major type of cell involved in the immune process is the *macrophage*. The B and T lymphocytes are rarely phagocytic—this is the function of the macrophage. After specific recognition of the invading antigen by the lymphocytes, the macrophage acts nonspecifically, and it moves by *chemotaxis* (movement along a chemical concentration of increasing gradient) to the site of the immune response. The macrophage ingests and eventually digests the antigenic inert particle or the living or dead microorganism responsible for engendering the immune response.

These major cell types may be subdivided into populations that interact by means of soluble mediators called *lymphokines* or *monokines*. Lymphokines are products of activated lymphocytes that exert regulatory effects upon other cells of the immune system. Monokines are products of activated microphages. The lymphokines or lymphocyte mediators are soluble substances produced by lymphocytes that help to amplify and regulate a variety of immune responses. They are not immunoglobulins. There are clearly many different lymphokines and they are classified on the basis of the target cells they affect. It is likely that they have more than one biological function. Lymphokines are generally synthesized and secreted by sensitized lymphocytes stimulated by a specific antigen; they are not stored in a preformed state. Most are proteins or glycoproteins, and while it has been shown that protein synthesis inhibitors prevent their formation, their exact structures are undetermined. Some play a role in humoral reactions and others in cell-mediated responses. The soluble mediators allow such activities as help, suppression, or cytotoxicity to be manifested by the target cells.

A given antigen induces proliferation and differentiation of clones of cells capable of producing antibodies in response to that antigen; a process called *clonal selection*. Each stimulated cell produces antibodies of only one specificity. Thus, the immense heterogenicity of antibodies to a given antigen results from a great diversity of responsive cells.

As previously indicated, antibodies are immunoglobulins (Igs), produced by B-cell-derived plasma cells during a humoral response to antigen. They are synthesized on polyribosomes attached to the rough endoplasmic reticulum of plasma cells upon inoculation of antigen into the host, and they are specific for that antigen. They have two functions—specific recognition of the antigen and effector functions, such as agglutination or lysis of bacteria, complement fixation, or opsonization.

Immunoglobulins are high-molecular-weight glycoproteins having symmetrical four-polypeptide chain structures composed of two heavy and two light chains held in configuration by disulfide linkages. Based upon serological characteristics of the heavy chains, five distinct classes or isotypes have been found—IgG, IgA, IgM, IgD, and IgE. Subclasses of these isotypes have also been found. Bonds between chains—heavy-heavy or heavy-light—are by disulfide bridges with the number and positions of these being characteristic of different classes and subclasses of immunoglobulins. See Fig. 1. In a given immunoglobulin molecule, all of the heavy chains

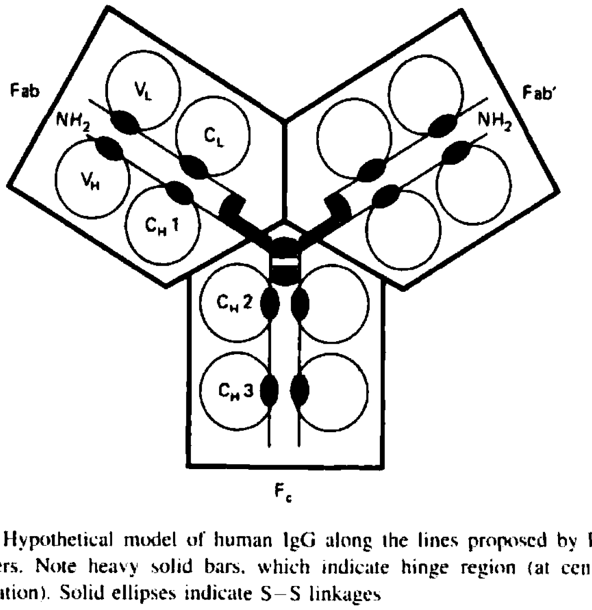


Fig. 1. Hypothetical model of human IgG along the lines proposed by Poljak and others. Note heavy solid bars, which indicate hinge region (at center of configuration). Solid ellipses indicate S–S linkages

are identical and, although there are two types of light chains—kappa and lambda—each of which may be associated with any heavy chain, both of the light chains in a given Ig are identical. Polymerization of the basic Ig configuration can occur, but IgG, IgD, and IgE occur only as monomers. IgA may be either monomeric or dimeric; IgM is pentameric. See Fig. 2.

In addition to the basic configurations of the immunoglobulin molecule, the light and heavy chains have variable and constant regions where some variability in amino acid sequences occurs. The variable regions of the antibody molecule contain the structures responsible for the antigenic specificity of the Ig. These are found in the amino terminal of the heavy and light polypeptide chains—the Fab portion obtained as a cleavage fragment following treatment with pepsin or papain. Since each antigen-binding region is composed of the variable region of one light and one heavy chain, an immunoglobulin molecule has two identical antigen binding sites. The antigen-binding site of every Ig molecule is structurally unique. Therefore, each Ig has unique antigenic determinants not shared by any other Ig molecule. These unique determinants are called the *idiotypes* of the particular immunoglobulin. On the other hand, an *allotype* is an antigenic specificity representing any one of a number of possible allelic markers present on a significant percentage of Ig molecules in an individual which are recognizable as foreign by another individual lacking that allotype. Allotypic determinants distinguish between the Igs of a particular isotype and are genetically determined by Mendelian laws in a manner similar to those that determine the ABO blood group. *Isotypic* determinants are found in the sera of normal individuals and differentiate the various classes and subclasses of heavy and light chains.

The F_c portion of the immunoglobulin molecule identified by papain cleavage is responsible for biological activity other than antigen binding, e.g., complement fixation, transplacental transfer, binding to cells such as macrophages and granulocytes, and the rate of synthesis and catabolism of the Ig molecule.

IgG and IgM are present in the highest concentrations throughout the body and compose the major portion of a systemic humoral response to

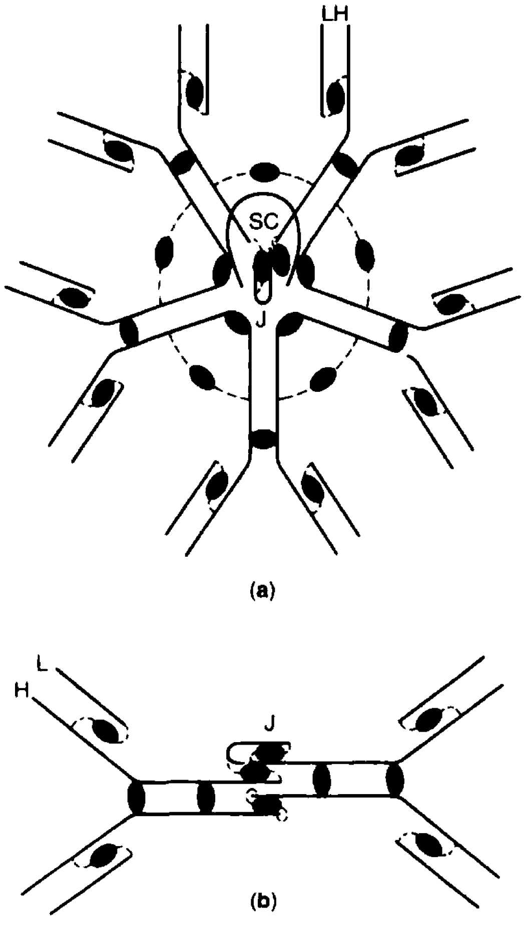

Fig. 2. Hypothetical models utilizing the clasp configuration proposed by Koshland, et al. (1975). **(a)** Pentameric IgM; **(b)** dimeric IgA. L = light chain; H = heavy chain; J = J chain. Solid ellipses indicate S–S linkages

antigenic challenge. IgM exists as a pentamer of five immunoglobulin molecules bound together by a protein molecule called a J chain. IgM has a molecular weight of approximately 900,000 and a sedimentation coefficient of 19S, and is thus referred to as 19S Ig. It is the main immunoglobulin of early humoral response, will fix complement and is not cytophilic. IgG is the major component of secondary humoral response, and its ability to diffuse through tissues makes it indispensable for host defense. It has a molecular weight of 150,000 and a sedimentation coefficient of 7S. Eighty percent of serum immunoglobulin is IgG and several subclasses of this immunoglobulin exist which have different functions, i.e., complement fixation, binding to macrophages or passage across the placenta.

IgA is the primary secretory immunoglobulin and occurs in tears, nasal and intestinal secretions, saliva, and bile. It is present as a 7S IgA, it is an 11S dimer with the monomeric structures joined by a J chain and linked to a glycoprotein called secretory component. Secretory IgA plays a role in initial protection against external pathogens, aggregates bacteria, and neutralizes viruses.

IgE, with a molecular weight of 190,000, has a short half-life and occurs at low concentrations in the serum. It is cytophilic and binds strongly to most cells and basophils. Plasma cells producing IgE are primarily found in gastrointestinal mucosa and along the respiratory tract. This immunoglobulin is responsible for immediate *hypersensitivity reactions*, since crosslinking by antigens of two IgE molecules causes the release of mediators such as histamine, SRS-A (Slow Reacting Substance of Anaphylaxis), and ECF-A (Eosinophil Chemotactic Factor) which are responsible for the immediate hypersensitivity reactions. Hence, IgE plays a definitive role in allergies and may have a part in providing resistance to parasites and in protection of mucosal surfaces.

IgD occurs in extremely low concentrations in serum and has a short serum half-life. It has a molecular weight of 170,000–200,000, is monomeric, and fixes complement. Otherwise its role is unknown; it may act as a cell surface receptor on B lymphocytes.

Associated with humoral responses involving antibodies is *complement*. The *complement system* is a complex system of 18 plasma proteins circulating in inactive form in the extracellular liquid. It is the principal humoral effector of immunologically induced inflammation. It plays a crucial role, both in immunologically induced and nonspecific resistance to infection and in the pathogenesis of tissue injury. The products of complement activity regulate a number of biological events including the release of mediators from mast cells, which increases vascular permeability. Activation of complement involves a series of steps, each one generating a new active component that, in turn, activates the next component and so on. There are two major pathways of complement activation—the classical pathway and the alternate or properdin pathway. The classical pathway is initiated by the binding of antigen to antibody (two molecules of IgG or one molecule of IgM). The alternate pathway does not require the presence of antigen-specific antibody, but can be activated by endotoxin, bacterial cell-wall polysaccharides, and aggregated immunoglobulins. The ability to be initiated before an immune response can occur makes the alternate pathway a first line of defense against microorganisms. The ultimate result of complement activation is lysis of the invading cell. Mediators produced during the activation sequence play major roles by allowing *immunoadherence, opsonization*, or *chemotaxis* to occur, but others, such as *anaphylatoxins* may be harmful to the host. The importance of complement to normal host defense is illustrated by many pathologic conditions and high susceptibility to infections seen in persons with congenital complement deficiencies.

INCINERATION. Disposal of solid and liquid organic waste materials by burning at temperatures 1200 to 1500°C. This method is approved by the EPA for use on very toxic organic chemicals and chemical wastes. Use of specially equipped incinerator ships for burning chemical wastes at sea has become common place.

INCLUSION COMPOUNDS. Notwithstanding the immense number and great variety of inclusion compounds, all of them may be classified into three main categories being either a complex, a cavitate, or a clathrate

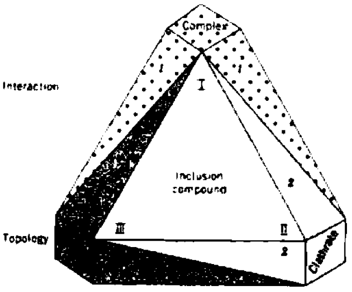

Fig. 1. Classification/nomenclature of host–guest type inclusion compounds, definitions and relations: (*1*) coordinative interaction, (*2*) lattice barrier interaction, (*3*) monomolecular shielding interaction; (I) coordination-type inclusion compound (inclusion complex), (II) lattice-type inclusion compound (multimolecular/extramolecular inclusion compound, clathrate), (III) cavitate-type inclusion compound (monomolecular/intramolecular inclusion compound)

according to the criteria given in Figure 1. Typical examples for each class of inclusion compounds are the crown complexes, the calix-cavitates, and the hydroquinone clathrates, but in many of the recently known inclusion situations there are borderline cases treated as complex-clathrate hybrids (coordinatatoclathrates or clathratocomplexes depending on the dominant inclusion character.) By way of contrast, the description addition compound (adduct) may be used to the best advantage if a cavity does not exist either at the host molecule or in the lattice buildup. Inclusion compound, therefore, is the generic term of choice which refers to the presence of any not precisely defined cavity. In a more detailed topological characterization, there are two-dimensional open intercalates (layer- or sandwich-type inclusions), one-dimensional open channel inclusions (tubulates), and totally enclosed cage inclusions (cryptates).

Intramolecular Cavity Inclusions: Cavitates

Cavitates include crown macroring inclusion compounds (coronates), cryptates, podates, cyclophane host inclusion compounds, calixarene inclusion compounds, cyclodextrin and amylose inclusion compounds, cucurbituril inclusion compounds, molecular cleft inclusion compounds, and anionic guest inclusion compounds.

Extramolecular Cavity Inclusions: Lattice-Type Inclusion Compounds Clathrates

These compounds include Hofmann- and Werner-type inclusion compounds, inclusion compounds of urea, thiourea and selenourea, inclusion compounds of gossypol, inclusion compounds of phenolic hosts, inclusion compounds of deoxycholic acid (choleic acids), inclusion compounds of macrocyclic and oligocyclic lattice hosts and recently designed organic host lattices.

Preparation and Characterization of Inclusion Compounds

There are several ways to prepare inclusion compounds. In solution, they may simply be formed by dissolving together host and guest in a common solvent. Inclusion formation in solution applies only for intramolecular cavity inclusions and complexes. Crystalline inclusion compounds may be prepared by crystallization from the guest solvent or by cocrystallization of host and guest from an inert solvent. Solid inclusion compounds are also formed by direct exposure of the host to the vapor or liquid guest or, sometimes, by grinding solid host and guest together. Moreover, replacement of an included guest has been demonstrated in particular cases.

Appropriate guest molecules are those that have a suitable size and shape to accommodate the host cavity and that complement the host cavity chemically.

Stabilities of inclusion compounds span a wide range. Some are very stable at ambient conditions and require heating to considerable temperatures or treatment under high vacuum to cause decomposition. Others are only stable when in contact with mother liquor or excess guest solvent from which the inclusion compound was grown. A simple yet informative way for estimation of inclusion stabilities is to relate the decomposition point of the inclusion compound to the usual boiling point of the respective guest liquid.

Uses

Inclusion compounds open up a wide area of applications. An important aspect in this connection is the specific microenvironment created by the host enclosure of the guest which exerts an influence on the physical spectroscopic, chemical, and other properties of the guest.

Retardation and Control. This influence may manifest itself in a reduced volatility, and therefore, lower possible storage and handling problems of a compound when included; toxic and hazardous substances become safer.

Shielding and Stabilization. Inclusion compounds may be used as sources and reservoirs of unstable species. The inner phases of inclusion compounds uniquely constrain guest movements, provide a medium for reactions, and shelter molecules that self-destruct in the bulk phase or transform and react under atmospheric conditions.

Solubilization and Activation. Compounds included in a host take solubility properties of the host shell, and thus, become more soluble when trapped in polar or apolar media, depending on the nature of the host. This leads to important uses in chemical synthesis known as the phase-transfer principle.

Organized Media Effects. Another general reason for using host-guest inclusion chemistry in synthesis is controlled selectivity and artificial enzyme mimicry.

Sensing. Crown compounds modified by responsible chromogenic groups (chromoionophores) proved valuable tools for measuring metal ions and even enantiomeric guest concentrations in solution. Ion selective electrodes based on crown compounds and podands as the sensitive component have broad analytical applications from industrial wastewater control to clinical bedside monitoring of blood.

INDICATOR (Chemical). A substance which shows by a color change, or other visible manifestation, some change in, or particular condition of, the chemical nature of a system. Thus acid-base indicators may be used to indicate the end point of a particular neutralization reaction, or they may also be used to indicate the pH value of a system. For example, there are over fifty useful indicators for determining pH, covering the range from 0 to 14. Although indicators still are used in connection with colorimetric pH determinations and are extensively applied, sometimes in the form of dye-impregnated paper tape, for ascertaining the approximate pH of soils, swimming pools, and fish tanks where convenience and cost are predominating factors, indicators for pH and other chemical determinations are not nearly so important as they were before the advent of improved electrometric instrumental analytical techniques. Several pH (hydrogen ion indicators) are listed in Table 1.

Indicators also are useful in following oxidation-reduction reactions, precipitation reactions, and, in general, throughout all volumetric analysis, and in many other chemical control operations.

TABLE 1. pH RANGES AND COLOR CHANGES OF SELECTED INDICATORS

Indicator	pH range of color change	Color change with Increasing pH
Alpha naphtholbenzein	0–0.8	Colorless to yellow
Methyl violet	0.2–1.9	Yellow to blue-violet
Para methyl red	1.0–3.0	Red to yellow
Thymolsulfonphthalein (Thymol Blue)	1.2–2.8	Red to yellow
	8.0–9.6	Yellow to blue
Methyl orange	3.3–4.5	Red to yellow
Methyl red	4.2–6.2	Red to yellow
Aurin (rosolic acid)	6.2–7.2	Amber to pink
Phenolsulfonphthalein (Phenol Red)	6.8–8.5	Yellow to red
Phenolphthalein	8.3–10.2	Colorless to purple
Thymolphthalein	9.4–10.7	Colorless to blue
Sodium nitrobenzeneazo-salicylate (Alizarin Yellow R)	10.1–12.0	Yellow to red
Malachite green	11.4–13.0	Blue-green to colorless
1,3,5-Trinitrobenzene	12.0–14.0	Colorless to orange

INDICATOR, pH. See **pH (Hydrogen Ion Concentration).**

INDIUM. [CAS: 7440-74-6]. Chemical element symbol In, at. no. 49, at. wt. 114.82, periodic table group 13, mp 156.6°C, bp 2, 078–2, 082°C, density 7.31 g/cm^3 (20°C). Elemental indium has a face-centered tetragonal crystal structure. Indium is a silver-white metal, softer than lead, malleable, ductile, and crystalline. It is stable in dry air, but upon heating in air burns with a blue flame to form indium trioxide In_2O_3. Up to a temperature of 100°C, the element does not decompose H_2O. Indium becomes a superconductor at 3.37 K. The element dissolves in HCl, H_2SO_4, or HNO_3, but not in NaOH. Metallic indium combines readily with chlorine and sulfur. 113In is the only nonradioactive isotope and is in isotopic abundance of 4.23%. ^{115}In, with an extremely long half-life of 6×10^{14} years, accounts for the other 95.77% of naturally-occurring indium. Other radioactive isotopes include ^{107}In through ^{112}In, ^{114}In, ^{116}In, and ^{117}In. The half-lives of these isotopes are relatively short, measured in minutes, hours, or days. First ionization potential 5.785 eV; second, 18.86 eV; third, 28.03 eV. Oxidation potentials $In \rightarrow In^{3+} + 3e^-$, −0.34 V; $In \rightarrow In^+ + e^-$, −0.25 V.

Other important physical properties of indium are given under **Chemical Elements**.

Indium occurs in very small amounts in zinc blende, tungsten, tin and iron ores of certain localities. The recovery of indium from zinc flue dust (sometimes, 1 part per thousand) is effected by treating with a slight deficiency of HCl and allowing to stand. The residue is subjected to a series of treatments until finally pure indium sulfate is obtained, a solution of which when electrolyzed yields compact indium metal. A thin surface layer of indium is used on some bearings.

As the result of spectroscopic studies, the element was discovered by Reich and Richter in 1863.

On the scale of nonferrous metals, the production of indium is very limited, annual production probably not exceeding 1.3 million troy ounces (40.4 million grams). The availability of the element is affected by zinc production because it is a minor coproduct in the refining of zinc ores. The metal, in the form of an electroplate over lead and silver, has been used in aircraft bearings, the primary benefit being improved corrosion resistance. Indium also has been used as a dopant for germanium diodes and transistors. Several significant semiconductor compounds have been formulated, including InAs, InSb, and InP. The oxide has been used in electroluminescent panels. Indium alloys readily with several metals and it has been found particularly effective as a low-melting point fusible alloy when alloyed with bismuth, lead, tin, and cadmium. The eutectic alloy of indium-tin is an effective solder for glass-to-glass or glass-to-metal seals. With a melting range of 700–800°C, copper-gold-indium and copper-silver-indium alloys are used as brazing materials. The eutectic alloy of mercury, thallium, and indium has a solidifying temperature of −63°C, considerably below the mp of mercury, a feature that makes the alloy attractive for seals, switches, and thermometers for low-temperature applications. Control rods for nuclear reactors sometimes are produced from an alloy of silver, indium, and cadmium. Indium is also used in the manufacture of low-pressure sodium lamps. Indium for electroplating generally is furnished as the normal sulfate $In_2(SO_4)_3 \cdot 9H_2O$, the acid salt $In_2(SO_4)_3 \cdot H_2SO_4 \cdot 7H_2O$, or the basic salt $In_2O(SO_4)_2 \cdot 6H_2O$.

Chemistry and Compounds

Since indium has only three electrons in its valence shell, it is an electron acceptor. Indium trihalides include the trifluoride, trichloride, tribromide, and triiodide. They can be prepared by heating the metal or oxide in the halogen acid, or in the case of the trichloride and

tribromide, by use of the halogen acid, or in the case of the trichloride and tribromide, by use of the halogen itself. Indium sesquisulfate forms double salts like the alums with alkali metal sulfates. A monohydrogen sulfate, $HIn(SO_4)_2 3\frac{1}{2} H_2O$, is known. Other compounds of indium(III) include the oxide (and its gelatinous hydrate), nitride, the nitrate, and the sulfide, selenide, and telluride.

Indium(II) compounds include the oxide, sulfide, fluoride, and chloride. They are prepared either by reduction of the corresponding trivalent compounds or, in the case of the chloride, by heating the metal in hydrogen chloride. They disproportionate, under suitable conditions, to give as end products the metal and the stable trivalent compound. Like gallium, indium(II) chloride is diamagnetic, having the structure $In^+[InCl_4]^-$.

Indium(I) compounds are formed by reduction of the corresponding In(III) compounds with hydrogen (on heating) or with indium metal, as in the case of the chloride. They are reactive compounds, the chloride disproportionating with water to form the metal and $InCl_3$; the oxide being oxidized on heating in air to the sesquioxide; and the sulfide reacting in dilute acids to form the sesquisulfide.

A number of indium trialkyls have been prepared, starting from the trimethyl, and some diaryl compounds are known, such as the diphenyl bromide. The lower trialkyls are tetramers. Like aluminum, indium forms a polymeric hydride, $(InH_3)_n$, from which tetrahydroindates, such as the lithium compound, $LiInH_4$, can be derived.

Like aluminum and gallium, indium forms a number of chelated oxycompounds, almost all of which are of 6-coordinate type. They include the stable crystalline inner complexes of which the β-diketones coordinate in the proportion of 3 molecules of diketone per atom of indium. Trioxalato as well as dioxalato salts are known, and compounds such as 8-quinolinol and substituted 8-quinolinols form trimolecular chelate rings involving nitrogen and donor oxygen.

INDOLES. Indole is a heteroaromatic compound consisting of a fused benzene and pyrrole ring, specifically benzo[*b*]pyrrole. The indole ring is incorporated into the structure of the amino acid tryptophan and occurs in proteins and in a wide variety of plant and animal metabolites.

Properties

Indole is a colorless solid, mp 53–53°C, which is easily soluble in most organic solvents but sparingly soluble in water. Indole has a musty odor which is very persistent and its derivatives have some applications in the formulation of fragrances.

The industrial source of indole has been isolation from coal-tar distillate. Several patents for the manufacture of indole have been issued with aniline and ethylene glycol, aniline and ethylene oxide, 2-ethylaniline, and *N*-ethylaniline as the starting materials.

Reactivity

Indole is a heterocyclic analogue of naphthalene. The basic reactivity patterns of indole can be understood as resulting from the fusion of an electron-rich protein pyrrole ring with a benzene ring.

Reactions include electrophilic aromatic substitution (e.g., halogenation, nitration, *C*-acylation, and alkylation), *N*-alkylation, arylation, lithiation and subsequent transformations, and oxidation.

Syntheses

Although there are a wide variety of indole ring syntheses, most of the more useful examples fall within a small number of groups. Indole syntheses usually start with an aromatic compound, either monosubstituted or ortho-disubstituted.

Processes include the Fischer indole synthesis from arylhydrazones and related sigmatropic syntheses, reductive cyclizations of nitro compounds, the Madelung synthesis from anilides and related base-catalyzed condensations, and transition-metal catalyzed cyclizations.

Biologically Active Indole Derivatives

Synthetic Derivatives of Indoles as Pharmaceuticals. Thousands of indole derivatives have been prepared and evaluated as potential pharmaceuticals. Of those which have been put into use perhaps the most important are the nonsteroidal antiinflammatory agent, indomethacin, and the β-adrenergic blocker, pindolol.

Naturally Occurring Compounds. Many derivatives of indole are found in plants and animals where they are derived from the amino acid tryptophan. Several of these have important biological function or activity. Serotonin functions as a neurotransmitter and vasoconstrictor. Melatonin production is controlled by the circadian cycle and its physiological level influences daily and seasonal rhythms in humans and other species. Indole-3-acetic acid is a plant growth stimulant used in several horticultural applications.

The largest single class of naturally occurring indoles are the plant alkaloids. These occur with a wide range of structural diversity and are typically derived from tryptophan and terpenoid structural units. Several of these compounds are pharmacologically significant. Reserpine acts as a tranquilizer and hypotensive agent. The dimeric vinca alkaloids, vincristine and vinblastine, are used in the treatment of Hodgkin's disease, leukemia, and other forms of cancer. Derivatives of the ergot alkaloid lysergic acid are used in the treatment of migraine and the diethylamide is lysergic acid diethylamide.

Toxic Indole Derivatives. There are several documented cases where indole derivatives, both natural and of synthetic origin, have been linked to pathological effects in humans. 3-Methylindole, which is produced by bacterial fermentation in cattle, can lead to pulmonary edema. The pyridoindoles Trp-P-1 and Trp-P-2 are genotoxic substances which originate from pyrolysis of tryptophan and have been identified in foods cooked at excessively high temperatures. 4-Chloro-6-methoxyindole, which can be extracted from fava beans, yields a potent mutagen on interaction with nitrate ion.

INDUSTRIAL BIOTECHNOLOGY. In the broad sense, *industrial biotechnology* is the practical application of scientific principles of biology learned over many decades to the development and manufacture of useful products. In modern terms, this includes the use of knowledge gained from studies in cell biology, molecular biology, and gene-transfer techniques. See also **Molecular Biology**.

In a more restricted sense, industrial biotechnology is frequently referred to as *industrial microbiology*—because in a large number of bioprocesses, living substances in the form of yeasts, molds, bacteria, etc. are used as raw materials. For centuries, processes that depend upon living substances have existed, fermentation being a notable example. The scope of biology-related manufacturing, so to speak, was greatly expanded with the appearance of antibiotics, pioneered by Alexander Fleming in 1929 and soon followed by the bioprocessing of microorganisms to produce antibiotics in large quantities. The science of biology was impacted in the 1950s by a breakthrough in our knowledge of the DNA molecules, which led to gene recombination technology. The impact was felt early and continues today in industrial biological processes and products. As bioprocessing

progressed from the traditional fermentation industries through the massive production of antibiotics and other pharmaceuticals to the current and potential application of gene-transfer techniques on an industrial scale, the nomenclature changed. A preferred term for the foregoing activities is now *industrial biotechnology*.

Starting Materials—Microorganisms

Four kinds of microorganisms make up the raw materials for most biochemical processes. They are:

A. *Eukaryotes*—cells or organisms whose DNA is organized into chromosomes with a protein coat and surrounded by a nuclear membrane. Eukaryotes contain organelles, such as mitrochondria. The latter function and furnish the cells with their main energy supply. Yeasts and molds, the eukaryotes in common use, are fungi.

1. *Yeast (Ascomycetes)*, notably the *Saccharomyces* (called *sugar fungus* by Meyen, 1837). Among the most industrially important are *S. cerevisiae* (used in making alcoholic beverages and bread); *S. cerevisiae var. ellipsoideus*, *S. bayanus*, and *S. beticus* (used in making wine); *S. uvarium* (used in brewing); and *Kluyveromyces fragilis* (used in whey disposal). *K. fragilis* was formerly called *S. fragilis*.

   Yeasts play a major role in biochemical processes, but notably participate in (a) *fermentation*, where simple sugars and other chemicals are transformed into the desired intermediate or end-products of the process; and (b) *respiratory (oxidative) metabolism*. This respiratory activity of oxidative dissimilation is characteristic of many species of yeast. For example, during aerobic growth, sugar is oxidized to carbon dioxide and water, with the release of large amounts of energy. Other biochemical processes in which yeasts participate include amination, condensation, deamination, decarboxylation, esterification, hydrolysis, lipolysis, pectinolysis, and proteolysis, among others. See also **Yeasts and Molds**.

2. *Molds* are filamentous and of numerous varieties. They grow as a branched system of threadlike hyphae rather than as single cells. In bioprocessing molds play a positive role, as in the instance of *Penicillium roqueforti* used as a culture in making certain cheeses; or *Penicillium chrysogenum* used in the production of penicillin antibiotics. Molds also have a significant negative side in biochemical processing because of the degradative roles they play in causing food spoilage and human disease, not to mention plant and crop damage. When food processing vessels and machines are not kept clean, so-called *dairy* or *machinery mold* may be found in the equipment. The presence of this mold may be indicative of serious microbial contamination.

   Molds are widely distributed throughout nature. Critical to the growth of molds is availability of sufficient moisture. Some molds are quite resistant to adverse conditions, including high temperature.

B. *Prokaryotes*—cells or organisms that have only one chromosome. They have no nuclear membrane or mitochondria.

3. *Bacteria* (normally unicellular), of which many are used in bioprocessing (see also **Bacteria**), including: *Lactobacillus bulgaricus* (used in making yogurt); *Gluconobacter suboxidans* (vinegar); *Clostridium acetobutylicum* (acetone and butanol); *Corynebacterium glutamicum* (flavor enhancing nucleotides); *Methylophius methylotrophus* (single-cell proteins); *Propionibacterium* (vitamin B_{12}); *Bacillus* (enzymes—proteases); *Xanthomonas campestris* (polysaccharides—xanthan gum); *Mycobacterium* (pharmaceuticals—steroids); *Streptomyces* (anti biotics—amphotericin, streptomycin, tetracyclines, etc.); *Esc herichia coli* (by way of recombinant DNA technology to produce insulin, human growth hormone, somatostatin, interferon, etc.); and *Bacillus thuringiensis* (bioinsecticides).
4. *Actinomycetes*—a group of branching unicellular organisms, which reproduce either by fission or by means of special spores or conidia. They usually form a mycelium which may be of a single kind, designated as substrate or vegetative, or of two kinds, substrate and aerial. The actinomycetes are closely related to the filamentous bacteria and some authorities regard them as prototypes from which both fungi and bacteria were derived. These microorganisms have been prolific sources of several thousand antibiotics, although only a relatively few of these have been produced commercially in very large quantities.

Classes of Bioproducts Made from Microorganisms

The principal commercially important products made from the microorganisms previously mentioned include:

1. *Microorganisms per se*—for use in a wide variety of bioprocesses.
2. *Large molecules*, including enzymes.
3. *Primary metabolic products* (compounds required for their growth).
4. *Secondary metabolic products* (compounds that are not essential to their growth).

The primary and secondary metabolites that are important commercially normally are of relatively low molecular weight, usually 1500 daltons[1] or less. For comparison, an enzyme may range from about 10,000 to millions of daltons.

Commercial Applications of Microbial Cells

There are two major classes of the commercial use of microbial cells:

1. *Protein sources*, of which the most important current product is called *single-cell protein*, used in animal feedstuffs. See also **Proteins**.
2. *Bioactive ingredients* for use in bioprocessing. In bioprocessing, chemical reactions are usually referred to as *biological conversions* (even though they proceed at the molecular level) in processes where microorganisms are the major participants. The term *microbial transformation* is also used.

For large numbers of end-objectives, microorganisms as participants have a number of advantages over nonbiological reactants. For example, the latter involve substantial energy exchange (either requiring heating or cooling). Also, nonbiological processes usually are conducted in a solvent medium and often in the presence of inorganic catalysts. Both solvent and catalyst are possible sources of product pollution. Further, a large percentage of biological conversions do not yield undesirable byproducts which must be removed in separate purification operations. Once separated, profitable uses must be found for the byproducts, or they must be disposed in a costly, nonpolluting way.

In biological conversions, water is usually the solvent and temperatures and pressures are at reasonable levels, as dictated by the properties of most natural living substances. When a specific enzyme is used in a biological conversion, outstanding specificity maintains because a given enzyme usually will catalyze but one specific kind of reaction. As pointed out by Demain and Solomon (see reference), an enzyme can be caused to select one isomer, or molecular form of a compound, in a mixture of forms to produce a single isomer of the product. These characteristics account for the high yields that are typical of biological conversion, sometimes reaching nearly 100 percent.

The production of enzymes is the major target of numerous biological conversions. In years past, the principal sources of enzymes were extraction products from plant and animal sources. The application of DNA technology has made large inroads in the production of "synthetic" enzymes.

Products of commercial importance extend well beyond enzymes and include the production of large molecules, such as polysaccharides. Xanthan is an example. This is a gum widely used in food processing. See also **Xanthan Gum**.

Fermentation Industry. *Primary metabolites* of importance in the fermentation field include amino acids, purine nucleotides, vitamins, and organic acids. Specific products include citric acid, riboflavin (vitamin B_2), and cobalamin (vitamin B_{12}). Check alphabetical index pertaining to specific vitamins. Of the *secondary metabolites*, antibiotics are the most

[1] Dalton = atomic mass unit.

important. In the past, about three-quarters of all antibiotics have been obtained from the actinomycetes, and a very large percentage of these have stemmed from a single genus, *Streptomyces*. See also **Antibiotics**.

The process of fermentation has been known for at least 4000 years, notably in connection with the arts of making wine, leavened bread, brews (beer), and for decades, for example, in connection with naturally produced vinegar. In most fermentation, the microorganisms effect the desired biological transformations (serving in a way that is somewhat comparable to intermediate chemicals used in conventional organic synthesis and not present in the final product). Usually, at some point in the bioprocess, the earlier invaluable microorganisms must be killed because their presence in the final product would lead to numerous undesirable characteristics, including spoilage.

Examples of organic synthesis by way of fermentation are given in Figs. 1 and 2.

Bioprocessing Methodologies

Bioprocessing equipment must be designed to meet the environmental requirements of whatever microorganisms are used. As well understood for a century or more, enzymes created by the microorganisms catalyze the desired biological conversions in a highly efficient manner, as exemplified by the conversion of sugars into ethanol and carbon dioxide. A major advancement in fermentation occurred a number of years ago when brewers found that instead of relying on microorganisms to create the desired enzymes, they could add the enzymes manufactured separately and available from commercial sources to the fermentation vessel directly. Many bioprocesses are not so simple as producing alcohol from sugar, but require cadres of enzymes to effect the biological transformation of the substrate by initiating a number of reactions (transformations) that involve numerous specific enzymes.

The environmental requirements of microorganisms are quite demanding. Process parameters must be carefully controlled to gain full efficiency, or indeed to permit the bioprocess to continue at all. This contrasts with a considerably greater flexibility permitted when dealing with nonliving reactants and catalysts. Such parameters include temperature control and pH (hydrogen ion concentration) within very narrow limits. Sufficient water of specified purity acts as the processing medium. Although enzymes can be preserved by drying, there is no catalytic activity in the absence of water.

An Additional requirement, not encountered in effecting nonbiological reactions, is the need to provide nutrition for the living microorganisms. They require a source of carbon that normally furnishes energy for metabolism. In some cases, this requirement is met by one of the starting raw materials, such as carbohydrates (sugar in the case of alcohol fermentations). Considerable investigation for certain bioprocesses has targeted other sources of carbon, including hydrocarbons. It has been learned that some industrially important microorganisms can exist on these nutritional carbon sources. Sometimes a period of adaptation is required and because of lack of efficiency, the use of such alternative carbon sources is frequently uneconomic. But with so many products now being produced by microorganisms, research continues and effective uses are expected to

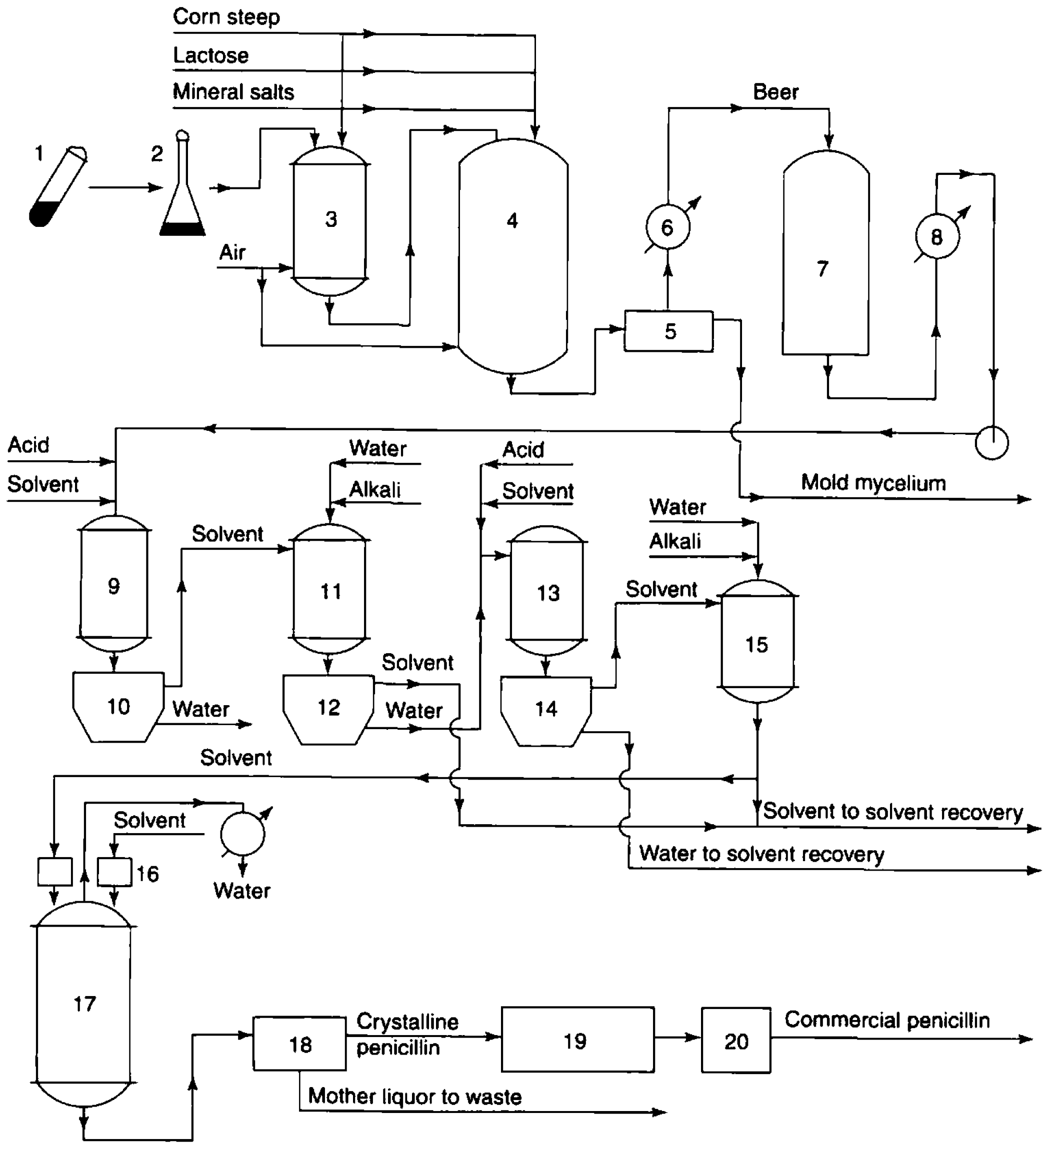

Fig. 1. Schematic representation of materials flow in penicillin manufacturing: (1) agar slant culture, (2) bran spore culture, (3) seed tank, (4) fermentor, (5) filter, (6) brine cooler, (7) storage tank, (8) brine cooler, (9) mixing tank, (10–15) separation operations, (16) bacteriological filters, (17) crystallizer, (18) filter, (19) dryer, (20) finishing operations

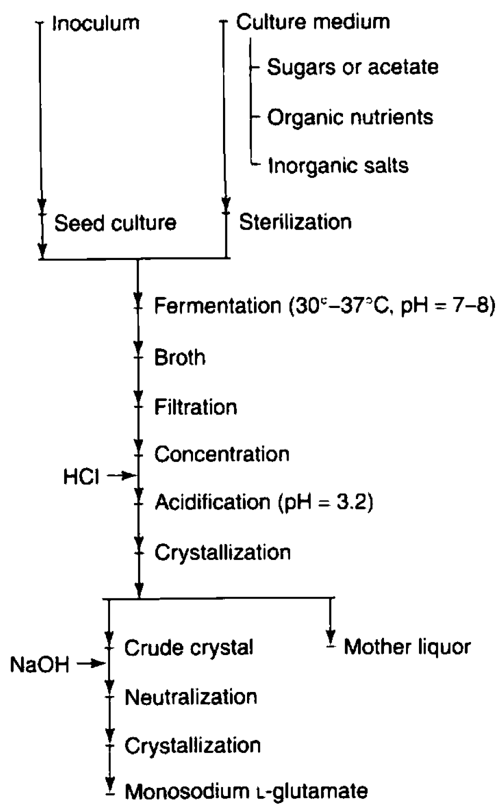

Fig. 2. Preparation of monosodium l-glutamate by fermentation. Although not involving genetic engineering, this process as pioneered by Japanese microbiologists was very advanced when introduced in 1956. Currently, almost all common amino acids can be produced by amino acid fermentation and in terms of very high tonnage production

be found. Hydrocarbon sources considered have included petroleum and natural fats (soybean oil, etc.). The important point is that the demonstrated versatility of enzyme mechanisms bodes well for much further exploitation of those characteristics in the future.

In addition to provision of carbon, other nutrients required by microorganisms embrace nitrogen, phosphorus, and oxygen, all elements of which are part of the structural and functional molecules of the cell. Smaller quantities of micronutrients are needed. The requirement for cobalt in the synthesis of cobalamin is one of these obvious requirements.

In connection with oxygen, there is an interesting situation because some microorganisms are *anaerobic* (requiring *absence* of oxygen), while others are *aerobic* (needing an ample supply of oxygen). Normally, oxygen is furnished by pumping large volumes of air through the mixture. An advancement in this procedure is the use of enriched air (over 21% oxygen).

A further important parameter in bioprocessing is that of providing adequate mixing to ensure that the several ingredients will be within immediate vicinity of each other. Depending upon the particular microorganism, they remain continually suspended in the watery medium, desirable from a processing standpoint, but some tend to collect in clusters; others tend to take the form of slimes.

To date, bioprocessing is primarily conducted on a batch basis. This provides flexibility in shifting the products to be made from time to time and, in particular, any failure to provide aseptic conditions may result in the condemnation of only one batch versus what could happen in the case of a continuous process. Notably, in the case of pharmaceutical biologicals, it is practical to keep track of the product by batch number from start to final use. Even with these kinds of problems, however, the many attractions of continuous processes are being thoroughly studied and applied in limited instances.

Genetic Engineering—State of the Art

As development of the concept of recombinant DNA progressed after its discovery in the early 1970s, great promise was given for the "engineering" of new plant species and varieties, new designer drugs, and new processes. In the 1970s, there were continual predictions of an "explosion" in such new product development. As of the early 1990s, however, there have been fewer dramatically improved products developed than had been initially contemplated. Actually, only comparatively few products are now moving from the laboratory to the processing plant. Over 77 small-scale field trials of genetically engineered tomato, potato, alfalfa, cucumber, corn (maize), and cotton have been conducted in several growing regions. The first food processing aid produced by a genetically engineered microorganism (the enzyme rennet) was approved by the U.S. Food and Drug Administration in March 1990. Most scientists in the field, however, maintain their confidence that the applications of genetic engineering in the food system alone are seemingly unlimited. Because of hunger problems throughout so much of the world, genetically engineered agriculture may prove to be the ultimate solution.

The principal steps required to genetically engineer a "new plant" are illustrated very schematically in Fig. 3.

In 1991, an expert in food biotechnology observed the following. (1) The public, in general, is not enamored with food biotechnology. (2) Public concerns continue pertaining to the potential long-term unanticipated effects of modifications of food. (3) Although willing to take modest risks, the public becomes very conservative in terms of food modifications on infants, children, and the chronically ill. (4) The public challenges corporation-sponsored university research in this area of technology.

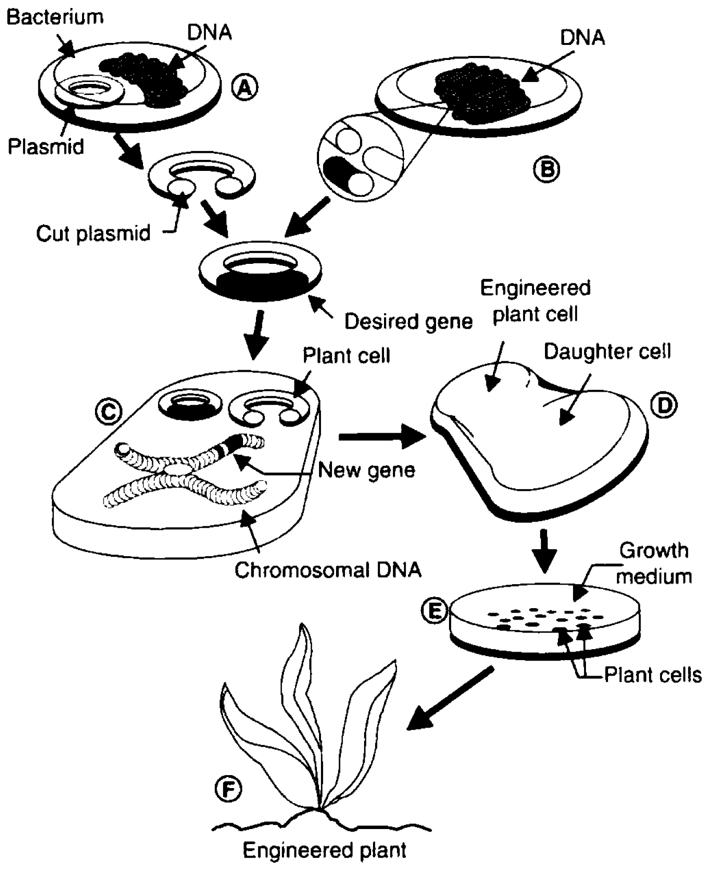

Fig. 3. Major steps in producing a genetically engineered plant: (**a**) Plasmid (a circular piece of DNA found outside the chromosome in bacteria) is removed from the bacterium and cut open by using restriction enzymes. Plasmids are the main tool for inserting new genetic information into the microorganisms of plants. Restriction enzymes are proteins that recognize specific gene sequences on a chromosome and cut DNA at these sites. (**b**) The gene of interest is cut out of the chromosomal DNA of another organism and "pasted" into the plasmid by using ligase enzymes. A ligase enzyme is one that splices segments of DNA together. (**c**) The plasmid is put back into the bacterium and mixed with plant cells. The bacterium duplicates the plasmid and transfers the new gene into the chromosomal DNA of the plant cell. (**d**) When the plant cell divides, each daughter cell receives the new gene, giving the whole plant a new trait or characteristic. (**e**) Plant cells are placed on special growth media to promote the formation of callus (unorganized tissue). After shoots grow from the callus, the plantlets are transferred to traditional media that stimulates roots to grow. (**f**) The plantlets are transferred to soil and grow to maturity. (*After Volpo and Monsanto*)

(5) The public has lost confidence in governmental regulatory actions pertaining to genetic engineering in the food field.

Attempts to provide sociological answers to scientific problems are beyond the purview of this encyclopedia. Provided such answers are forthcoming, biotechnology can be applied effectively to the solution of some of the following technical problems, particularly in terms of agriculture and food production:

- Develop temperature-tolerant plants that can survive in warmer or cooler climates. Frost damage causes more than $14 billion per year worldwide in crop losses.
- Engineer plants that can withstand drought conditions. For example, if salt-tolerant varieties can be developed, sea water could be used for irrigation.
- Improve ways for certain crop plants, such as corn (maize) and wheat to fix their own nitrogen from the atmosphere, thus reducing fertilization costs by $ billions per year.
- Engineer insect and pest resistance into plants, thus not only reducing the cost for chemical control applications, but also alleviating the environmental problems related to agricultural chemicals.
- Develop plants that have nutritional values superior to those obtainable from the existing natural varieties. One example, would be that of increasing various amino acids contained in the edible portions of the plant.

The foregoing are only part of a larger genetic research agenda. See Harlander (May 1991) reference listed.

INERT. A term used to indicate chemical inactivity in an element or compound. Helium, neon, and argon are practically inert gaseous elements; carbon dioxide is a gaseous compound of low activity. Ingredients added to mixtures chiefly for bulk and weight purposes are said to be inert.

INERT GASES (The). The elements of group 18 of the periodic classification sometimes are referred to as the Inert Gases, or the Noble Gases. In order of increasing atomic number, they are helium, neon, argon, krypton, xenon, and radon. The elements of this group are characterized by their closed shells or subshells of electrons. They generally are considered as having zero valence. The name of this group derives from the lack of chemical activity which the elements display, forming compounds only under abnormal conditions (high pressures, strong electrical fields, etc.).

INFORMATION RETRIEVAL. The literature of chemistry and associated fields has increased enormously since 1980. Establishment of subspecialties and newly defined disciplines as well as increased research output have led to an explosion of journals, books, and on-line databases, all of which attempt to capture, record, and disseminate this plethora of knowledge. Tertiary reference tools in chemistry and technology (e.g., *Kirk-Othmer*, 4th ed.) help track the primary literature. Excellent references that discuss basic chemical information tools are *The Literature Matrix of Chemistry*, *Chemical Information Sources*, and *How to Find Chemical Information*.

Retrieval of chemical information will continue to be an issue of accessing what is available in the fastest, most cost-effective manner. Changes in the ways information is located and retrieved will be driven by technological advances in computer hardware, development of software, and progress in telecommunications. The resources available through Internet are increasing daily. Content of electronic databases has remained basically the same; what has changed are the tools to access the information. Publishers continue to explore the possibilities of electronic media. Ease of information access, for example, through the use of a natural language interface, or the ability to query multilingual databases using a single language, is another emerging issue. The Special Interest Group on Information Retrieval of the Association of Computing Machinery (SIGIR ACM) meets annually to address these and other information issues. Proceedings of their meetings provide an overview of advances in information technology and access. As technology becomes more complex, issues of ownership, copyright protection, reuse of retrieved information, and access costs will need to be examined and resolved.

Libraries and information centers are rapidly moving from purchase and ownership of print and on-line resources to rapid access to these resources; a change in philosophy from "just in case" to "just in time." Libraries are making hard decisions about what to purchase and what to exclude because of the magnitude and cost of a complete collection of available information. These factors have forced severe cutbacks in what is actually bought as well as increases in cooperative purchasing and loan agreements between libraries on the local, regional, national, and even international levels. Increased computer power and technology have made geographic boundaries and limitations obsolete. Documents, such as journal articles, can be obtained quickly from other libraries and commercial document delivery vendors. Paper copy remains the preferred format for delivery of such documents. Documents can be delivered by regularly scheduled mail, by overnight delivery, or by facsimile transmission.

Although electronic publishing of journals is in its infancy, more and more full text journals are becoming available on-line, allowing printing of a document from the user's computer. The limitation of ASCII format (text only, no graphics) is being addressed by vendors. The American Association for the Advancement of Science's publication *Online Journal of Current Clinical Trials*, which debuted in July 1992, supports text and nontext and publishes a paper within days of acceptance. The Research Libraries Group has produced ARIEL, a software package that allows image scanning of a document transmitted through Internet. ARIEL provides images and text of greater resolution than fax and uses standard personal computer (PC) hardware.

Location of and access to chemical and technical information other than journal articles is available through computerized information networks. Electronic bulletin board systems (BBS) provide a telecommunications tool to anyone who has a computer and a modem. Questions can be posted and read by thousands of bulletin board users worldwide, and files and software are easily transferred from virtually anywhere to one's computer.

Networks. The rise in popularity and use of Internet has dramatically changed the way information is disseminated. Internet is a worldwide link of thousands of separately administered computer networks of many sizes and types. Each of these networks is connected to as many as tens of thousands of computers; the total number of individual Internet users is in the millions.

The three basic Internet applications of remote login, electronic mail, and file transfer are building blocks of more sophisticated applications that offer increased functionality and ease of network use. Tools such as Gopher, Wide Area Information Servers (WAIS), and World Wide Web (WWW) go beyond the three basic Internet functions to make information on the network easier to locate and use. Detailed descriptions of these tools are available. This trend toward more powerful, user-friendly networked information resource access systems should continue as Internet grows and matures.

Copyright. Any discussion of emerging technologies in storage and retrieval of information leads to a question of copyright compliance. Copyright in the electronic and computer age, using the internal and external networks and document delivery mechanisms outlined above, is a complex and unresolved issue. One of the primary reasons for using document delivery services, other than for obtaining information that is not locally available, is copyright compliance. Document suppliers generally handle payment of any required copyright fees. In the electronic and computer age, establishing who owns a particular piece of information can be difficult, as can determining what can legally be done with information once it is obtained.

Budgeting. Changes in the storage and retrieval of chemical information require that libraries and information centers now consider not only what should be purchased but also what monies should be allocated for the purchase of information in nonprint formats such as CD-ROMs (compact disk read-only memory) and on-line databases. Coupled with this is budgeting for the cost of hardware and software to enable the rapid and cost-effective delivery of needed information. The geometric increase in sources, both printed and on-line, has increased the role of the information specialist as an expert in the delivery of chemical information. Retrieval from increasingly diverse and complex sources becomes the paramount issue for searchers of chemical literature in the 1990s.

On-Line Database Resources

The on-line information industry has grown dramatically since 1972 when Dialog Information Services, Inc. (Dialog) offered the first publicly available commercial databases. Databases covering virtually all important subject areas were developed, and significant publications became available via thousands of bibliographic, abstract, textual, directory, and numeric databases. For electronic databases to be made available publicly, development was required in three primary technologies: computers, communications, and databases themselves.

Database Producers. Producers of databases, also known as database publishers or information providers, determine the content of the databases, produce them, and typically lease or license them to private organizations or database vendors. Database producers may be categorized as government, not-for-profit, commercial/industrial, and mixed.

Primary database vendors that offer or are developing fixed price options include Mead Data Central, Dow Jones News/Retrieval and DataTimes, NewsNet, Dialog, and OCLC. The environment of the 1990s is one in which database vendors and producers are competing for survival, and end users are leading the way to what could represent significant growth in the on-line database industry. Vendors include BRS Online Products, Cambridge Crystallographic Data Centre, Chemical Information Systems, Data-Star, DIALOG Information Retrieval Service, ESA-IRS, MDL Information Systems, Inc, Mead Data Central, MEDLARS, ORBIT ONline Service, Questel, and STN International.

Chemical Information and Search Methods and Services

Chemical information is reported and recorded in many forms, and a wide variety of databases have evolved to collect the various types of information. Bibliographic, business, structure, numeric, spectra, and reaction databases currently are available.

Bibliographic–Technical. These include Agrochemical Handbook, Analytical Abstracts (AA), APILIT, APIPAT, CA File, CA Registry File, CA Search CAB ABSTRACTS, Ceramic Abstracts, Chemical Engineering and Biotechnology Abstract (CEBA), Chemical Journals of the American Chemical Society (CJACS), Chemical Journals of the Royal Society of Chemistry, Chemical Safety NewsBase (CSNB), Chinese Patent Abstracts in English Database, CLAIMS, COMPENDEX PLUS, CORROSION, Current Biotechnology Abstracts (CBA), Current Patents (Evaluation/Fast-Alert), Dissertation Abstracts Online, EMBASE, Energy Science & Technology, EPAT, European Directory of Agrochemical Products, GenBand, INPADOC, INSPEC, JAPIO, Rapra Abstracts, SciSearch, Thomas Register Online, U.S. Patents Fulltext, World Patent Index (WPI), World Surface Coatings, and World Textiles.

Business–Industrial. These include ABIINFORM, BIOBUSINESS BUSINESSWIRE, CENDATA, Chemical Industry Notes (CIN), Commerce Business Daily, Conference Papers Index, Dialog Journal Name Finder, Dialog Product Name Finder, DISCLOSURE DATABASE, Dun's Market Identifiers, ERIC, Federal Register, Food Science and Technology Abstracts, Harvard Business Review, Health Periodicals Database, Health Planning and Administration, ICC International Business Research, International Pharmaceutical Abstracts (IPA), INVESTEXT, MANAGEMENT CONTENTS, Marquis Who's Who (MWW), MATERIALS BUSINESS FILE, NTIS Bibliographic Database, Nursing and Allied Health, PHARMACEUTICAL NEWS INDEX (PNI), Pharmaceutical Business News, Pharmaprojects, Pollution Abstracts, PR Newswire, PTS News, PTS PROMPT, SEC ONline, Textile Technology Digest, Textline, THOMAS REGISTER ONLINE, TOXLINE, Trade and Industry, and World Textiles.

Structure. Structure searching involves matching a query compound against a machine-readable file of chemical structures. Structure searching determines if a compound is present in a file and retrieves it along with any associated information. Chemical structure files are compiled as novel chemicals, and compounds are registered and given unique identifiers, e.g., the CAS Registry Number, which is assigned sequentially to each new structure entering the system.

Substructure searching involves retrieval of all the compounds in a file containing some specified portion of a chemical structure, irrespective of the rest of the molecule in which the query substructure occurs.

Databases include the Beilstein File, the Gmelin File, the Registry File, the Description, Acquisition, Retrieval, and Correlation File, and the Structure and Nomenclature Search System.

Numeric. Researchers routinely use reported numeric measurements and data in their work. Numeric databases include the Beilstein Handbook of Organic Chemistry, the Gmelin Handbook of Inorganic and Organometallic Chemistry, property data networks [the Materials Property Data Network Inc. (MPD) and Chemical Property Data Network (CPDN)], and TDS NUMERICA.

Cambridge. The Cambridge Structural Database is an integrated system of programs for searching, retrieving, and analyzing data on more than 96,000 organic and organometallic structures, which were determined by x-ray and neutron diffraction. About 15,000 compounds a year are being added to the database.

Spectra. The ability to consult collections of standard spectra is crucial in the analysis of unknown compounds. A long history of data collection efforts has been aimed at these applications. Among the best known of the published handbooks are the Sadtler Spectral Data Sheets, which include ir, Raman, and nmr spectra. On-line sources include the Chemical Information System, SpecInfo, and The Canadian Scientific Numeric Database Service (CAN/SND).

Reactions. CASREACT File is a chemical reaction database containing over 118,500 records with reaction information derived from documents covered in the Organic Section of *Chemical Abstracts*. The file is available from STN.

Integrated Systems. Until recently, each of the numerous databases and sources of information available to chemists and technologists had to be searched individually, and selected results either printed for file storage or downloaded to an in-house or private computer system for easy future access.

Molecular Design Limited (MDL) has marketed an Integrated Scientific Information System (ISIS), which provides the capability to query multiple systems, including binary, text, proprietary, and relational databases across global networks, thereby providing transparent desktop access to multiple autonomous data sources.

Patent Information and Search Methods/Services

Patents are unique as primary source documents because of their stylized format, specialized language, presence of legally significant claims, descriptive drawings, and frequent disclosure of chemical compositions as generic (Markush) structures. A comprehensive review of electronic databases that contain patent information, including legal aspects, is

available. Databases include bibliographic databases [World Patents Index, U.S. Patents, CLAIMS, APIPAT, EPAT, JAPIO, INPADOC], and PHARM.

Full-Text Databases. Two vendor-provided full-text patent databases are LEXPAT, produced by Mead Data Central, and PATFULL, produced by Dialog Information Services.

Chemical Substructure Databases. Several patent databases are searchable by chemical substructure. These are designed to give higher relevance of retrieval when searching chemical compounds than the bibliographic or full-text databases. They include MPHARM, WPIM (World Patents Index Markush), and MARPAT.

CD-ROM Databases. Since about 1989, CD-ROM format bibliographic and image patent databases have become available as current awareness, reference, or image storage and retrieval tools. The databases are designed for stand-alone PC or local network use, and in some cases they may be alternatives to retrieving patent information on-line. U.S. patent information resources available on CD-ROM include APS (Automated Patent Searching), CASSIS, FullText, OG/PLUS, PatentImages, and PatentView.

The European Patent office ESPACE series of CD-ROM products are ESPACE-EP, ESPACE-FIRST, ESPACE-UK, ESPACE-WORLD, and ESPACE-ACCESS.

MARKUSH TOPFRAG. Derwent's TOPFRAG family of products is PC-based software that automates the selection of search codes and strategies.

Environmental and Safety Information and Search Methods and Services

There are public and private databases. Public databases are produced by the government and private enterprise and are commercially available through database vendors, such as STN, DIALOG, BRS, ORBIT, and NLM, and through various universities. Private databases are produced by government agencies, corporations, or other organizations for in-house use by their employees or others affiliated with them. The information in these databases may be made available on a need-to-know basis to individuals or corporations in the public or private sectors. Knowledge of the existence of private databases is usually obtained by personal contact within an organization or thorough disclosure in published literature. Private industrial databases are not usually accessible by the public, although information contained in them on hazardous materials must be reported to the EPA under provisions of TSCA (Toxic Substances Control Act) Section 8e.

Public Databases. The most comprehensive list of publicly available databases is the two-volume *Gale Directory of Databases*.

Private (EPA) Databases. The U.S. EPA maintains a list of approximately 600 current information systems, as well as some of the models and databases used within the organization. The list is published in *Information Systems Inventory* (ISI) which is updated yearly and maintained by the Information Management and Services Division of the Office of Information Resources Management.

On-Line Search Aids

MACCS-II. The Molecular Access System is a chemical information management system from Molecular Design Limited (MDL), San Leandro, California. It offers menu-driven graphical input for building, maintaining, and accessing chemical structures and any associated data, e.g., chemical and physical properties, biological activity, toxicity data, pricing, safety, and supplier information.

MACCS-II enables direct interface with other database management systems, such as the Relational Database Management System (RDBMS) and Oracle, so that databases that contain text and numeric data, for which special interfaces are normally needed, can be constructed.

Optical Disk-Based Information and Document Image Systems

Optical-based storage technology has joined paper, microfilm, and electronic/magnetic technologies as another medium for the storage, retrieval, and management of information. Optical media differ from magnetic media in that the information is encoded and read by means of laser optics. Information stored on optical disk may be either in a searchable text format (ASCII) or in a format containing only bit-mapped images, usually obtained as output from a scanner. Through the scanning and digitization process, pages that consist of printed text, graphics, photographs, drawings, handwriting, tables, etc., are converted to their binary representation and are stored as bit-mapped images on the optical media. The information stored on optical disk often has counterparts in other formats, such as printed publications or on-line databases or files. Advantages of document imaging systems for complementing, enhancing, or replacing traditional paper- or microfilm-based systems include increased storage capacity, ease of access via automated retrieval, simultaneous searching and viewing at multiple workstations, speed of access and delivery resulting in productivity gains, improved customer service, document security, document integrity via preservation and elimination of lost or misfiled documents, and networking and integration capabilities for these systems. Among the types of optical media that have been developed, the two most common for information storage and retrieval systems are both optical disk-based systems, namely CD-ROM and WORM (write once read many).

Several projects such as CORE (Chemistry On-Line Retrieval Experiment) at Cornell University, Project Mercury at Carnegie-Mellon University, Right-Pages at AT&T, and Red Sage at the University of California, San Francisco are in progress and illustrate the issues arising from implementation of on-line information systems that combine text and image.

Private Bibliographic and Text Databases

Personal computers have introduced new ways to handle private bibliographic and text files. The most important factors to consider to achieve satisfactory results in building a bibliographic or text database are the type of information to be stored and the needs of the user. Types of information include correspondence, research results and documentation, meeting notes, and bibliographic references. Needs of the user to be considered should include the potential number of users of the database, restrictions for the access and display of the information because of privacy or proprietary reasons, and the retrieval mechanisms (e.g., by keyword, authority list, controlled vocabulary, author, title, date, or other document or information attributes). In addition, criteria for selecting and encoding information for the database need to be established.

The type of hardware or computer system to be used and the potential size of the database should also be considered. Another factor frequently overlooked in private database creation is commitment to the support and maintenance of the database. Support involves training users, solving software and hardware problems, and upgrading the software when new features become available or are needed by the end user. Maintenance of the database include adding new information, deleting information no longer wanted, and correcting information in the database when errors are detected. Software packages available for building databases range from generic personal computer database management systems, which require customizing to software designed specifically for bibliographic files. Most of the software is for Macintosh or IBM compatible PCs. Some examples are PROCITE, NOTEBOOK II, ENDNOTE, LIBRARY MASTER, PERSONAL FILE SYSTEM, ASKSAM, BASISPLUS, and PERSONAL LIBRARIAN.

INFRARED RADIATION. The region of the electromagnetic spectrum between the wavelength limits 0.7 and 1,000 micrometers. The lower

wavelength limit is set to coincide with the upper limit of the visible radiation region. Radiation of wavelength greater than 1,000 micrometers is generally considered of the microwave spectrum. Both limits are arbitrary. The infrared region is sometimes broken down into three subregions: (1) the *near-infrared region* (0.7–1.5 micrometers); (2) the *intermediate-infrared region* (1.5–20 micrometers); and (3) the *far-infrared region* (20–1,000 micrometers).

Infrared radiation is produced principally by the emission of solid and liquid materials as a result of thermal excitation and by the emission of molecules of gases. Thermal emission from solids is contained in a continuous spectrum, whose wavelength distribution is described by

$$ {}_{\lambda}d\lambda = \frac{2\pi c^2 h \varepsilon_\lambda}{\lambda^5}\,\frac{1}{e^{ch/\lambda kT}-1}\,d\lambda $$

where λ = spectral radiant emittance of the solid into a hemisphere in the wavelength range from λ to $(\lambda + d\lambda)$.
c = velocity of light
h = Planck's constant = 6.62 × 10 − 27 erg/second
ε_λ = spectral emissivity
k = Boltzmann's constant = 1.38 × 10 − 16 erg/K
T = absolute temperature of the solid emitter, K

The spectral emissivity, ε_λ, is defined as the ratio of the emission at wavelength λ of the object to that of an ideal blackbody at the same temperature and wavelength. When ε_λ is unity, the foregoing equation becomes the Planck radiation equation for a black body.

Gaseous emission of infrared radiation differs in character from solid emission in that the former consists of discrete spectrum lines or bands, with significant discontinuities, while the latter shows a continuous distribution of energy throughout the spectrum. The predominant source of molecular radiation in the infrared is the result of vibration of the molecules in characteristic modes. Energy transitions between various states of molecular rotation also produce infrared radiation. Complex molecular gases radiate intricate spectra, which may be analyzed to give information of the nature of the molecules or of the composition of the gas.

Spectral Emittance

The spectral radiant excitance of a blackbody at various temperatures is shown in Fig. 1. It is apparent from the figure that blackbody radiation from emitters at temperatures below about 2000 K falls predominantly in the infrared region. An emitter that exhibits at all wavelengths is called a *gray-body* radiator. Most solid radiators show a general decrease in spectral emittance with increasing wavelength in the infrared; however, over limited spectral ranges, many materials are approximately gray-body radiators. Radiators that approach the characteristics of ideal blackbodies can be made in the form of uniformly heated cavities. A relatively small aperture, through which the cavity can be observed, serves as the source of blackbody radiation.

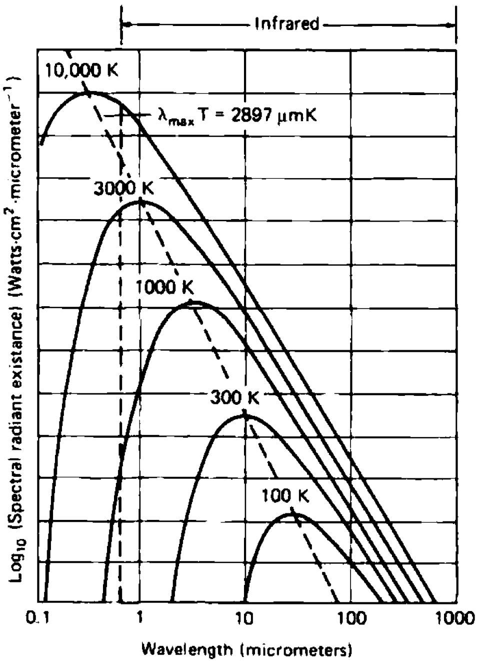

Fig. 1. Spectral radiant excitance of a blackbody at various temperatures

Propagation

Infrared radiation propagates through various media and, in general, is subject to absorption, which varies with the wavelength of the radiation. Molecular vibration and rotation in gases, which are related to the emission of radiation, are also responsible for resonance absorption of energy. The lesser gases in the atmosphere exhibit pronounced absorption throughout the infrared spectrum. However, nitrogen and oxygen do not absorb significantly in the infrared region. Water vapor, carbon dioxide, and ozone are responsible for strong absorption in the infrared. The absorption of radiation is so prevalent that those spectral bands in which relatively little absorption occurs are identified as atmospheric windows.

Solid and liquid materials show, as a rule, strong absorption in the infrared. There are, however, many solids that transmit well in broad regions of the infrared spectrum. Many materials, such as water and silica glasses, which show little absorption in the visible, are opaque to infrared radiation at wavelengths greater than a few micrometers. Many of the electrically insulating crystals, such as the alkali halides and the alkaline-earth halides, which transmit well in the visible, also are transparent to much of the near- and intermediate-infrared spectrum. Several of the semiconductor materials absorb strongly in the visible, but become transparent in the infrared beyond certain wavelengths characteristic of the semiconductor.

Detection of the presence, distribution and/or quantity of infrared radiation requires techniques which are, in part, unique to this spectral region. The frequency of the radiation is such that essentially optical methods may be used to collect, direct, and filter the radiation. Transmitting optical elements, including lenses and windows, must be made of suitable materials, which may or may not be transparent in the visible spectrum.

The detector for infrared represents the most unique component of the detection system. Photographic techniques can be used for part of the near-infrared region. Photoemissive devices, comparable to the visible- and ultraviolet-sensitive photocells, are available with sensitivity extending to about 1.3 micrometers. The intermediate-infrared region is most effectively detected by photoconductors. These elements, photosensitive semiconductors, are essentially photon detectors, which respond in proportion to the number of infrared photons in the spectral region of wavelength. This wavelength corresponds to the minimum photon energy necessary to overcome the forbidden gap of the semiconductor. All spectral regions from ultraviolet through visible, infrared, and microwaves, can be detected by an appropriately designed thermal element, which responds by being heated by the absorption of the incident radiation. In the infrared region, thermal detectors take the form of thermocouples, bolometers, and pneumatic devices. The thermal devices, in general, are not sensitive or as rapidly responding as photoconductors.

A very practical application of infrared radiation is found in radiant heating. Solid radiators, such as hot tungsten filaments, alloy wires, and silicon carbide rods are used widely as sources of infrared to provide surface heating by radiation. Commercially available infrared lamps are extensively used in specially designed ovens for drying painted and enameled surfaces.

Infrared Imagery

Infrared technology, sometimes called "night vision," has been used for several years in both military and commercial applications. The effectiveness of IR detectors was dramatically demonstrated during the military operation, Desert Storm, in 1991. These detectors, not previously demonstrated in actual war situations, were tremendous aids in achieving bombing target accuracy, not only from aircraft but from land vehicles as well. See series of images given in Figs. 2 and 3. Infrared imaging of the earth's surface from satellites also has become much more precise over the past decade. These topics are described in more detail in the articles on **Photography and Imagery**; and **Satellite (Scientific and Reconaissance)**.

Infrared Spectroscopy[1]

Scientists have long used infrared absorption as a means of probing the structure of molecules. Studying the manner in which specific wavelengths

[1] Information on infrared analytical instrumentation furnished by Rodney M. Durham, Instruments Division, Infrared Industries, Inc., Santa Barbara, California.

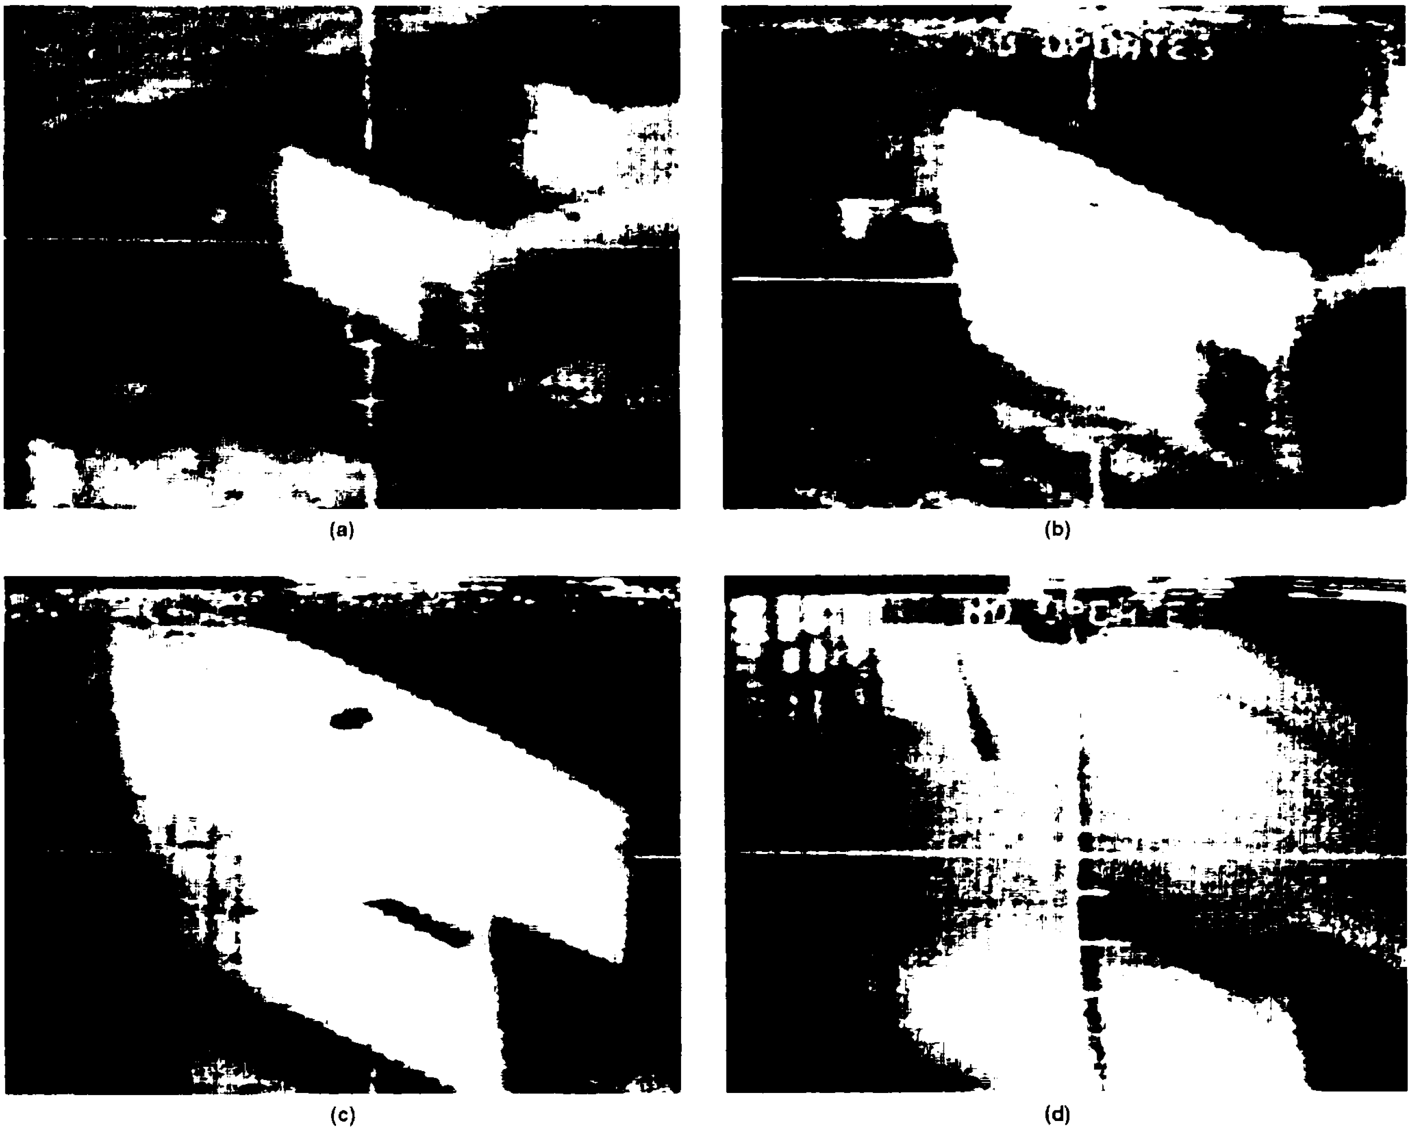

Fig. 2. Second-by-second image of target taken by an attack *aircraft*. (*McDonnell Douglas photo*)

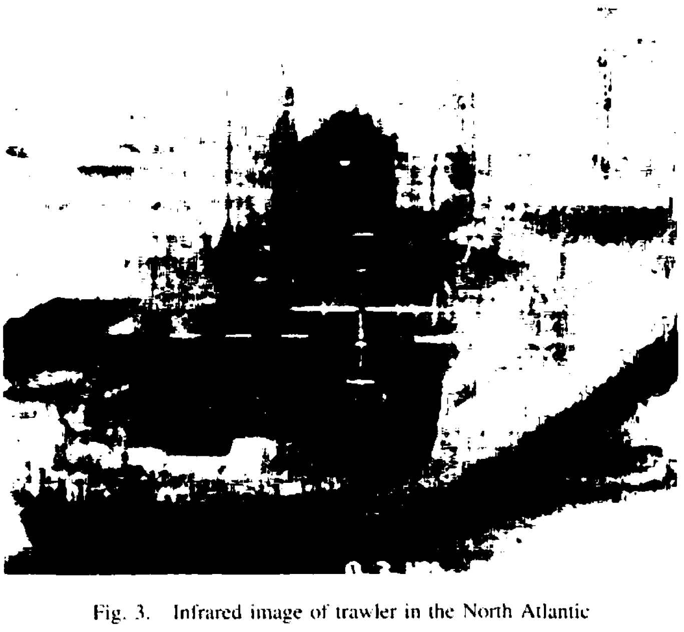

Fig. 3. Infrared image of trawler in the North Atlantic

of infrared energy excite vibration and rotation in molecules reveals information about the molecule that can be used to determine what and how many molecules are present.

The *infrared spectrophotometer* is the principal instrument used by scientists for these measurements. Most laboratory spectrophotometers are of a dispersive design, i.e., a prism or grating is used to separate the spectral components in the source radiation. Modern infrared spectrophotometers have a wide wavelength range from 2 to 50 micrometers. They find use in research, quality control, and analytical service laboratories.

Ultrafast IR spectroscopy is a comparatively recent development. Chemical reactions can be studied on the picosecond and femtosecond time scale. For example, as described by Stoutland, Dyer, and Woodruff (Los Alamos National Laboratory), the dynamics after CO dissociation from CO-ligated hemoglobin and myoglobin have been investigated by monitoring the CO chromophore. These studies have provided not only evidence for the sub-picosecond dissociation of CO, but also structural information. Other researchers have used ultrafast IR spectroscopy to investigate energy transfer dynamics of organometallic molecules both in solution and on surfaces. Such information is central to understanding chemical activation and how thermally activated reactions occur. Recent experiments have provided complementary information on surfaces.

As pointed out by Stoutland, "The general principles of ultrafast laser experiments are well known. All ultrafast experiments are variants on the 'pump-probe' scheme, in which time resolution is obtained by spatial delay of a probe pulse relative to the pump, or excitation, pulse (1 ps = 3.0 mm)."

Short IR pulses can be generated in a number of ways. Typically, these are based on Raman scattering processes or nonlinear mixing schemes or the related optical parametric oscillator. Much more detail is given in the Stoutland reference listed.

Infrared Process Analyzer

This instrument has evolved from the laboratory spectrophotometer to satisfy the specific needs of industrial process control. While dispersive instruments continue to be used in some applications, the workhorse infrared analyzers in process control are predominantly nondispersive infrared (NDIR) analyzers. The NDIR analyzer can be used for either gas or liquid analysis. For simplicity, the following discussion addresses the NDIR gas analyzer, but it should be recognized that the same measurement principle applies to liquids. The use of infrared as a gas analysis technique is certainly aided by the fact that molecules, such as nitrogen (N_2) and oxygen (O_2), which consist of two like elements, do not absorb in the infrared spectrum. Since nitrogen and oxygen are the primary constituents of air, it is frequently possible to use air as a zero gas.

Many different analyzer configurations have been developed to address the diverse needs of the industrial process control industry. The basic constituents of an NDIR analyzer are: (1) a source of infrared radiation; (2) a means of restricting the wavelength range of the source radiation; (3) a means of detecting the infrared radiation; (4) a sample chamber to hold the gas or liquid to be measured; (5) a means of modulating the source radiation; and (6) electronics to process the signal generated by the source energy falling on the detector.

Microphone Detectors

Many IR process analyzers installed over the past several years have utilized *microphone detectors*. These detectors generally are the *Veingerov single-sided microphone* system or the *Luft balanced condenser microphone* system. These detectors are shown schematically in Figs. 4 and 5. See also Hill-Powell reference. The microphone detector uses an absorbing gas as its detecting medium. When radiation reaches the detector (that the sensitizing gas will absorb), the gas heats up and expands. This causes a diaphragm to distend. The diaphragm movement varies the condenser microphone capacity, which is part of an electric circuit that generates an electrical output signal. Both analyzers use dual sources, which are chopped to alternately allow energy to pass through a sample cell and a reference cell.

If the sample cell contains a nonabsorbing zero gas, such as nitrogen, the modulated beams reaching the detector through the two paths are of equal amplitude. In the case of the Veingerov single-sided detector, the chopper is configured so that, at any given time, the sum of the cross-sectional areas of the two beams as seen by the detector equals the total cross-sectional area of a single beam, so that, when no absorbing sample is present, a constant signal is produced, and the output is zero. When a sample is present, the sample and reference path signals become imbalanced and a signal at the chopper frequency is developed. The amplitude of this signal is a function of the concentration of the gas present in the sample cell.

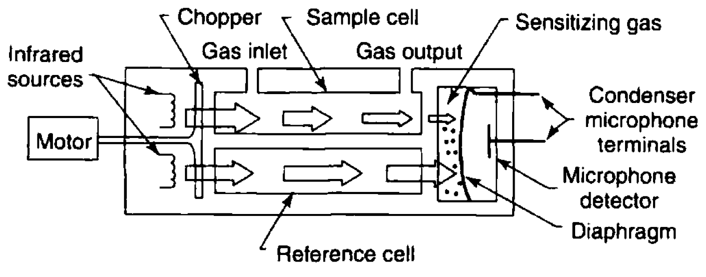

Fig. 4. Nondispersive infrared analyzer with a Veingerov-type detector

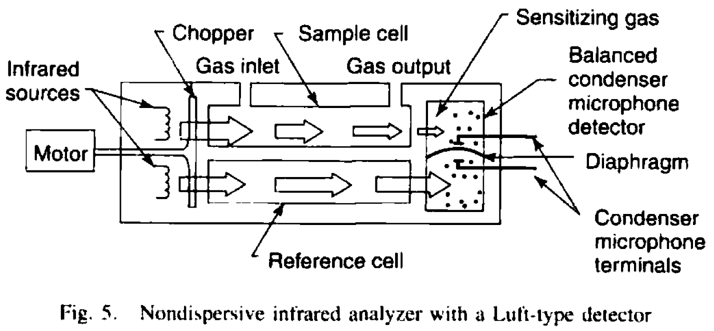

Fig. 5. Nondispersive infrared analyzer with a Luft-type detector

The Luft detector (Fig. 5) operates similarly, but the detector has two chambers separated by a diaphragm. The signal generated by the presence of an absorbing gas in the sample cell is at twice the chopping frequency. This is an advantage over the single-sided microphone detection system since it is less susceptible to vibration caused by imbalance of the chopper motor. Having separate chambers does, however, allow for the possibility of a change occurring in one-half of the detector and not the other and thus resulting in zero drift. More recently, infrared process analyzers have been introduced which use a Luft-type detection system but replace the diaphragm with flow sensors. The flow of gas from one chamber to another is sensed by the flow sensor rather than by using a capacitance detection technique. This is claimed to eliminate one of the major modes of detector failure—failure of the thin diaphragm. For a given path length, process analyzers which use the microphone detector are more effective than those analyzers which use solid state detectors and optical filters at measuring low concentrations of gases which have a lot of structure in their absorption band. This structure results from the molecular rotation spectrum being superimposed on the vibration spectrum and is easily resolved in the simpler molecules such as carbon monoxide, methane, and ammonia.

Solid-State Detectors

The most recent generation of NDIR analyzers have evolved to satisfy the frequently harsh industrial environments encountered. These analyzers utilize solid-state sensors for the detection of infrared radiation. Most frequently used sensors are lead selenide (PbSe), thermopiles, or pyroelectric detectors. The gas analyzers generally are configured as single-path instruments, dual-beam with a reference path, or dual-channel with a reference filter.

Single-beam instruments find use where low cost is important, but where stability requirements are not stringent. Generally, this is true when the measurement period is short and frequent rezeroing is practical. Changes in source intensity due to power variation or changes in detector sensitivity due to temperature fluctuations are reflected directly in the output as zero drift. To avoid this, a reference path is commonly used. The dual-beam configuration is shown in Fig. 6. The source energy is modulated by a chopper blade. This allows the source to alternately pass through the reference and sample paths. The reference path is always free of absorbing gas so the detector is exposed to the source through a path unaffected by the presence of the sample. This signal is monitored by an automatic gain control circuit, which holds the reference signal level constant. If the source intensity or detector sensitivity change, the gain control will correct for it in both the reference and sample channels. Sync pickups monitor the chopper position and alert the electronics when the sample or reference path is irradiated. A narrow bandpass optical filter is located in front of the detector to limit the infrared energy and sensitize the analyzer to a particular gas absorption band. The signals generated by the two optical paths are synchronously demodulated. When an absorbing gas is introducing, the signal reaching the detector through the sample path is attenuated and the magnitude of the detected signal corresponds directly to the concentration of the sample gas present in the sample cell.

A reference optical filter can be used as an alternative to the reference path. This requires that a spectral window exist where is no interference from the sample. The 3.8 to 3.9 micrometer spectral region is frequently used in NDIR gas analyzers for this purpose. The spectral curves of Fig. 7

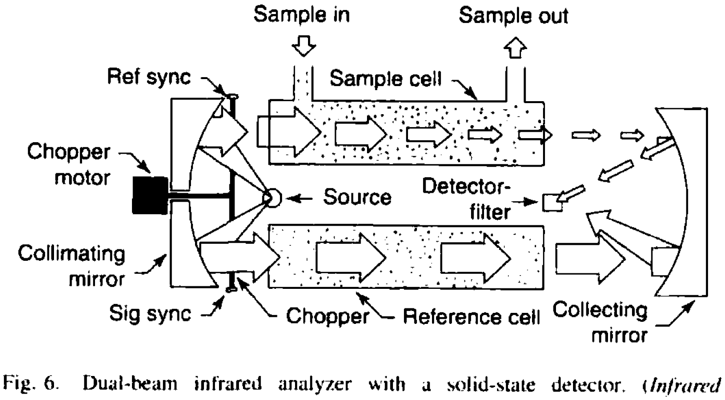

Fig. 6. Dual-beam infrared analyzer with a solid-state detector. (*Infrared Industries, Inc*)

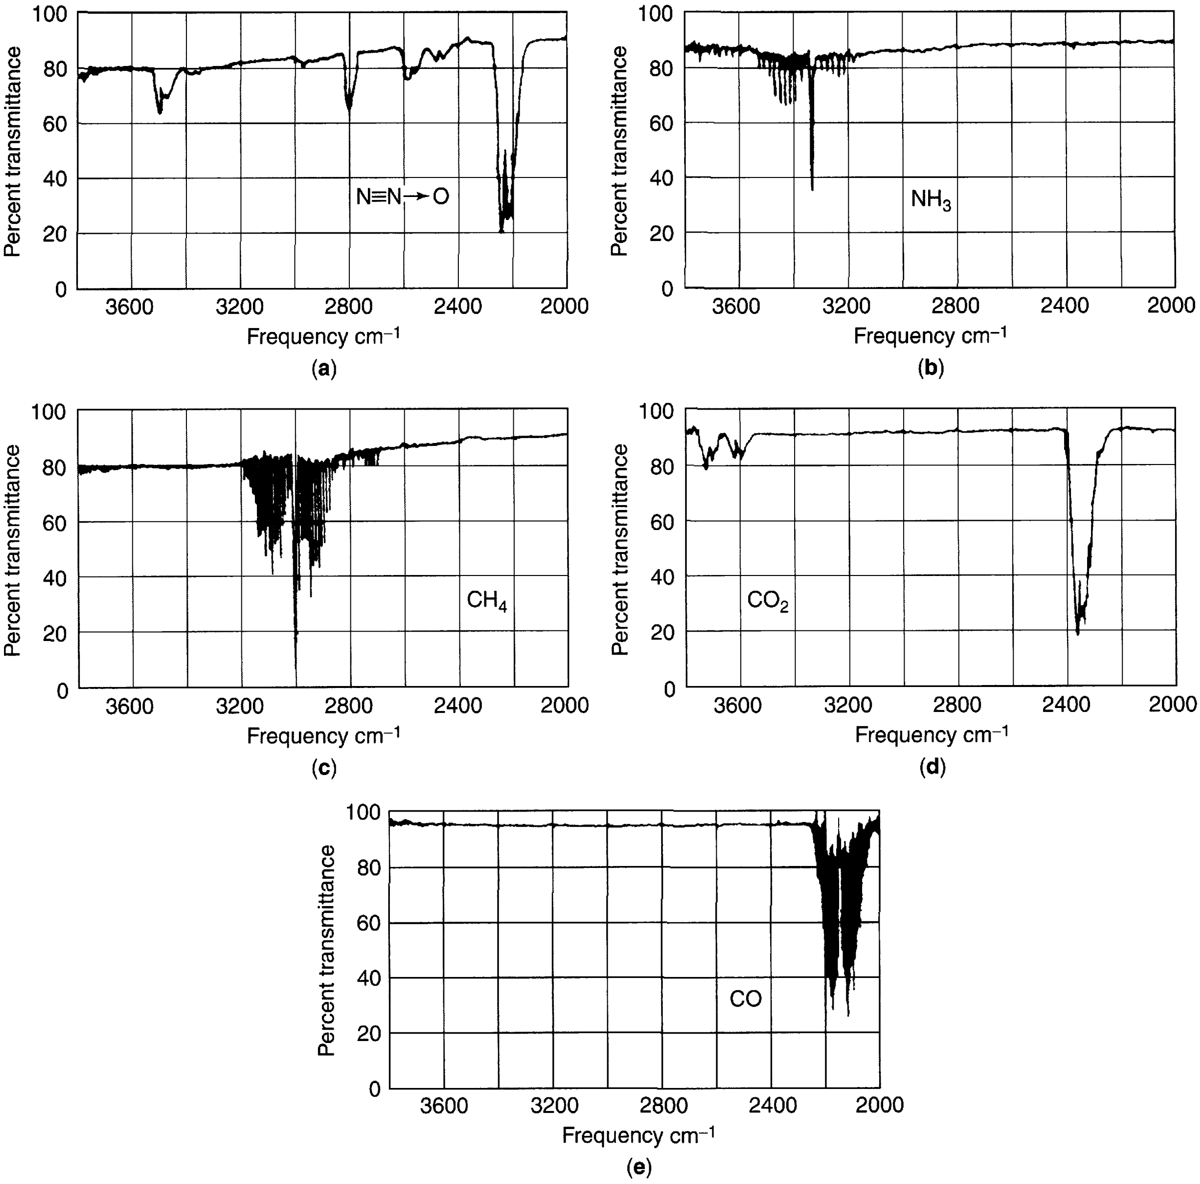

Fig. 7. Infrared spectra: (**a**) nitrous oxide, (**b**) ammonia, (**c**) methane, (**d**) carbon dioxide, (**e**) carbon monoxide. (*Sadtler Research Laboratories*)

show that this spectral window will work well as a reference for measuring CO, CO_2, CH_4, or NH_3. It would be unsuited for nitrous oxide.

The dual-channel (reference filter) configuration is shown in Fig. 8. The reference filter and the sample filter, which define the spectral region of interest, are mounted on a spinning chopper wheel. As the chopper spins, it alternately positions the filters in the optical path. The signal is demodulated in a similar manner to the dual-beam approach. In order for the reference

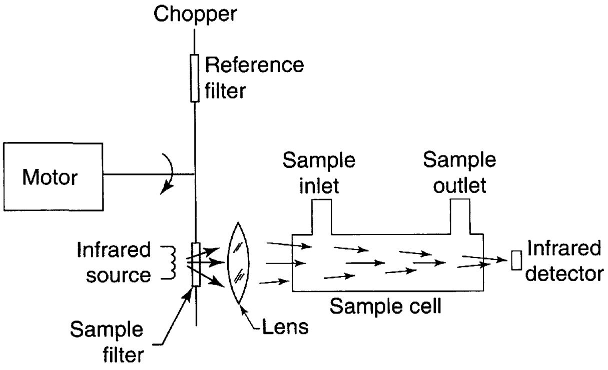

Fig. 8. Dual-channel nondispersive infrared analyzer with a solid- state detector. (*Infrared Industries, Inc*)

filter to be effective, it is important that the performance of the source and detector behave the same in the sample and reference spectral regions. The spectral properties of the source and detector are functions of temperature and must be controlled precisely, or zero and span drift will result.

Uses of IR Analyzers

Many gases can be monitored with IR analyzers. The petrochemical industry, for example, monitors CO_2 in the manufacture of ethylene oxide and ammonia. Acetylene is monitored during the production of acetylene and vinyl chloride. The metals industries use the analyzers to monitor CO_2 in steel converting and soaking pit operations. Carbon monoxide is monitored during heat treating, aluminum powder processing, and tin plant annealing. The food industry monitors CO_2 in greenhouses, storage facilities, and fermentation processes. The analyzers also find use in monitoring for explosive and toxic hazards, as well as for stack gases in pollution control systems.

Typical gases and concentrations measured by NDIR analyzers are given in Table 1.

Other Applications

Optical-electronic devices of many kinds have been designed to determine the direction of weakly radiating remote objects by means of detection of their infrared emission. Detailed maps of the earth's surface can be made from aircraft at night by observing the varying infrared emission of the ground. For security, personnel can be detected in total darkness by infrared radiation. Such devices require the detection of low-level

TABLE 1. REPRESENTATIVE GASES AND CONCENTRATIONS MEASURED BY NDIR ANALYZERS

Gas	Range (Full scale concentration) Minimum (ppm)	Maximum (percent)
Ammonia	1000	100
Butane	300	100
Carbon monoxide	500	100
Carbon dioxide	200	100
Ethylene	1000	100
Ethane	500	100
Ethylene oxide	1500	100
Hexane	400	5
Methane	400	100
Nitrous oxide	150	100
Propane	400	100
Sulfur dioxide	400	100
Water vapor	1500	10

radiation in the intermediate-infrared region. Optical lenses or mirrors are used to collect the observed radiation and concentrate it onto the sensitive infrared detector. High-gain, low-noise amplifiers must be used to increase the weak signal from the detector. The wavelength of detection is such that angular resolution capability, as set by diffraction, is much greater with infrared devices than with radars. Infrared photography is described under **Photography and Imagery**.

Astronomy. The potential of using the infrared portion of the electromagnetic spectrum for investigating celestial bodies and interstellar space has been considered by some astronomers for a number of years. This concept was first proposed by William Herschel. It has only been within the last few decades, however, that serious experiments in infrared astronomy have been made.

Solar Energy

The sun's total radiation output is approximately equivalent to that of a blackbody at 10,350°R (5750 K). However, its maximum intensity occurs at a wavelength that corresponds to a temperature of 11,070°R (6150 K) as given by Wien's displacement law. A figure plotting solar irradiance versus spectral distribution of solar energy is given in Fig. 9. See also **Solar Energy**.

Infrared Laser Chemistry

The application of IF lasers to chemical reactions is described in entry on **Photochemistry and Photolysis**.

Infrared Radiation Sources

Blackbody radiation sources are accurate radiant energy standards of known flux and spectral distribution. They are used for calibrating other infrared sources, detectors, and optical systems. The radiating properties of a blackbody source are described by Planck's law. Energy distribution

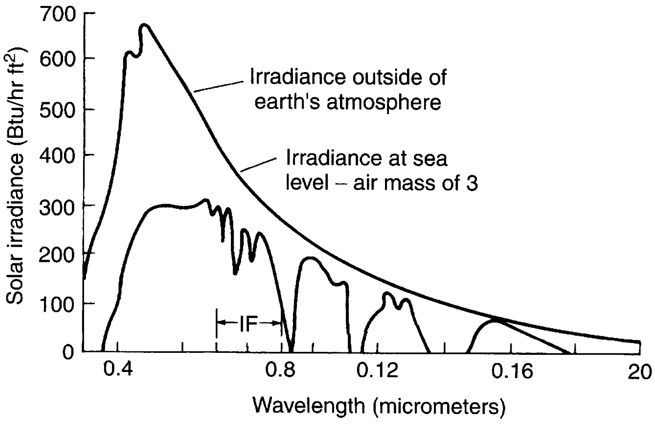

Fig. 9. Spectral distribution of solar energy

for blackbody sources at different temperatures is shown in previously mentioned Fig. 1. A blackbody radiation source with its temperature controller is shown in Fig. 10. The specifications of this unit include: temperature range, 100–1000°C; cavity diameter, 1 inch (25.4 mm); aperture diameter (in steps) from 0.0125 in (0.3175 mm) to 0.6 in (15.24 mm); emissivity, 0.99 ± .01; field of view, 20 degrees; internal thermocouple, platinum versus platinum-10% rhodium. Radiation sources are also available for use in the infrared region which have an emissivity somewhat less than one. The Nernst glower is a graybody source, which finds frequent use in spectrophotometers. The emissivity of a Nernst glower (Fig. 11) is a function of wave length, averaging approximately 0.6 from 2 to 15 micrometers. The glower element will not conduct electricity when cold, thus the unit must be heated to approximately 400°C before it will begin to conduct. The unit will operate at a temperature from 1500–1950 K with an expected life of several hundred hours.

INGOT. A casting designed for reduction by hot working to a semifinished product such as a billet or to a finished product such as a bar, plate, or sheet. Steel ingots are cast in massive cast-iron ingot molds, which extract the heat faster than a sand mold and facilitate both the casting and handling of the ingots. See also **Iron Metals, Alloys, and Steels**.

INHIBITOR. (1) A compound (usually organic) that retards or stops an undesired chemical reaction, such as corrosion, oxidation or polymerization. Examples are acetanilide, which retards decomposition of hydrogen peroxide and salicylic acid, used to prevent prevulcanization of rubber. Such substances are sometimes called negative catalysts. (2) A biological antagonist used to retard growth of pests and insects and in medicine.

INITIATORS (Anionic). In anionic polymerization, the reactive propagating intermediate generated by the initiation reaction is an anion, i.e., a species which carries a formal negative charge, with a corresponding positively charged counterion. In living anionic polymerization, the kinetic steps of chain termination and chain transfer are absent. This unique aspect of many anionic polymerizations provides a methodology for preparing polymers with control of the significant variables affecting polymer properties including molecular weight, molecular weight distribution, block copolymer composition, and microstructure, as well as molecular architecture (linear, branched, and cyclic macromolecules). An important consideration for preparation of polymers with well-defined structures and low degrees of compositional heterogeneity is the choice of a suitable initiator.

In general, an appropriate initiator is a species which has approximately the same structure and reactivity as the propagating anionic species, i.e., the pK_a of the conjugate acid of the propagating anion should correspond closely to the pK_a of the conjugate acid of the initiating species. If the initiator is too reactive, side reactions between the initiator and monomer can occur; if the initiator is not reactive enough, then the initiation reaction may be slow or inefficient.

The general relationship between monomer structural type, pK_a and appropriate initiating species is shown in Table 1. Those monomers which form the least stable anions, i.e., which have the largest values of pK_a for the corresponding conjugate acids, are the least reactive monomers and require the use of the most reactive initiators as shown in Table 1.

TABLE 1. RELATIONSHIPS BETWEEN MONOMER REACTIVITY, CARBANION pK_A STABILITY, AND SUITABLE INITIATORS

	pK_a [a]		
Monomer type	In DMSO[b]	In H_2O	Initiators[c]

[e] $Ar_2CO^{\cdot-}$.

Alkali Metals

The use of alkali metals for anionic polymerization of diene monomers is primarily of historical interest. The electron-transfer mechanism of the anionic polymerization of styrenes and 1,3-dienes initiated by alkali metals has been described in detail; the dimerization of radical anion intermediates is the important step.

Aromatic Radical Anions

Many aromatic hydrocarbons react with alkali metals in polar aprotic solvents to form stable solutions of the corresponding radical anions. These solutions can be analyzed by uv-visible spectroscopy and stored for further use.

Sodium naphthalene and other aromatic radical anions react with monomers such as styrene by reversible electron transfer to form the corresponding monomer radical anions which rapidly dimerize.

Monomers which can be polymerized with aromatic radical anions include styrenes, dienes, epoxides, and cyclosiloxanes. Aromatic radical anions which are too stable do not efficiently initiate polymerization of less reactive monomers; thus the anthracene radical anion cannot initiate styrene polymerization.

Alkyllithium Compounds

Anionic polymerization of vinyl monomers can be effected with a variety of organometallic compounds; alkyllithium compounds are the most useful class. A variety of simple alkyllithium compounds are available commercially. Most simple alkyllithium compounds are soluble in hydrocarbon solvents such as hexane and cyclohexane and they can be prepared by reaction of the corresponding alkyl chlorides with lithium metal.

Simple alkyllithium compounds are aggregated in solution, in the solid state, and even in the gas phase. The important differences between the various alkyllithium compounds are their degrees of aggregation in solution and their relative reactivity as initiators for anionic polymerization of styrene and diene monomers.

The kinetics of initiation reactions of alkyllithium compounds often exhibit fractional kinetic order dependence on the total concentration of initiator, consistent with initiation by the unassociated form of the alkyllithium.

The use of aliphatic solvents causes profound changes in the observed kinetic behavior for the alkyllithium initiation reactions with styrene, butadiene, and isoprene, i.e., the inverse correspondence between the reaction order dependence for alkyllithium and degree of organolithium aggregation is generally not observed. Also, initial rates of initiation in aliphatic solvents are several orders of magnitude less than those observed, under equivalent conditions, in aromatic solvents. Furthermore, pronounced induction periods are observed in aliphatic hydrocarbon solvents.

The relative reactivities of alkyllithiums as polymerization initiators are intimately linked to their degree of association. In the following the average degree of association in hydrocarbon solution, where known, is indicated in brackets after the alkyllithium. For styrene polymerization,

the relative reactivity of alkyllithium initiators is menthyllithium > *sec*-C_4H_9Li > *i*-C_3H_7Li > *i*-C_4H_9Li > *n*-C_4H_9Li > *t*-C_4H_9Li. For diene polymerization, menthyllithium > *sec*-C_4H_9Li > *i*-C_3H_7Li > *t*-C_4H_9Li > *i*-C_4H_9Li > *n*-C_4H_9Li.

Alkyllithium compounds are primarily used as initiators for polymerizations of styrenes and dienes.

Quantitative Analysis of Alkyllithium Initiator Solutions. The amount of carbon-bound lithium is calculated from the difference between the total amount of base determined by acid titration and the amount of base remaining after the solution reacts with either benzyl chloride, allyl chloride, or ethylene dibromide.

Copolymerization Initiators. The copolymerization of styrene and dienes in hydrocarbon solution with alkyllithium initiators produces a tapered block copolymer structure because of the large differences in monomer reactivity ratios for styrene ($r_s < 0.1$) and dienes ($r_d > 10$). In order to obtain random copolymers of styrene and dienes, it is necessary to either add small amounts of a Lewis base such as tetrahydrofuran or an alkali metal alkoxide (MtOR, where Mt = Na, K, Rb, or Cs).

Difunctional Initiators

These initiators are of considerable interest for the preparation of triblock copolymers, telechelic polymers, and macrocyclic polymers.

Aromatic radical anions, such as lithium naphthalene or sodium naphthalene, are efficient difunctional initiators. However, the necessity of using polar solvents for their formation and use limits their utility for diene polymerization.

The methodology for preparation of hydrocarbon-soluble, dilithium initiators is generally based on the reaction of an aromatic divinyl precursor with two moles of butyllithium.

Although a plethora of divinyl aromatic compounds have been investigated as precursors for hydrocarbon-soluble dilithium initiators, the only system which has been demonstrated to produce a hydrocarbon-soluble dilithium initiator is based on 1,3-bis (1-phenylethenyl)benzene.

Functionalized Initiators

The use of alkyllithium initiators which contain functional groups provides a versatile method for the preparation of end functionalized polymers and macromonomers. For a living anionic polymerization, each functionalized initiator molecule produces one macromolecule with the functional group from the initiator residue at one chain end and the active carbanionic propagating species at the other chain end.

Other Initiators

Other initiators include cumyl potassium, 1,1-diphenylmethylcarbanions, fluorenyl carbanions, enolate initiators, and alkoxide-type initiators.

Health and Safety Factors

Hydrocarbon solutions of alkyllithium compounds are air and moisture sensitive and should be either handled in an inert atmosphere or by using syringes using recommended procedures for handling air-sensitive compounds. Alkyllithium reagents react with acidic compounds that contain reactive hydrogens such as water, alcohols, phenols, acids, and even primary and secondary amines. The reaction of butyllithium with water produces butane and lithium hydroxide, which can lead to spontaneous ignition in the presence of oxygen. Contact of alkyllithium solutions with air does not generally lead to spontaneous ignition; however, if large surface areas are formed, for example in a spill, spontaneous ignition can occur. Carbon dioxide fire extinguishers must not be used because carbon dioxide reacts exothermically with alkyllithium compounds. It is prudent to have an all-purpose fire extinguisher available when working with these organometallic compounds. Suitable fire-extinguishing chemicals include powdered limestone and powders containing sodium chloride and sodium bicarbonate.

INITIATORS (Cationic). Cationic polymerization may be induced by a variety of physical (high energy radiation, direct or indirect uv radiation, electroinitiation) and chemical methods (protic acids, Friedel-Crafts acids, stable cation salts, cation donor in conjunction with a Friedel-Crafts acid). The most important initiating system is the cation donor (initiator)/Friedel-Crafts acid (coinitiator) system, which has found many applications. Butyl rubber, a copolymer of isobutylene and isoprene containing 0.5–2.5% isoprene to make vulcanization possible, is the most important commercial polymer made by cationic polymerization. Another important commercial application of cationic polymerization is the manufacture of polybutenes, low molecular weight copolymers of isobutylene, and a smaller amount of other butenes used in adhesives, sealants, lubricants, viscosity improvers, etc.

Unless one is working with superdried systems or in the presence of proton traps, adventitious water is always present as a proton source. Polymerization rates, monomer conversions, and to some extent polymer molecular weights are dependent on the amount of protic impurities; therefore, well-established drying methods should be followed to obtain reproducible results.

In place of a proton source, i.e., a Brønsted acid, a cation source such as an alkyl halide, ester, or ether can be used in conjunction with a Friedel-Crafts acid. Initiation with the ether-based initiating systems in most cases involves the halide derivative which arises upon fast halidation by the Friedel-Crafts acid, MX_n. The efficiency of the initiator/coinitiator system depends greatly on the monomer in question. As a general rule, the stability (reactivity) of the initiating cation should be close to that of the propagating chain end. Since initiation involves two subsequent events, i.e., ion generation and cationation, species on the two extremes are less active or may be completely inactive, because they form ionic species very slowly and/or in extremely low concentration, or would form ions in high concentration that are, however, too stable to cationate the monomer.

The activity of an initiating system is also affected by the nature of the Friedel-Crafts acid. The following Friedel-Crafts acidity scale can be established: $BF_3 < AlCl_3 < TiCl_4 < BCl_3 < SbF_5 < SbCl_5 < BBr_3$. The advantage of the $TiCl_4$ and the aluminum-based systems is their relative insensivity toward solvent polarity. The activity of the BCl_3- or BBr_3-based system is greatly solvent-dependent, i.e., sufficient activity only occurs in polar solvent.

Solvent polarity and temperature also influence the results. The dielectric constant and polarizability, however, are of little predictive value for the selection of solvents relative to polymerization rates and behavior. Evidently every system has to be examined independently. In cationic polymerization of vinyl monomers, chain transfer is the most significant chain-breaking process. The activation energy of chain transfer is higher than that of propagation; consequently, the molecular weight of the polymer increases with decreasing temperature.

Initiation by a carbocation source provides control of the head-group (controlled initiation) when used in conjunction with a Friedel-Crafts acid (e.g., $(C_2H_5)_3Al$, $(CH_3)_3Al$, $(C_2H_5)_2AlCl$, BCl_3 for isobutylene, or I_2 and zinc halides for vinyl ethers) where chain transfer to monomer is absent or negligible, or in the presence of a proton trap to abort chain transfer to monomer. That is, initiation from tertiary, allylic, and benzylic halides gives rise to macromolecules carrying tertiary, allylic, and benzylic head-groups. Initiation by halogens results in head-groups carrying the halogen. Controlled initiation, however, is achieved only when polymer formation from adventitious protic impurities is also absent or negligible.

A special case of controlled initiation is the inifer method. The word inifer (from *ini*tiator trans*fer* agents) describes compounds that function simultaneously as initiators and as chain transfer agents. The inifer technique provided the first carbocationic route toward the synthesis of telechelic (α, ω functional) polymers.

Although it was long believed that most Friedel-Crafts acids, particularly halides of boron, titanium, and tin, require an additional cation source to initiate polymerization, recent results show that in many systems Friedel-Crafts acids alone are able to initiate cationic polymerization.

The mechanism of initiation appears to be halometalation, as originally suggested by Sigwalt and Olah.

Many initiating systems used in the cationic polymerization of vinyl monomers can also be used to initiate ring-opening polymerization of cyclic monomers such as cyclic ethers, acetals, lactams, lactones, and siloxanes. Polymerization of cyclic monomers may involve different type of ionic as well as covalent growing species. Under certain conditions, termination processes may be absent. The polymerization of cyclic monomers, however, is almost always complicated by inter- and intramolecular chain transfer to polymer. The later results in cyclic oligomer formation. The extent of cyclic oligomer formation can be minimized in the polymerization of epoxides by the recently discovered activated monomer mechanism. Cyclic ether and acetal polymerizations are also important commercially. Polymerization of tetrahydrofuran is used to produce polyether diol, and polyoxymethylene, an excellent engineering plastic, is obtained by the ring-opening polymerization of trioxane with a small amount of cyclic ether or acetal comonomer to prevent depolymerization.

Recently a variety of initiating systems have been described that allow not only controlled initiation but also controlled propagation in the polymerization of vinyl monomers. In these living polymerization systems, chain braking (chain transfer and irreversible termination) is absent. The key to these living polymerizations is the high stability of the growing end, where the nucleophilic counteranion interacts strongly with the cationic active site. Living polymerizations have also been reported with initiating systems, forming nonnucleophilic counteranions in the presence of added Lewis bases (electron donors) and, in the presence of common ion salts, shifting the ionic dissociation equilibrium toward the nondissociated species. With these systems, rapid advances have been made toward the synthesis of well-defined materials with controlled architecture, molecular weight, molecular weight distributions and end-functionalities by cationic polymerization.

Since the discovery of living cationic systems, cationic polymerization has progressed to a new stage, where the synthesis of designed materials is now possible.

INITIATORS (Free-Radical). Free-radical initiators are chemical substances that, under certain conditions, initiate chemical reactions by producing free radicals. Initiators contain one or more labile bonds that cleave homolytically when sufficient energy is supplied to the molecule. The energy must be greater than the bond dissociation energy (BDE) of the labile bond. Radicals are reactive chemical species possessing a free (unbonded or unpaired) electron. Radicals may also be positively or negatively charged species carrying a free electron (ion radicals). Initiator-derived radicals are very reactive chemical intermediates and generally have short lifetimes, i.e., half-life times less than 10^{-3} seconds.

The principal commercial initiators used to generate radicals are peroxides and azo compounds. Lesser amounts of carbon–carbon initiators and photoinitiators, and high energy ionizing radiation are also employed commercially to generate radicals.

There are three general processes for supplying the energy necessary to generate radicals from initiators: thermal processes, microwave or ultraviolet (uv) radiation processes, and electron transfer (redox) processes. Radicals can also be produced in high energy radiation processes. Once formed, radicals undergo two basic types of reactions: propagation reactions and termination reactions.

Radicals are employed widely in the polymer industry, where their chain-propagating behavior transforms vinyl monomers into polymers and copolymers. The mechanism of addition polymerization involves all three types of reactions discussed above, i.e., initiation, propagation by addition to carbon–carbon double bonds, and termination.

Two other important commercial uses of initiators are polymer cross-linking and polymer degradation.

Structure–Reactivity Relationships. Much has been written about the structure–reactivity of radicals. No single unifying concept has satisfactorily explained all radical reactions reported in the literature. A longstanding correlation of structure and reactivity involves comparisons of the energies required to homolytically break covalent bonds to hydrogen. It is assumed that this energy, the hydrogen bond dissociation energy (BDE), reflects the stability and the reactivity of the radical coproduced with the hydrogen atom. However, this assumption should really be limited to radical reactivity and selectivity in hydrogen atom abstraction reactions, and can be particularly misleading for reactions with polar transition states, in which radicals can behave either as nucleophiles or electrophiles. Nevertheless, the correlation of radical reactivity with BDE is quite useful. Table 1 shows some general BDE values for the formation of various carbon and oxygen radicals from various precursors. According to the theory, the higher the BDE, the higher the reactivity and the lower the stability of the radical formed by removal of a hydrogen atom.

The choice of an initiator for a given radical process depends on the reaction conditions and reactivity of the initiator. These two factors must be balanced so that the desired reaction is achieved.

Activation Parameters. Thermal processes are commonly used to break labile initiator bonds in order to form radicals. The amount of thermal energy necessary varies with the environment, but absolute temperature, T, is usually the dominant factor. The energy barrier, the minimum amount of energy that must be supplied, is called activation energy, E_a. A third important factor, known as the frequency factor, A, is a measure of bond motion freedom (translational, rotational, and vibrational) in the activated complex or transition state. E_a and A are known as the activation parameters and, along with T, are related to the decomposition rate, k_d, by the equations:

$$k_d = Ae^{(-E_a/RT)} \text{ or } \ln k_d = \ln(A) - E_a/RT$$

Half-Life. Once these activation parameters have been determined for a initiator, half-life times at a given temperature, i.e., the time required for 50% decomposition at a selected temperature, and half-life temperatures for a given period, i.e., the temperature required for 50% decomposition of an initiator over a given time, can be calculated. Half-life data are useful for comparing the activity of one initiator with another when the half-life data are determined in the same solvent and at the same concentration and, preferably, when the initiators are of the same class.

Commercial initiators are primarily organic and inorganic peroxides, aliphatic azo compounds, certain organic compounds with labile carbon–carbon bonds, and photoinitiators.

Organic Peroxides

Organic peroxides are compounds possessing one or more oxygen–oxygen bonds. They have the general structure ROOR′ or ROOH, and decompose thermally by the initial cleavage of the oxygen–oxygen bond to produce two radicals:

$$\text{ROOR}' \rightarrow \text{RO}\cdot + \cdot\text{OR}'$$

Following radical generation, the radicals produced (RO· and R′O·) can initiate the desired reaction. However, when the radicals are generated in commercial applications, they are surrounded by a solvent, monomer, or polymer "cage." When the cage is solvent, the radical must diffuse out of this cage to react with the desired substrate. When the cage is monomer, the radical can react with the cage wall or diffuse out of the cage. When the cage is polymer, reaction with the polymer can occur in the cage. Unfortunately, other reactions can occur within the cage and can adversely affect efficiency of radical generation and radical reactivity. If the solvent reacts with the initiator radical, then solvent radicals may participate in the desired reaction.

TABLE 1. BOND DISSOCIATION ENERGIES

Precursor	BDE, kJ/mol[a]
$(R)_3C-H$	381
$(R)_2CH-H$	406
RCH_2-H	418
CH_3-H	439
RO–H	439
RCOO–H	444
C_6H_5-H	469
HO–H	498

TABLE 2. COMMERCIAL ORGANIC PEROXIDE CLASSES

Organic peroxide class	Structure[a]	10-h $t_{1/2}$[b], [c], °C
diacyl peroxides		21–75
dialkyl peroxydicarbonates		49–51[d]
tert-alkyl peroxyesters		38–107
OO-tert-alkyl *O*-alkyl monoperoxycarbonates		99–100
di(*tert*-alkylperoxy)ketals		92–110
di-*tert*-alkyl peroxides	*t*-R–OO–*t*-R	115–128
tert-alkyl hydroperoxides	*t*-R–OO–H	e
ketone peroxides	 + other structures	e

[a] $x = 0$ or 1.
[b] Temperature at which $t_{1/2} = 10$ h.
[c] In benzene, unless otherwise noted.
[d] In trichloroethylene (TCE).
[e] Not applicable.

TABLE 3. COMMERCIAL AZO INITIATORS

Name	Structure
2,2′-azobis[4-methoxy-2,4-dimethyl]-pentanenitrile	2,2′-azobis [2,4-dimethyl]-pentanenitrile	2,2′-azobis [isobutyronitrile]	2,2′-azobis[2 methylbutyronitrile]	1,1′-azobis[cyclohexane-carbonitrile]	4,4′-azobis[4-cyanovaleric acid]	dimethyl-2,2′-azobis-[2-methylpropionate]	azobis[2-acetoxy-2-propane]	2,2′-azobis[2-amidinopropane]dihydro-chloride	
Two secondary propagating reactions often accompany the initial peroxide decomposition: radical-induced decompositions and β-scission reactions. Both reactions affect the reactivity and efficiency of the initiation process.

Approximately 100 different organic peroxide initiators, in well over 300 formulations, are commercially produced throughout the world, primarily for the polymer and resin industries.

The eight classes of organic peroxides that are produced commercially for use as initiators are listed in Table 2. Included are the 10-h half-life temperature (i.e., the temperature at which 50% of the peroxide decomposes in 10 h) ranges for the members of each peroxide class.

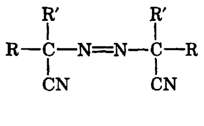
Inorganic Peroxides

Inorganic peroxide–redox systems have been employed for initiating emulsion homo- and copolymerizations of vinyl monomers. These systems include hydrogen peroxide–ferrous sulfate, hydrogen peroxide–dodecyl mercaptan, potassium peroxydisulfate–sodium bisulfate, and potassium peroxydisulfate–dodecylmercaptan. Potassium peroxydisulfate, KSO (or the corresponding sodium or ammonium salt), is an inorganic peroxide that is used widely in emulsion polymerization (e.g., latexes, rubbers, etc), usually in combination with a reducing agent.

When handling and using peroxide initiators, care should be exercised because they are thermally sensitive and decompose (sometimes violently) when exposed to excessive temperatures, especially where they are in their pure or highly concentrated states. However, they are useful as initiators because of their thermal instability. What may be a safe temperature for one peroxide can be an unsafe temperature for another, since peroxide initiators encompass a wide activity range. Because some peroxides are shock- or friction-sensitive in the pure state, they are generally desensitized by formulating them into solutions, pastes, or powders with inert diluents. All manufacturers' literature should be carefully scrutinized and the peroxide safety literature should be reviewed before handling and using specific peroxide initiator compositions.

Azo Compounds

Generally, the commercially available azo initiators are of the symmetrical azonitrile type:



The symmetrical azonitriles are solids with limited solubilities in common solvents. Some commercial aliphatic azo compounds and their 10-h half-life temperatures are listed in Table 3.

Care should be exercised in handling and using azo initiators in their pure and highly concentrated states, because they are thermally sensitive and can decompose rapidly when overheated. Although azonitriles are generally less sensitive to contaminants, the same cautions that apply to peroxides also should be applied to handling and using azo initiators. The manufacturers' safety literature should be read carefully. The potential toxicity hazards of decomposition products must be considered when using azonitriles.

See also **Azo and Diazo Compounds**.

Carbon–Carbon Initiators

Carbon–carbon initiators are hexasubstituted ethanes that undergo carbon–carbon bond scission when heated to produce radicals. The thermal stabilities of the hexasubstituted ethanes decrease rapidly as the sizes of the alkyl groups increase. The 10-h half-life temperature range of this class of initiators is very broad, extending from about 100°C to well above 600°C. An extensive compilation of half-life data on carbon–carbon initiators has been published. The commercially available carbon–carbon initiators are tetrasubstituted 1,2-diphenylethanes which undergo homolyses to generate low energy, *tert*-aralkyl radical pairs. Three carbon–carbon initiators are currently available commercially, 2,3-dimethyl-2,3-diphenylbutane (**1**), 3,4-dimethyl-3,4-diphenylhexane (**2**), and 1,1,2,2-tetraphenyl-1,2-bis(trimethylsiloxy)-ethane (**3**).

Other Radical Generating Systems

There are many chemical methods for generating radicals reported in the literature that do not involve conventional initiators. Most of these radical-generating systems cannot broadly compete with the use of conventional initiators in industrial polymer applications owing to cost or efficiency considerations. However, some systems may be well-suited for initiating specific radical reactions or polymerizations, e.g., grafting of monomers to cellulose using ceric ion.

Initiation Through Radiation and Photoinitiators

High energy ionizing radiation sources (e.g., x-rays, γ-rays, α-particles, β-particles, fast neutrons, and accelator-generated electrons) can generate radical sites on organic substrates. If the substrate is a vinyl monomer, radical polymerization can occur. If the substrate consists of a polymer and a vinyl monomer, then polymer cross-linking, degradation, grafting of the monomer to the polymer, and homopolymerization of the monomer can all occur. Radical polymerizations of vinyl monomers with ionized plasma gases have been reviewed.

Initiation of radical reactions with uv radiation is widely used in industrial processes. In contrast to high energy radiation processes where the energy of the radiation alone is sufficient to initiate reactions, initiation by uv irradiation usually requires the presence of a photoinitiator, i.e., a chemical compound or compounds that generate initiating radicals when subjected to uv radiation. There are two types of photoinitiator systems: those that produce initiator radicals by intermolecular hydrogen abstraction [benzophenone, 4-phenylbenzophenone, xanthone, thioxanthone, 2-chlorothioxanthone, 4, 4′-bis(*N*, *N*′-dimethylamino)benzophenone (Michler's ketone), benzil, 9,10-phenanthraquinone, and 9,10-anthraquinone] and those that produce initiator radicals by photocleavage [α,α-dimethyl-α-hydroxyacetophenone, (1-hydroxycyclohexyl)-phenylmethanone, benzoin ethers (methyl, ethyl, isobutyl), α,α-dimethoxy-α-phenylacetophenone, α,α-diethoxyacetophenone, 1-phenyl-1,2-propanedione, 2-(*O*-benzoyl)-oxime, diphenyl(2,4,6-trimethylbenzoyl)phosphine oxide, and α-dimethylamino-α-ethyl-α-benzyl-3,5-dimethyl-4-morpholinoacetophenone].

Economic Aspects

The principal worldwide producers of organic peroxide initiators (and their trade names) include Elf Athochem (Luperco, Luperox, Lupersol, Lucidol (U.S.), Luchem, Alperox, Decanox, Peroximon, and Retilox), Akzo-Nobel (Trigonox, Perkadox, Cadox, Cadet, Laurox, Liladox, Kenodox, Lucidol (Europe), Butanox, and Cyclonox), Aztec (Aztec), Peroxid-Chemie (Interox), Witco (Esperox, Esperal, USP, Quickset, and Hi Point), Nippon Oil & Fats Company (Nyper, Perbutyl, Percumyl, Perhexa, Permek, and Peroyl), Norac (Superox), Hercules (DiCup, VulCup), and Sanken Kako (Sanperox). The principal worldwide producers of organic azo initiators are DuPont (Vazo), Elf Atochem (Ficel), and Wako. The worldwide market for organic azo initiators is small, being only about 10% of the market for organic peroxide initiators. Ciba Geigy is a significant supplier of photoinitiators (Darocur, Irgacure). The market for these initiators has been reviewed. Because most of the consumption of organic peroxides and azo initiators is in the developed countries, market growth in the 1990s is expected to be modest, i.e., 2–3% annually.

INORGANIC CHEMISTRY. A major branch of chemistry that is generally considered to embrace all substances except hydrocarbons and their derivatives, or substances that are not compounds of carbon, with the exception of carbon oxides and carbon disulfide. The chemical compounds, which are based upon chains or rings of carbon atoms, which are termed organic compounds, are studied under the separate heading of organic chemistry. See also **Organic Chemistry**.

Inorganic chemistry covers a broad range of subjects, among which are atomic structure, crystallography, chemical bonding, coordination compounds, acid-base reactions, ceramics, and the various subdivisions of electrochemistry (electrolysis, battery science, corrosion, semiconduction, etc.). See also **Acids and Bases**; **Ceramics**; **Chemical Composition**; **Chemical Elements**; **Compound (Chemical)**; **Coordination Compounds**; **Corrosion**; and **Semiconductors**. It is important to state inorganic and organic chemistry often overlap, most importantly in the sub-discipline of organometallic chemistry. For example, chemical bonding applies to both disciplines; electrochemistry and acid-base reaction have their organic counterparts; catalysts and coordination compounds may be either organic or inorganic.

Inorganic chemistry is based upon physical chemistry and forms the basis for mineralogy and materials chemistry. It often overlaps with geochemistry, analytical chemistry, environmental chemistry and organometallic chemistry. See also **Mineralogy**; and **Physical Chemistry**.

The range of inorganic chemistry includes both molecular compounds, which exist as discrete molecules, and crystals, whose structures are described by infinite lattices of regularly-ordered atoms and which are studied by crystallography and solid-state chemistry. See also **Solid-State Chemistry**.

Regarding the importance of inorganic chemistry, R. T. Sanderson has written: "*All* chemistry is the science of atoms, involving an understanding of why they possess certain characteristic qualities and why these qualities dictate the behavior of atoms when they come together. All properties of material substances are the inevitable result of the kind of atoms and the manner in which they are attached and assembled. All chemical change involves a rearrangement of atoms. Inorganic chemistry [is] the only discipline within chemistry that ... examines specifically the differences among all the different kinds of atoms."

Major branches of inorganic chemistry include:

- Minerals, such as salt, asbestos, silicates, ...
- Metals and their alloys, like iron, copper, aluminum, brass, bronze, ...
- Compounds involving non-metallic elements, like silicon, phosphorus, chlorine, oxygen, for example water
- Metal complexes

Commercially important inorganic substances include silicon chips, transistors, LCD screens, fiber optical cables and many catalysts.

Organometallic chemistry combines aspects of organic chemistry with those of inorganic chemistry, and is formally defined as the study of compounds containing metal-carbon bonds, although many "organometallic compounds" contain no such bonds. See also **Organometallic Compounds**. Among the simplest organometallic compounds are the metal carbonyls, in which carbon monoxide binds to a metal through the carbon. Vitamin B12, whose active site is similar to that of hemoglobin, is a naturally-occurring, metabolically-important organometallic compound containing large organic components (corrin and protein) and a metal, cobalt, bonded to carbon.

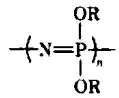
INORGANIC HIGH-POLYMERS. The most commercially successful inorganic polymers to date are the polysiloxanes, owing to their unique high temperature stability, low temperature flexibility, and a number of other advantageous properties such as low surface energy and room-temperature vulcanizability.

Because of increasing technological needs in the area of high performance materials there has been a growing interest in the synthesis and development of new inorganic polymers. The polyphosphazenes and the polysilanes have shown the most promise in this area during the last two decades. In addition to these two, other novel inorganic polymer systems have also recently been developed.

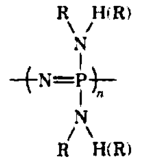
Polyphosphazenes

The polyphosphazenes, sometimes also referred to as polyphosphonitriles, are the most chemically versatile inorganic polymers known to date. Based on their method of synthesis, two different types of phosphazene polymers are now in existence and are undergoing parallel development. The first type, bearing substituents on phosphorus bonded mostly via phosphorus-oxygen and phosphorus–nitrogen linkages, was developed in the mid-1960s as soluble, hydrolytically stable polymers. Polymers of the second type, with substituents linked via direct phosphorus–carbon bonds were first reported in the early 1980s and since then they have also seen significant development.

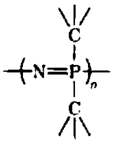
Synthesis. The synthesis of poly(dichlorophosphazene), the parent polymer to over 300 macromolecules of types (**1**) and (**2**), is carried out via controlled, ring-opening polymerization of the corresponding cyclic trimer, $(N = PCl_2)_3$.



(**1**)



(**2**)



(**3**)

Properties. One of the characteristic properties of the polyphosphazene backbone is high chain flexibility which allows mobility of the chains even at quite low temperatures.

The thermal stability of polymers of types (**1**) and (**2**) is dependent on the nature of the substituents on phosphorous. Polymers with methoxy and ethoxy substituents undergo skeletal changes and degradation above about 100°C, but arloxy and fluoroalkoxy substituents provide higher thermal stability. Most of the P–N- and P–O-substituted polymers either depolymerize via ring-chain equilibration or undergo cross-linking reactions at temperatures much above 150–175°C.

Phosphazene polymers are inherently good electrical insulators unless side-group structures allow ionic conduction in the presence of salts. Polyphosphazenes also exhibit excellent visible and uv-radiation transparency when chromophoric substituents are absent.

Another valuable characteristic of many phosphazene polymers is their flame-retardant behavior and low smoke generation on combustion.

A remarkable feature of phosphazene polymers of types (**1**) and (**2**) is that appropriate substituents (which are readily attached) can be used as toggle switches to turn several properties, such as hydrolytic stability and electrical conductivity, on and off.

Applications. The P–O- and P–N-substituted polymers have so far shown the greatest commercial promise. The fluoroelastomers possess good rubber properties with the added advantages of being nonburning, hydrophobic, and solvent- and fuel-resistant. In addition to these, because of flexibility down to about −60°C, these polymers have been used in seals, gaskets, and hoses in army tanks, in aviation fuel lines and tanks, as well as in cold-climate oil pipeline applications. These polymers have also found application in various types of shock mounts for vibration dampening.

The aryloxyphosphazene polymers, on the other hand, have been used primarily in wire and cable coatings and jackets and as fire-resistant, low smoke, closed-cell foams and sound-barrier sheets.

Biomedical Applications. In the area of biomedical polymers and materials, two types of applications have been envisioned and explored. The first is the use of polyphosphazenes as bioinert materials for implantation in the body either as housing for medical devices or as structural materials for heart valves, artificial blood vessels, and catheters.

The second type of biomedical application utilizes the versatile chemistry of polyphosphazenes to generate bioactive polymers. Two approaches have been developed: one is to tie or physically entrap biologically active molecules using the phosphazene backbone as the carrier or encapsulant. The other is to attach bioactive molecules to a hydrolyzable (degradable) phosphazene backbone that releases the active species on breakdown of the backbone to harmless species that can be metabolized or directly excreted.

Two crucial aspects of the design of bioactive polyphosphazenes have been carefully developed. One involves the hydrophilicity or hydrophobicity of the polymer, and the other is the stability of the polymer or tactical substituent linkages that allow release of the active agent or ensure its potency to be retained in the bound form.

Polymers Bearing Metal Complexes. A large number of polymers with side groups containing metal complexes have been reported. The complexes are linked to the phosphazene backbone primarily through a ligand on a substituent, although linkages through the skeletal nitrogen or through direct metal-phosphorus bonding with the skeletal phosphorus atoms have also been utilized.

Solid Electrolyte Applications. Among other potentially useful polymers synthesized by the versatile macromolecular substitution process are polymers based on oligoether substituents or heterocyclic substituents that have been under intense investigation for solid electrolyte battery applications. The most promising of these is poly [bis(methoxyethoxyethoxy)phosphazene (MEEP).

Polymers with Alkyl and Aryl Substituents on P

Even though partially alkyl- and aryl-substituted polyphosphazenes are accessible via the ring-opening polymerization followed by the macromolecular substitution route, polymers in which all substituents are attached through direct phosphorus–carbon bonds are not yet accessible by this method.

Synthesis. The first fully alkyl/aryl-substituted polymers were reported in 1980 via a condensation–polymerization route. In addition to providing fully alkyl/aryl-substituted polyphosphazenes, the versatility of the process has allowed the preparation of various functionalized polymers and copolymers.

Properties. The condensation–polymerization reaction yields alkyl- and aryl-substituted polymers with average molecular weights in the range 40,000 to 250,000 (M_n ranges from 20,000 to 100,000). In general, the polymers are soluble in chlorinated solvents such as CH_2Cl_2 and $CHCl_3$. Polymers with phenyl substituents are also soluble in tetrahydrofuran.

The P–N backbone remains quite flexible with small, unbranched alkyl substituents on phosphorus.

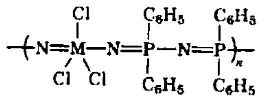
Alkyl- and aryl-substituted polyphosphazenes exhibit onset of decomposition at between 350 and 400°C.

Applications. Polymers with small alkyl substituents are ideal candidates for elastomer formulation because of quite low temperature flexibility, hydrolytic and chemical stability, and high temperature stability. In light of the biocompatibility of polysiloxanes and P–O- and P–N-substituted polyphosphazenes, poly(alkyl/arylphosphazenes) are also likely to be biocompatible polymers. A third potential application is in the area of solid-state batteries.

Phosphazenes Containing Skeletal Carbon, Sulfur, and Metal Atoms

The first phosphazene polymers containing carbon, sulfur, and even metal atoms in the backbone have been reported. These were all prepared by the ring-opening polymerization of partially or fully chloro-substituted (or fluoro-substituted) trimers containing one hetero atom substituting for a ring-phosphorous atom in a cyclotriphosphazene-type ring.

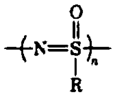
An example of polyphosphazene incorporating metal atoms is (**4**), where M = M_0 or W.



(**4**)

Poly(alkyl/aryloxothiazenes)

The synthesis of a new class of inorganic polymers (**5**) with a backbone consisting of alternating sulfur(VI) and nitrogen atoms, and with variable aklyl or aryl substituents as well as a fixed oxygen substituent on sulfur, has recently been accomplished. These polymers are structurally analogous to poly(alkyl/arylphosphazenes).

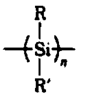


(**5**)

Synthesis and Properties. The synthesis of (**5**) follows a straightforward route based on readily accessible starting materials and on some novel reactions in organo-inorganic sulfur chemistry, as well as on polycondensation chemistry analogous to that utilized in the preparation of poly(alkyl/arylphosphazenes). The polymers exhibit some interesting characteristics that appear to be related to their unusual repeat unit.

Polysilanes

The polysilanes (**6**) are a unique class of polymers that exhibit σ-conjugation along the backbone.



(**6**)

Synthesis of Polysilanes. The most commonly utilized method is based on the Wurtz-type alkali metal coupling of dichlorosilanes. Other synthesis methods include dehydrogenative coupling, ring-opening polymerization, polymerization of masked disilenes, electrochemical synthesis, and polymer modification.

Properties. Most unsymmetrically substituted dialkyl and alkyl/aryl homopolymers as well as copolymers are soluble in solvents such as tetrahydrofuran or toluene. The longer Si–Si bond length, compared with the C–C bond length, allows quite a bit of flexibility in the backbone such that glass-transition temperatures as low as $-76°C$ (for poly(*n*-hexylmethylsilane)), have been observed. On the other hand, as expected, aryl substitution brings about significant increases in T_g. Thus, polysilanes cover the range from rubbery elastomers to brittle solids. Polysilanes are chemically inert to air and water at ordinary temperature, but their reactivity increases in solvent.

Electronic Properties. What distinguishes polysilanes from virtually all other polymers is their backbone σ- conjugation. This lead to strong electronic absorption in the near-uv from a $\sigma - \sigma$ transition.

The polysilanes are normally electrical insulators, but on doping with AsF_5 or SbF_5 they exhibit electrical conductivity up to the levels of good semiconductors.

Polysilanes absorb electromagnetic energy and undergo chain scission. This is an extremely important property of these polymers in terms of applications. Photochemistry is exhibited both in solution and in the solid state.

Applications. Polysilanes are used in the manufacture of β-silicon carbide, microlithography, xerography, and photoinitiation.

Polygermanes

Soluble and well-characterized polygermane homopolymers, $(R_2Ge)_n$, and their copolymers with polysilanes have been prepared by the alkali metal coupling of diorgano-substituted dihalogermanes, via electrochemical methods, and by transition-metal catalyzed routes, as with the synthesis of polysilanes.

The polygermanes exhibit many of the same electronic properties as polysilanes, including near-uv photoabsorption, thermochromism, photobleaching, as well as nonlinear optical activity, and have seen a fair amount of theoretical and experimental investigation. However, despite similarities with polysilanes, polygermanes appear to be unlikely candidates for commercial exploitation.

INOSITOL. A constituent of body tissue. In purified form it is used as a nutrient and dietary supplement in some foods and feed-stuffs. The chemical name of inositol is hexahydroxycyclohexane, CAS: 87-89-8, $C_6H_6(OH)_6 \cdot 2H_2O$. There are nine isomeric forms of inositol. Myoinositol or meso-inositol (*cis*-1,2,3,5-*trans*-4,6-hexahydroxycyclohexane) is the isomer that possesses essential nutrient activity. The substance, often identified as a vitamin, is found in small amounts in many vegetables, citrus fruits, cereal grains, liver, kidney, heart and other meat. The commercial source is corn (maize) steep liquor. In addition to its use in nutrition, it finds use in medicine and as an intermediate for organic syntheses.

INSECTICIDE. A substance that kills or interferes in the life cycle of certain insects and is thus useful for reducing and controlling insect populations. The reduction or elimination of such populations is desirable for several reasons. (1) Preventing the spread of certain diseases by insects that serve as transmitters or carriers of infective organisms. Thus, insecticides are used widely as a public health measure. (2) Preventing or reducing the damage caused by insects eating and inhabiting food plants, trees, and other crops. Such damage, without control, sometimes approaches 100% and averages 25% or more in some regions of the world. (3) Preventing or reducing physical property damage, notably of wood, cloth, and other materials of an organic nature that attracts certain insects as a source of food and place of habitation. Termites and moths are examples. (4) Reducing or eliminating discomfort, annoyance, and sometimes injury that results from the immediate presence of insects on or near people and domestic and farm animals. Ticks and face flies are examples.

Classification of Insecticides

Insecticides may be classified and characterized in many ways. (1) By their *selectivity*, i.e., their ability to control or not to control different forms, varieties, and species of insect, they range from compounds which have a rather *narrow control spectrum* and thus enable the user to eradicate or reduce selected target insects, all the way to *wide spectrum* insecticides that will destroy practically all insects, including those of a beneficial nature that are of positive economic importance. (2) By the manner in which insecticides *interact* with the insect enemy or target. That is: (a) whether or not a chemical requires overwhelming contact with the insect, or where the chemical acts systemically within and throughout the insect once local contact is made; (b) how the chemical interferes with the life process of the insect; for example, is it a stomach poison, or does it interfere with the insect's nervous or respiratory system, etc.; (c) how the insecticide enters the body of the insect, i.e., via the alimentary or respiratory system, etc.; and (d) whether or not the primary function of the chemical is to kill the insect, or essentially to sterilize the insect sexually and thus reduce insect population in this manner. (3) By application—is the insecticide a solid, liquid, or gas? Can it be sprayed, dusted, or incorporated into bait? Can it be worked into the soil? It is miscible with oil, water, or both? Can it be applied by aircraft? (4) By the useful life or persistence of the chemical, i.e., a few days, weeks, or months. (5) In terms of safety to humans and livestock and pets. Insecticide dangers range from highly toxic, to moderate, light, and low toxicity. Quite important, is the insecticide harmful to bees, fishes, other wildlife, or to adjacent crops and orchards should a spray or dust of the material drift away in the wind from the immediate point of application? (6) By the chemical structure of the insecticide, i.e., chlorinated hydrocarbon, organic phosphate, etc., and how produced—extracted from natural bacterial and biological materials or synthesized from basic raw materials and chemical intermediates. (7) By cost, a very important and practical consideration for large food producers, health authorities, and other users.

Selectivity and Spectral Range of Insecticides. There is no practical universal insecticide because such a chemical, to successfully eradicate all forms of insect life, would be dangerous to other life forms. There are,

however, multipurpose pesticides, such as hydrogen cyanide gas, which are used *most carefully and with the ultimate of safety provisions* to kill not only all insects within a given area or space, but all other animal life forms as well. Some insects are much easier to destroy than others. Thus, numerous compounds are available to control aphid, fly, leafhopper, and trip, whereas only a few chemicals are effective against fire ant and certain beetle and weevil species.

Action of Insecticides. The average user of insecticides is essentially interested in the results of insecticide application rather than the exact manner in which these chemicals act upon the life and life cycle of the insect. But, there are some important distinctions that govern both the timing and selection of a given insecticide. For example, some chemicals are much more effective in destroying larvae or nymphs than when applied to insects in the adult stage, or vice versa. Also, some perennial crop plants and orchards are undamaged by certain chemicals (dormant sprays, for example) during winter inactivity, whereas the same chemicals would cause severe damage if applied during springtime budding. Also, the food producer, by taking advantage of multifunction compounds, can reduce the number of control chemicals required and hence the number of applications.

Control chemical manufacturers frequently offer combined formulations. In addition to blending acaricides with insecticides, molluskicides, etc., it is not uncommon to blend in herbicidal compounds. Usually, however, as the blending becomes more complex, the selection becomes more difficult, because great care must be taken to ensure the following: (1) That the chemicals will mix well without destroying any of their intended effectiveness (many control chemicals are weakened or destroyed, for example, if mixed with strongly alkaline materials, such as lime, or with sulfur-bearing compounds). (2) That the mixture is truly customized to the crop at hand, and that the combination is not used on other crops without specifically checking. And (3) that there will be no unexpected environmental damage. A combination of chemicals may be entirely effective and safe when applied to a specific crop or area, whereas it may be inappropriate if used on other crops and other areas that may be adjacent to pastures and streams or lakes and thus be dangerously polluting. For crops of large economic value and commonly grown, manufacturers offer numerous crop-specific formulations.

Nomenclature of Insecticides. It is estimated that there are well over 100,000 pesticide formulations and perhaps half of these would be basically classified as insecticides. Although the basic chemicals used may number in the hundreds, variations arise from the many thousands of possible formulations, not only combinations of materials, but formats (sprays, wettable powders, emulsifiable concentrates, dusts, baits, etc.). Added to this are the scores of control chemical manufacturers worldwide. Each manufacturer markets products under trade names—names that are essentially coined for their marketing charisma and infrequently connoting the content or purpose of the product. Thus, there are scores of equivalent (or essentially equivalent) products, adding to the difficulty of selecting these chemicals. Unfortunately, the generic chemical names of the majority of insecticide chemicals are long and complex and essentially meaningless to persons who are not well versed in organic and biochemistry. There are also a number of frequently revised directories of control chemicals and considerable information is available from various government agencies and universities. See list of references at end of this entry. This situation of nomenclature is quite similar to that which applies to generic and trade name drugs and pharmaceuticals.

Toxicity of Insecticides. Even though insecticides and other pesticides vary greatly in toxicity, all may be considered hazardous if they are not handled properly and with precautions. The following elementary rules are always worthy of repetition. (1) Observe all directions, restrictions, and precautions on pesticide labels. It is dangerous, wasteful, and, in some regions and countries, illegal to do otherwise. (2) Store all pesticides behind locked doors in original containers with labels intact. (3) Use pesticides at correct dosage and intervals to avoid excessive residues and injury to plants and animals. (4) Apply pesticides carefully to avoid drifting of the compounds to nearby fields, lakes, and streams. (5) Bury surplus pesticides and destroy used containers so that contamination of water and other hazards will not result. (6) Certain pesticides must not be used during a specified period just prior to harvest because of the danger to workers and pickers who will be handling the product and because of the danger of inadequately washing away or otherwise removing residues prior to releasing the commodity to the consumer. (7) Do not mix two or more compounds without prior knowledge of their compatibility. (8) When in doubt concerning the applicability of a given compound to a given situation, such as a specific crop, seek advice from local sources of expertise, such as extension service representatives, reliable suppliers, neighboring users who have faced similar problems, regional colleges and universities, and agricultural experiment stations. Above all, the final responsibility for safe usage rests with the person who ultimately applied the chemicals.

In the United States, when registering insecticides, pesticides, and other control chemicals, regulatory agencies have been using acute LD_{50} values to determine the toxicity category and the words or symbols that must be placed on labels and containers. For this purpose, the test animals usually are rats, mice, or rabbits, but other mammals are sometimes used. The LD_{50} value is the dosage of the chemical at which 50% of the test animals are killed. It is based on the body weight of the animal and is expressed in milligrams of the chemical per kilogram of animal (mg/kg). One mg/kg = 1 part per million (ppm). Thus, the lower the LD_{50} value, the higher the toxicity of the chemical. The usual way of administering chemicals to test animals is by mouth, application to the skin, and in some cases, by inhalation. Toxicity may be either acute or chronic. Acute refers to rather quick action from a single exposure, whereas chronic refers to the toxic effect of many exposures over a period of time.

Chemistry of Insecticides

In classifying compounds used as insecticides, from the standpoint of chemical characteristics and structure, the most fundamental division separates the inorganic from the organic chemicals. The latter are by far the most widely used. Acaricides, bactericides, fungicides, and nematicides, along with insecticides, are included in the following descriptions.

Inorganic Compounds. These control chemicals are comparatively simple compounds and include calcium and lead arsenates, elementary sulfur and inorganic sulfur compounds, such as calcium polysulfide (lime-sulfur) and sodium thiosulfate. Because of their effectiveness against certain fungus infections, these compounds are more frequently considered as fungicides than as insecticides. This is also true of a number of copper, zinc, and other metal inorganics, such as copper carbonate, copper oxychloride, copper sulfate, and copper-zinc sulfate. It should be pointed out that Paris Green (cupric acetoarsenite), one of the older and once widely used inorganic insecticides, essentially has been phased out in most regions of the world because of the effects of chronic arsenic poisoning of workers and users who come in contact with the substance. This was particularly true in the case of vineyard workers a number of years ago.

A number of other metals, such as iron and tin, enter into insecticide and pesticide compounds, but as part of an organic chemical structure, as exemplified by triphenyltin hydroxide. Such compounds are sometimes referred to as organometallics (or, specifically in the case of tin, as organotins). Mercury compounds are rapidly being phased out because of their long-term toxic residual effects as pollutants, particularly of fresh and saline waters. Regulations vary from one country to another.

A few other inorganic chemicals, more frequently identified as multi-purpose pesticides than as insecticides, do have very strong insecticidal properties. These compounds are used sparingly, often requiring special permits in some places, and with the greatest of safety cautions observed. Such compounds would include calcium cyanide, carbon bisulfide, carbon tetrachloride, hydrogen cyanide, paraformaldehyde, and phosphine.

Organic Compounds. A listing of categories of organic chemicals used reads like the table of contents of an organic chemistry text, with relatively few subfamilies of organic compounds not represented in one way or other.

Alcohols. The open straight or branched chain (alkyl, aliphatic) saturated alcohols, such as methanol, ethanol, up through tetradecanol, etc., are not powerful insecticides, although they are somewhat more effective than the related hydrocarbons (methane, ethane, etc.). As is evidenced in other areas of activity, these alcohols increase in insecticidal effectiveness roughly in proportion to their molecular weight (number of carbon atoms in compound). This is an effect, however, which levels off when from 9 to 12 carbons (molecular weight of 144 to 186) are present in the chain. For example, although not a direct measure of insecticidal activity, nonyl (9 carbons) and decyl (10 carbons) alcohols are most effective in reducing the sprouting of stored potatoes. Beyond this point, a greater number of carbon atoms does not increase the effectiveness.

Unsaturated and Cyclic Alcohols. Although these compounds show somewhat stronger insecticidal effectiveness, as compared with the saturated aliphatic alcohols, this added strength is still not sufficient

to warrant their serious considerations as insecticides. Some of these compounds, however, do make effective herbicides.

Aldehydes. The aldehydes possess greater insecticidal effectiveness than the alcohols, formaldehyde, for example, serving as a stomach poison. The compound also exhibits strong bactericidal and fungicidal activity. Formaldehyde tends to polymerize into paraformaldehyde, the pesticidal properties of which are considerably less than those of formaldehyde. The same increasing effectiveness with increasing molecular weight exhibited by the alcohols also applies to the aldehydes.

Metaldehyde, the polymer of acetaldehyde, is a widely used molluskicide and is effective in the control of snails. Some of the unsaturated aldehydes are more potent in their pesticidal and herbicidal effectiveness. However, only a few compounds are of commercial significance, notably acrolein and related compounds, which are used as aquatic herbicides in connection with water reservoirs and systems. Some aldehydes also have growth-regulating properties. See also **Plant Growth Modification and Regulation**.

Amines. This class of organic compounds also exhibits the same relationship between molecular weight and insecticidal activity as previously described. In the case of aliphatic amines, studies of toxic potency against house fly larvae have shown that the most effective compound is di-*n*-octylamine, with the compounds of higher or lower molecular weight in the series proving less toxic. Effectiveness also improves as one proceeds from the aliphatic amines to the aromatic amines, noting, for example, the greater toxicity of aniline as compared with hexylamine. Although *o*-iodoaniline and 2,5-dichloroaniline demonstrate some toxicity for caterpillar and louse, respectively, generally and perhaps surprisingly, inclusion of halogen atoms within the aromatic amine nucleus does not promote greater toxicity. Some toxicity increase is shown, however, when nitro groups are introduced into the nucleus. Diphenylamine, a diarylamine, is effective against lice and at one time enjoyed wide use for troops during wartime.

The insecticidal usefulness of the amines is hindered by their tendency to severely injure plants (phytotoxic effects) to which they may be applied. Advantage of this property, however, is taken by using some amine compounds as herbicides. Examples include benefin, nitralin, and trifluralin.

Carbonic Acid Derivatives. Mixed esters of carbonic acid display toxic potency as acaricides and fungicides, including their inhibiting action against powdery mildew. When sulfur is introduced into the structure, as in the case of the mixed esters of thio- and dithiocarbonic acids, the acaricidal and fungicidal toxicity is further increased. Derivatives of thio- and dithiocarbonic acids used commercially include carbon bisulfide (CS_2) and 6-methylquinoxaline-2,3-dithiocyclocarbonate (*Morestan*), an effective acaricide, fungicide, and insecticide.

Carbamic Acid Derivatives. A rather large number of commercially available food crop control chemicals fall into this category of organic compounds. Carbamic acid (or aminoformic acid) is NH_2COOH, but is best known in the form of its salts and esters. Several insecticides are found among the aryl esters of *N*-methylcarbamic acid, whereas the alkyl esters of *N*-arylcarbamic acids possess strong herbicidal powers, particularly in connection with undesired monocotyledonous plants.

The biological and physiological actions involved in the toxicity of the carbamates to animal and plant life processes are quite complex and not fully understood. It has been established that the esters of *N*-alkylcarbamic acids with insecticidal properties inhibit cholinesterase. Of the *N*-methylcarbamic acid ester series, the most powerful insecticidal compound is 1-naphthyl-*N*-methylcarbamate, the basis for such commercially produced compounds as carbaryl, naphthyl carbamate, and Sevin. Other important carbamate-type acaricides, fungicides, insecticides, and nematicides include Aldicarb, Allyxycarb, Aminocarb, Bassa, Benomyl, Buffencarb, Carbendazim, Carbofuran, Ethiofencarb, Formetanate, Knockbal, Landrin, Mancozeb, Maneb, Meobal, Metacrate (Tsumacide), Metiram, Mexacarbate, Pirimcarb, Promecarb, and Propoxur (Baygon). Most of these names are proprietary.

Thio- and Dithiocarbamic Acid Derivatives. The derivatives of thiocarbamic acid are essentially herbicidal in nature. See also **Herbicides**. However, excellent nematocidal effectiveness is illustrated by the dithiocarbamic acid derivatives, notably by sodium N-methyldithiocarbamate (Vapam), which serves the multipurpose of not only eradicating nematodes, but many insects and weeds as well. It is frequently used as a soil sterilant.

In the case of the alkali metal salts of alkyldithiocarbamic acids, studies have shown that the fungicidal, nematocidal, and herbicidal effectiveness decreases as the length of the alkyl radical is increased. In terms of nematicidal activity, the esters of alkyl- and dialkylcarbamic acids is greater than the salts. Toxicity is greatest in the methyl and ethyl esters and decreased as the number of carbons in the ester radical increases.

Commonly available (check regulations) bactericides, fungicides, insecticides, and nematicides that fall into this category include: Carbothion, Eptam, Ferban, Nabam, Propineb (zinc bearing), TEC, Thiram, Zineb, and Ziram. Most of the foregoing names are proprietary.

Aliphatic Carboxylic Acids. Studies indicate a very low pesticidal activity for the aliphatic monobasic acids (acetic, propionic, etc.) and the dibasic carboxylic acids (oxalic, fumaric, maleic, etc.). As is usually expected, the pesticidal activity of the acids increases when halogen atoms are introduced to displace hydrogens in the alkyl radicals. Examples of this effect include the monohaloacetic acids, which are sometimes used commercially. The salt *calcium propionate* is used in bread- and cheese making as a preservative for its mild antibactericidal and fungicidal effects. Generally, the fluorine-containing derivatives are more toxic than those compounds with chlorine atoms. As can be expected, the unsaturated compounds exhibit greater toxicity than their saturated counterparts.

Alicyclic Carboxylic Acids. With exception of copper-bearing compounds, such as copper naphthenate, which is strongly fungicidal, the free alicyclic acids are not important as control chemicals. This is not the case, however, for a number of their derivatives. The natural pyrethrins and their synthetic analogs are included in this category. Among them are Allethrin, Barthrin, Bioallethrin, Cinerin I, Cyclethrin, Dimethrin, Furethrin; as well as Neopyanimin, Pyresy, Pyrexcel, and Pyrocide. Most of the foregoing names are proprietary.

The alicyclical carboxylic acid derivatives also include a family of growth-regulating compounds, known as the *gibberellins*. See also **Gibberellic Acid and Gibberellin Plant Growth Hormones**; and **Plant Growth Modification and Regulation**.

The alicyclic carboxylic acid derivatives have been studied extensively and, to date, with the exception of the compounds already mentioned, relatively few have been found to possess commercially important potential as pesticides. An exception is dimethyl carbate (Dimelton), which finds use as a repellent for certain blood-sucking diptera. The compound frequently is mixed with other pesticides.

Aromatic Carboxylic Acids. As in the case of aliphatic and the alicyclic carboxylic acids, the free aromatic acids (benzoic, naphthenic, etc.), their halogen and nitro derivatives, as well as their alkali metal salts, possess a lower insecticidal effectiveness. However, for some species of mite, the benzyl ester of benzoic acid is very effective. As a general rule, the incorporation of chlorine or other halogen atoms in the benzoic acid and benzyl alcohol configurations accentuate the biological power. Introduction of chlorine into the para position of the benzyl radical appears to provide a maximum effect against both egg and adult mite. Further enhancement of acaricidal potency is obtained by the presence of amino, hydroxy, and nitro groups. For codling moth and body louse, the aliphatic esters of anisic, anthranoic, and salicylic acids have toxic effectiveness. Chlorobenzilate is an effective selective acaricide, useful against numerous species of mite, including the tracheal mite which is parasitic to honeybee.

Numerous other aromatic carboxylic acids possess some bactericidal, fungicidal, and herbicidal characteristics, as well as growth-regulating properties. Salicylanilide, the amide of salicylic acid, is effective against leaf mold and tomato brown spot.

Heterocyclic Compounds. Quite a large number of insecticides and other pesticides as well as herbicides are heterocyclic compounds. The variations pertaining to structure and composition are so many that this is strictly a generalized, umbrella like classification. For the biochemist, organic chemist, entomologist, or other professional concerned in the development and theoretical aspects of control compound chemistry, other more detailed classifications are required. A first step toward this was undertaken by Melnikov. See list of references. Among important fungicides and insecticides in this classification are copper quinolate and Phenazim fungicide.

Aliphatic Hydrocarbons. After extensive research into the biological activity of the aliphatic hydrocarbons, relatively few of the pure (nonderivative) compounds have been found worthy of commercial attention. Popular for use in orchard spraying are the petroleum derivative oil sprays, which possess a good combination of acaricidal and insecticidal activity with low phytotoxicity. These sprays are effective against San Jose scale and mite.

Ethylene. For a number of years, has been used to hasten the ripening of some fruits. Although difficult to apply, ethylene is also an excellent defoliant. The insecticidal and nematocidal effectiveness of the halogenated aliphatic hydrocarbons is in proportion with the general chemical activity of these compounds. A number of these compounds have been used in the form of fumigants, notably in treating stored commodities and storage areas. Some of these include methyl bromide and DD pesticide.

Aromatic Hydrocarbons. Compounds in this category, such as benzene, naphthalene, xylene, etc.) have undergone extensive investigation. Although many of their derivatives are important, the pure compounds find little if any pesticidal use. Some of them, however, and in particular the xylenes, are used as solvents for carrying other control chemicals. For a number of years, naphthalene did enjoy large usage as a control agent against moth species. This has largely been replaced by synthetic compounds.

Halogen derivatives of benzene vary considerably in acaricidal and insecticidal toxicity, depending upon type, location, and number of halogen atoms introduced. Bromine appears to impart maximum effectiveness, followed by chlorine and fluorine. Biological activity increases with halogen atom introduction up to a total of three such atoms. A larger number tends to decrease effectiveness. Dichlorobenzene is more powerful than hexachlorobenzene. Loading a compound with bromine exhibits a greater effect than chlorine in reducing effectiveness.

Although there are eight stereoisomers of benzene hexachloride, only one of these, 1,2,3,4,5,6-hexachlorocyclohexane, is important commercially.

DDT (1,1,1,-trichloro-2,2-*bis* (*p*-chlorophenyl)ethane), now banned in many countries, is a derivative of an asymmetrical diarylethane and an effective insecticide. Paradichlorobenzene is an effective multipurpose pesticide. The compound is useful against sugarbeet weevil and in the control of phylloxera.

Ketones. Because of their rather weak insecticidal effectiveness, the ketones are used mainly as solvents for control chemical formulations.

Mercaptans. The aliphatic mercaptans with four or fewer carbon atoms have rather powerful insecticidal properties and can be used as fumigants against certain insect species. This is not true of those compounds containing over four carbon atoms; and also not true of aromatic mercaptans.

The control chemical interest of the mercaptans essentially is in the derivatives that incorporate chlorine or bromine. Methyl mercaptan rivals hydrogen cyanide as a powerful and useful fumigant. This compound is also an important intermediate in the synthesis of Captan and Folpet fungicides.

Some of the closely related organic sulfides and thioacetals have found commercial pesticidal use. These formulations include Mikazin, Fluoroparacide, and Fluorosulfacide. Names are proprietary in most cases.

Nitro Compounds. Biological activity of organic nitro compounds compares favorably against their pure (nonderivative) hydrocarbon compounds. However, this activity is considerably enhanced in terms of those nitro compounds that contain one or more halogen atoms. Bromine imparts a greater toxic power than chlorine. Many of the halonitro compounds command a wide spectrum of functionality, ranging from acaricidal, bactericidal, fungicidal, herbicidal, insecticidal, and nematicidal attributes. Some of their action is ascribed to their strong oxidizing properties. Examples of effective nitro compounds include chloropicrin and several related compounds, such as dichloronitroethane and chloronitropropane, as well as Binapapacryl acaricide-fungicide, Dicloran fungicide, Dinobuton acaricide, Dinocap acaricide fungicide, and Dinoterb acetate pesticide. Most of these names are proprietary.

Mercury Compounds. The powerful biological activity of mercury in simple compounds, such as the inorganic mercuric chloride, particularly against molds and other bacterial and fungus infections, has been recognized for generations. Also, the toxicity not only to microorganisms, but to higher animal forms also has been known and of major concern for a long time. Because of emphasis on environmental factors and safety during the past few decades, mercury-containing chemicals have been undergoing a phaseout in many countries. In connection with mercury compounds, it is interesting to note that many of these compounds have a good chemotherapeutic rating (or index), i.e., the dosage required to control a plant disease organism is many, many times smaller than the dosage that would be harmful to the plant. Some mercury compounds stimulate plant growth and yield.

Tin Compounds. Several organotin compounds are quite biologically active. Some of the simple inorganic tin salts, such as stannous or stannic chloride, have little if any pesticidal value. The fungicidal effectiveness is achieved by substituting alkyl or aryl groups for the chlorine atoms. A peak of insecticidal activity is achieved with the trialkyl- and triaryltins. It is interesting to note that the tetraalkyl- and tetraaryltins are essentially ineffective. Research has indicated that tributyltin chloride and tributyltin fluoride are the most active of the possible combinations. Most popularly used (check regulations) commercially are triphenyltin hydroxide and triphenyltin acetate.

Copper Compounds. Principally used as fungicides, copper inorganic compounds are widely applied. Of the organic copper compounds, the most commonly used are copper linoleate, copper naphthenate, and copper quinolate.

Zinc Compounds. Zinc is associated in a number of organic pesticides, notably Propineb fungicide, Zineb fungicide, and Ziram fungicide. Names are proprietary.

Phenols. As compared with the aliphatic alcohols, the phenols are more active biologically, but even with this greater activity, most of these compounds are not of practical commercial importance. Introduction of halogen, nitro, thiocyano, and some other groups increase their activity, the nitro group appearing to have the greatest insecticidal power. Included among these compounds are some that date back 50 years or more—dinocap (Karathane) acaricide-fungicide and dinobuton (Dinoseb) acaricide. The phenols tend to severely burn plants, a property that led to their use, commencing in the late 1930s, as contact, selective-type herbicides and desiccants.

Phosphorus Organics. Possibly the most extensive of all categories of organic compounds used as control chemicals, the organophosphorus compounds, are derived from the inorganic acids of phosphorus. It is estimated that the very fundamental compounds in this category number well over one hundred and that the commercial formulations resulting may number into the several hundreds. For study it is sometimes convenient to classify these compounds as derivatives of (1) phosphorous acid, H_3PO_3; (2) phosphoric acid, H_3PO_4; (3) thiophosphoric acid, $PS(OH)_3$; (4) pyrophosphoric acid, $H_4P_2O_7$; and (5) phosphonic acids (phosphine = PH_3).

Phosphorous Acid Derivatives. The principal control chemical potential of these organic phosphite compounds lies with their abilities as herbicides. Acaricidal, fungicidal, insecticidal, and nematicidal powers are comparatively weak. But, as is nearly always the case, the toxic potential increases with many different kinds of derivatives that can be prepared. Commercial products based upon derivatives include: DDVP (Dichlorvos) acaricide-insecticides; *tris*-(2,4-dichlorophenoxyethyl) phosphite (Falone); Gestid (Mevinphos, Phosdrin) acaricide-insecticide; Naled (Dibrom) acaricide-insecticide; and Phosphamidon acricide-insecticide. Most of these names are proprietary.

Phosphoric Acid Derivatives. The biological activity of the phosphates is considerably greater than the phosphites and notably among the mixed esters of phosphoric acid where one of the ester radicals is acidic. The toxicity of the resulting derivative is roughly proportional to the dissociation constant of the parent alcohol, phenol, or acid, the toxicity decreasing as the dissociation constant decreases. Research on the phosphoric acid mixed esters shows that the methyl derivatives are the most toxic. The toxicity of these types of compounds is believed to be the result of (1) high alkylating potential as regards certain biological nitrogen and sulfur constituents; and (2) elevated rates of hydrolysis.

Numerous proprietary examples of the derivatives of phosphoric acid include: Bromophos insecticide; Chlorpyrifos (Dursban) insecticides; Demeton (Mercaptophos) acaricide-insecticide; Diazinon acaricide-insecticide; Fenitrothion insecticide; Fensulfothion insecticide-nematicide; Fenthion acaricide-insecticide; Kitazin fungicide; Methyl Parathion (Metafos) acaricide-insecticide; Oxydemeton-Methyl acaricide- insecticide; Parathion (Thiophos) acaricide-insecticide; Vamidothion acaricide-insecticide; and Zytron insecticide. Most of these names are proprietary. Some of the compounds are banned in some countries.

Thiophosphoric Acid Derivatives. A fortunate combination of characteristics occurs in the phosphoric acid derivatives upon substitution of a sulfur atom for one of the oxygens of the parent compound. Namely, the toxicity of the derivatives to higher forms of life is substantially diminished, while at the same time, the acaricidal and insecticidal powers, with

few exceptions, remain strong. Derivatives of thiophosphoric acids may feature a thiono or a thiolo (most toxic) structure. Commercial preparations are usually mixed esters of thiophosphoric acid, as well as of dithio- and trithiophosphoric acids. The trithio compounds usually are markedly less effective than the dithio compounds.

Some commercial formulations based upon derivatives of the dithiophosphoric acids include: Azinphos-Methyl (Guthion) acaricide-insecticide; Carbophenothion (Trithion) pesticide; Dimethoate acaricide-insecticide; Disulfoton acaricide-insecticide; Malathion (Carophos) acaricide-insecticide; Mecarbam acaricide-insecticide; Menazon acaricide-insecticide; Phorate acaricide-insecticide; Phosalone acaricide-insecticide; and Phosmet (Imidan, Phthalodophos) acaricide-insecticide. Most of these names are proprietary. Some of these compounds are banned in some countries.

Pyrophosphoric Acid Derivatives. A pioneer among the phosphorus-containing organic control chemicals, tetraethyl pyrophosphate (Bladen, TEPP), was developed by Bayer AG in Germany in the early 1940s. The pyrophosphates are powerful contact-type acaricide-insecticides that have little or no tendency to function systemically. In addition to TEPP, some of the commercial formulations in this category include NPD, Pirophos, Schradcn, and Sulfotepp. Most of these names are proprietary. Some of these compounds have been banned in some countries.

Phosphonic Acid Derivatives. Very important in this category of proprietary compounds are Trichlorfon (Chlorophos, Dipterex, Dylox) and Trichloronate.

Other Organic Bases.

Quinones. As compared with the alcohols and aldehydes, the biological activity of the quinones is greater, notably in their actions as fungicides. Although benzoquinones exhibit relatively low activity, the presence of halogen and hydrocarbon radicals in the ring structure, as is true of many other organic compounds, significantly increases the effectiveness. Some of the derivatives of the quinones used commercially include tetrachlorobenzoquinone (*Chloranil*), which is particularly effective for disinfecting seed, and 2,3-dichloronaphthoquinone-1,4 (Dichlone, Phygon).

Sulfonic Acid Derivatives. The sulfonic acids, including their salts, have found value as agents for treating wool fabrics against species of moth for a number of years. One of these products is Eulan, a number of variations of which have been produced. Mitin-FF, a derivative of urea, also has been used in this way. To date, the free sulfonic acids have not played an important role as insecticides for crops.

Impressive activity against mite larva and egg has been shown by some of the aromatic esters of arylsulfonic acids. Some of the commercial formulations in this category include CPCBS (Chlorofenson, Ester Sulfonate, Ovex, Ovotran) acaricide.

Thiocyanates and Isocyanates. The intense biological activity of hydrogen cyanide has been known for scores of years. Similarly, derivative compounds have been known and used for many years. The derivatives of thiocyanic acid are particularly powerful fungicides and pesticides. Research has indicated that the straight-chain thiocyanates are more effective than those with branched chains and, as can be expected, introduction of halogen atoms into the compounds increases their toxicity. Some of the commercial formulations that fall into this overall category include Thiophanate fungicide; and Thiophanate Methyl fungicide. Regulations over usage must be checked.

Urea and Thiourea Derivatives. The value of urea as a fertilizer is well known. See also **Fertilizer**. However, the most elementary derivatives of urea show strong phytotoxic effects. Thus urea derivatives are widely used as herbicides. A number of derivatives of thiourea also show strong bactericidal and fungicidal activity. In this category are found Dodine fungicide and Guazatine fungicide.

Bacterial and Botanical Compounds as Insecticides and Control Chemicals

One of the long-established and better known of the botanical compounds is pyrethrum or pyrethrin insecticide. Known since the early 1800s, the active ingredient of this formulation is obtained from pyrethrum plants found in Africa and South America. Pyrethrin is considered to be one of the safest insecticides, but it is costly. The first synthesis of allethrin, the analog of pyrethrin, was developed in the late 1940s and is now widely used.

A much more recent natural insecticide, developed in the early 1960s, is Bacillus Thuringiensis-Berliner and, as indicated by the name, the compound is developed from living spores of the *Bacillus thuringiensis*, a bacterial strain that causes disease among certain types of insects.

Other naturally derived commercial insecticides include Evisect, Hellebore, nicotine sulfate, and Sabadilla insecticide.

An interesting concept of using specific antibodies as a potential insecticide has been proposed by Nogge, Giannetti, and associates at the Institut für Angewandte Zoologie (Bonn, Germany). See reference listed. It has been learned that many insects are able to absorb orally administered antibodies. The researchers found that when tsetse flies are fed on human blood, the hemolymph of the flies contains human albumin. Then, if the flies ingest antibodies to human albumin, they perish within a short time. It is observed that the albumin fraction in the insect's hemolymph disappears and osmoregulation is severely disturbed. Thus, antibodies may be used as a biological insecticide.

INSECTICIDE AND PESTICIDE TECHNOLOGY. The technology of controlling pests, notably in the area of food production, is undergoing serious examination and reevaluation.

Chemicals are and have been the main weapon for controlling agricultural pests for well over a century and will continue to be important for the foreseeable future. But within the last 20 years and notably the last decade, the total chemical approach to pest control has been subject to questioning and alternative approaches have been sought.

It no longer can be taken for granted that progress in pesticide technology will be confined to the research and development of new and improved chemicals. Progress in pesticide chemistry will continue to be important, but for the long term, actions commenced just a few years ago toward development of a *total systems concept of pest management* may represent the technology of the future. In the long term, this new technology may provide more effective pest control, coupled with a progressively lessened dependence upon chemicals.

A Retrospective View. When an important technology is at a crossroads, it is in order to glance back in an effort to clarify the forces which are bringing about a major change in direction. As early as 1828, it is reported that Persian (Iranian) farmers used pyrethrum (obtained from *Chrysanthemum coccineum*) as an insect control on certain farm crops. Rotenone, another naturally- derived organic chemical, has been used for pest control for over a century. Bordeaux mixture (copper sulfate and hydrated lime) has been used as a fungicide since the early 1880s. Inorganic arsenic compounds were used in German vineyards at the turn of the century and not banned until 1942.

Prior to the period just preceding, but mainly following World War II, pesticide chemicals were either inorganics or naturally derived and extracted organic compounds. Although there was an early awareness of the poisonous nature of most of these compounds, there was not an immediate connection made between poisoning insects and other pests during the growing period of a crop and possible poisoning of persons who might consume the produce after harvest. During this period, most likely it was generally assumed that the chemical insecticide would be confined to the foliage surfaces of the plants, later to be washed off by rain and in preparing produce for market. And, of course, it is true that a number of these compounds are contact-type pesticides, that is, their area of influence is confined to the surfaces to which applied. There was little, if any, understanding or consideration of possible systemic actions of such toxic materials, that is, the absorption of the poisons by the plant. Poisons were transported throughout the plant by its vascular system and thus

residuals remained in edible parts that, considering the analysis techniques then available, were extremely difficult to assay in minute quantities, even if suspected.

Numerous important findings of biochemistry, microbiology, and human and plant physiology were still unknown. The concepts of slow, prolonged poisoning processes were unknown and/or unappreciated. Based upon suspicions of arsenic-caused deaths, it was as recent as 1938 when a laboratory in Speyer, Germany studied 336 samples of wine bottled for sale that year and found to contain as much as 14.4 milligrams of arsenic per liter. Earlier vintages were found to contain as much as 24 milligrams per liter. It was later concluded that many vineyard workers, who regularly consumed "house wine" prepared from grape skins, succumbed to cancer of the liver after a latent period ranging from 10 to 35 years. Even in 1972, some 30 years after arsenic use in the vineyards of the Mosel and Kaiserstuhl regions had been banned, oldtime workers of the vineyards were expiring from arsenic-induced liver cancer.

Further, little was known and/or appreciated pertaining to the poisonous nature of the metabolites (compounds resulting from digestive processes) produced from certain pesticide chemicals, particularly those of an organic nature. Only during the last 40 to 50 years (a comparatively short period in terms of the total history of chemical pesticides) has the persistent nature of some chemicals been appreciated. This is also true of awareness of the large capacity of soils to retain chemical residuals for many years. When these two factors are coupled, excessive concentrations of chemicals can be built up over a period of years.

During the pre-World War II period, the world population was much smaller than today and the concentration of agricultural operations much less. Thus, the effect of certain pesticidal chemicals on birds, beneficial insects, livestock, fishes, and other forms of wildlife was less discernible. There certainly were various forms of warning, but these were noted only by comparatively few people. There was no popular awareness and concern as regards environmental problems.

A major alteration in insecticide and pesticide technology occurred as the result of what might be called a tremendous expansion in the field of organic chemicals. Pre-World War II efforts to synthesize dyes from coal tar chemicals were among the first efforts toward commercially expanding organic chemical synthesis. These efforts were shortly followed by the wartime needs for synthetic rubber, improved aircraft fuels, and an improvement of the earlier resins for the manufacture of plastic substitute materials for a host of applications. Knowledge and experience in organic chemistry multiplied several-hundredfold during the postwar period and spawned the petrochemical industry. Tens of thousands of new, previously unknown organic compounds were produced, for which in many instances uses had to be found.

Further expansion of commercial organic chemicals was greatly aided by the addition of natural gas as an almost ideal raw material. Although used for many years, a booming natural gas industry did not develop until shortly after World War II. The 1930s, 1940s, and 1950s became the age of miracle chemicals—with the introduction of new fibers, new plastics and resins, new coatings, and, importantly, new chemical pesticides. Mass production made it possible to produce many new chemical pesticides at a relatively low cost and their convenience in application was widely accepted by food producers. And the period was essentially without any major worries concerning possible deleterious side effects from their use. This period was also marked by a rapidly expanding worldwide population and greatly expanded food-producing operations. During this period, a great chemical pesticide industry and distribution system was created and, even more importantly, many food producers became highly dependent upon the use of pesticide chemicals. Many earlier farming practices were discarded in favor of wider application of chemicals and, at that time, apparently all for good reasons. Chemicals greatly reduced crop losses to insects and other pests, thus increasing effective yields from a given unit of land and labor. Chemicals still offer these advantages and, as of the late 1980s, this is still the general mode of food production operations in countries with advanced technology. The chemical trend, in fact, was again markedly accelerated a few decades ago by the introduction of herbicides, which, in turn, led to the concept of "no-till" farming.

The Apex of Conventional Chemical Pesticides. The wide acceptance of conventional chemical pesticides, not only by food producers for reasons previously given, but also by society in general, is exemplified by DDT (dichlorodiphenyltrichloroethane). This organic chemical was developed during the early 1930s by Paul Müller, a Swiss research scientist. In the early years of World War II, people were advised to use it without reservation on food and fodder plants, since it was said to be entirely harmless to warm-blooded animals. DDT was welcomed not only as an excellent control chemical for food production, but also as a public health measure against mosquitoes and other annoying and sometimes dangerous insects. Household preparations containing DDT and other related organic compounds were widely sold. Thus DDT in its early days exemplified the best of technology—a scientific breakthrough accompanied by completely positive economic and social benefits, as witnessed by the award of a Nobel Prize in 1948 to Müller.

Knowledge of the true nature of DDT was very slow in arriving. Not until the early 1950s did scientists at the U.S. Department of Agriculture find that although fodder treated with DDT caused no damage to the cows eating it, the health of their calves was severely impaired, sometimes with fatal results. The DDT was being passed along from cow to calf via the milk. These findings were confirmed in 1953 by experiments sponsored jointly by Swiss universities and pesticide manufacturers. The Swiss experimenters found that about one-tenth of the DDT sprayed from aircraft to control the May beetle settled on and was retained on the surface of pasture grass. Again, there was no apparent damage to the cows eating the grass, but their calves suffered the same effects as those previously described in the United States. It was also learned that the damage was principally to the nervous system of the animals.

In 1972, a group of German scientists discovered that a conversion product of DDT, a metabolite known as DDD, has a mutagenic effect. Some 30 or 40 years earlier, instrumental analytical techniques were not available to detect small residuals of highly complex organic chemicals and, further, the knowledge of human biology and biochemistry was but a fraction of that knowledge amassed during the period after World War II. In a way, possibly, the introduction of DDT marked the apex of conventional chemical pesticides, certainly not in terms of tonnages of chemicals produced, but in terms of their apparently trouble-free acceptance by society. Numerous chemical pesticides have been banned since the banning of DDT (in several countries) and the banning and tight governmental regulating trend continues at a rapid pace. In fact, some authorities believe that possibly the present period of questioning and suspicion of chemical pesticides may produce a net deficit for society. That is, society, on the one hand, might be fearful of the long-term effects of pesticidal chemicals, but, on the other hand, having learned to depend upon chemical pesticides for many years, may need all the assistance it can get from modern technology, including chemical pesticides, to feed an ever expanding world population.[1]

Possibly, the root of the fundamental biological problems resulting from widespread application of modern chemical pesticides extends back to the previously mentioned great expansion of organic chemicals that occurred during and just after World War II. With present knowledge of molecular biology and of proven carcinogens, although admittedly this knowledge is still extremely limited, it is almost certain that much more concern would have been expressed pertaining to the public release of many of the chemicals in use today. But once an entire business of chemical pesticide supply is established and once an industry (food production) takes on certain performance patterns, change becomes extremely difficult, particularly when satisfactory substitutes are not in view.

System Concept of Pest Management

The system approach to pest control involves not only a total look at the target pests and the plants to be protected, but an investigation of all elements which make up what might be termed a crop ecosystem. Particular

[1] A February 5, 1976 report of the study committee on pest control of the National Academy of Sciences expressed concern that "future agricultural productivity is threatened by a possible breakdown in chemical control of pests." Factors leading to this conclusion included: (1) the appearance of genetic resistance among "target" insect pests; (2) disruption of natural pest control mechanisms when beneficial insects as well as target pests are killed by a chemical compound toxic to a broad spectrum of insect life (the committee gave as an example the use of an organophosphate insecticide by California cotton growers for controlling the lygus bug that also kills certain predators which normally control the bollworm, a late-season pest); and (3) the effect of increasing constraints by laws and regulations on much needed chemical pesticides. Although not decrying the new laws and regulations, the study committee indicated that such regulations make more difficult and expensive the introduction of new pesticides to replace those already banned so that, if pesticide developers and suppliers are sufficiently discouraged, a serious gap in availability of effective control chemicals could result.

emphasis is placed upon the interactions of all elements; this emphasis, of course, involves a study of all feedback and any feedforward loops that may be present in the system. In essence, the systems approach represents applied ecology, which is basically a system-oriented science, but with the addition of numerous specialist viewpoints—physiology, biochemistry, engineering, entomology, botany, agronomy, economics, meteorology, and climatology, among others.

The long-range of objectives of the system approach are several: (1) to control food crop pests more effectively than is possible with chemical insecticides alone, even when these chemicals are used in excessive dosages; (2) to take full advantage of all natural factors that may act against the pests and in the favor of the plant; (3) to find new methods for combating high pest populations; (4) to improve crop yields as the result of optimizing favorable growth conditions; and (5) one hopes, to reduce the total cost of pest control by lowering the amount of control chemicals required for equivalent or better results.

It is obvious, of course, that the food producer cannot bring all the aforementioned skills together as they may pertain to a given crop ecosystem and make individual decisions as what to do next and when to do it in an effort to control pest populations. How is such very specialized information gathered in the first place? How is such information interpreted and translated into actions for the individual food producer?

The amount of data to be gathered just in the interest of applying the system approach to a limited number of major crops is staggering. A pioneering program developed by the Purdue University Agricultural Experiment Station (West Lafayette, Indiana) may, at some time in the future, point the way toward substituting information for hard chemicals in dealing with insect damage to crop plants. A program of this type requires the interest and intellectual cooperation of crop producers rather than simply depending upon chemical overkill of plant enemies.

In the early Indiana program, approximately one hundred alfalfa growers participated who essentially were dairy farmers who rely on alfalfa as the major source of protein for their herds. One of the initial tasks required was, to assess the level of alfalfa management practiced by program participants. This was accomplished by developing a 40-item questionnaire, which each cooperator completed and returned. A considerable variation in statewide insecticide and herbicide practices was found.

In developing the early data bank for the system, many actions were required: (1) collection of insect, alfalfa plant, and weed data from other cooperator's fields once each week for a season; (2) collection of weather data from appropriate agricultural weather stations on a daily basis, to be used as input into the alfalfa plant and weevil models to be developed later; (3) comparison of model output with actual grower field data and to make specific pest management recommendations based upon current insect, plant, and weather conditions; (4) input and storage of files of individualized alfalfa pest management advisories on a central computer; and (5) utilization of these data by cooperative extension agents by dissemination of advisories to the cooperating growers, using telephone, local radio station farm broadcasts, etc. Weather, obviously, plays a very important role in any pest management system. Thus, the Purdue program involved an excellent meteorological observing, forecasting, and communicating system.

Crop Ecosystem. What constitutes a crop ecosystem? This will vary considerably from one region within a state to another and probably can be determined practically only through making many observations. But it is possible, for example, that pest control information dispatched to producers in the southern half of one county may be applicable to producers of the same crop in the northern half of the adjoining county. In the long run, the system may take form of daily pest management advisories to food producers, possibly over local radio stations that for years have been featuring farm news of all kinds. Such an advisory might read along the following lines:

"Alfalfa weevil larval populations are on the increase and have reached sufficient levels in many cooperators' fields in southern Indiana to eventually result in economic losses. The alfalfa in these fields is still relatively short, averaging 4.6 inches and should (should not) be treated at this time. For growers in (such and such) areas, insecticide application should be delayed until more larvae have hatched so that a greater number can be controlled. Delay insecticide application for 7 to 10 days from this advisory. For growers in (such and such) areas, there are sufficient larval numbers and spraying should commence in accordance with previously given schedules."

Central to some pest management systems is a computerized simulator which, based upon the analysis of hundreds of past observations and experiments, can accept current weather information, for example, and read out the effects of the weather parameters. It thus provides directions for whatever pest control actions should or should not be taken at any given time. In essence, the simulator takes the place of numerous observers in the field and enables an information center to pass along directives in real time. A number of factors in addition to weather information, of course, can be input into the system. Needless to say, if such a network were established, all manner of other information pertaining to the crop ecosystem could be handled in addition to pest management data.

Such a system should be contrasted with the pest management means available today. Pest control information comes to the food producer from a number of sources: (1) pesticide chemical suppliers, who usually provide fundamental information on the application of their product, including precautionary information, safety measures to be taken, timing directions, etc.; (2) local extension personnel; and (3) special booklets, bulletins, etc., issued by state agriculture departments, giving specific directions as to types of acceptable pesticide chemicals, signs to watch for on the plant to diagnose pest conditions and stages, and general counsel pertaining to the timing of initial and repeat applications of chemicals—together, of course, with safety and precautionary information. But the prime limitation of this kind of information system is that it is not dynamic, it does not function in real time. Inputs of new information may range from one to several years and thus such bulletins do not always reflect the latest in chemical pesticide technology. And possibly the greatest weakness is the fact that this kind of information is based upon traditional pest control methods, as contrasted with the concepts of dynamic pest management.

Biological Pest Control Methods

The role of chemicals generated by insects in affecting the normal metabolism of plants has been known for many years. Less understood has been the role of chemicals generated by plants on the metabolic processes of insects. Research is beginning to demonstrate that some plants possess surprising chemical defense against attack by insects and other pests. Such defense chemicals operate in a variety of ways, and it has been mainly during the past 10 to 15 years that operation of these chemical defenses has been explained in a rudimentary way.

Pheromones. Some entomologists believe that insect pests may be controlled economically with a minimum of environmental disruption by exploiting the hormones and pheromones by which an insect regulates its growth, development, and behavior. Pheromones may be defined as chemicals which are secreted by one insect that affect the behavior of other individuals of the same species. Pheromones evoke several behavioral responses, but the sex-attractant pheromones are those most frequently mentioned by entomologists. It is believed that inasmuch as pheromones are natural substances the insects may be less likely to develop a resistance to them than to some synthetic organic insecticides. However, entomologists point out that insects are quite adaptable and that a change in their pheromones is a possibility.

Three approaches in the use of pheromones have appeared in the literature: (1) use of traps baited with sexual attractant material as a means for monitoring the infestation of areas with select insects; (2) similar use of traps, except on a massive scale, to attract males (female sex pheromone used as bait); and (3) "male confusion" technique, in which female sex pheromone is permeated in the air, frustrating the attempts of males to locate females.

The use of pheromones is particularly attractive because of the high selectivity of the method, enabling the destruction of pests by way of large reductions in future populations and doing this without interfering with the normal life and habits of beneficial insects.

Juvenile Hormones. These are organic chemicals that are present in insects during the greater part of the insect's development. It is only during metamorphosis (period when a larva changes into an adult) that these chemicals are absent. When juvenile hormones are applied to insects during metamorphosis, the adults produced are deformed and lack the capacity for further development and soon die. Because juvenile hormones are relatively simple compounds, synthetic analogs are not too difficult to prepare and thus can be used as effective insecticides. However, timing if very critical because effectiveness is limited to the relatively short period of metamorphosis. If applied before or after this period, the compounds are essentially ineffective. Wide use of these chemicals could become

practical if tied into a computerized pest management system control center as previously described. See also **Junvenile Hormones**.

Antiallatotropins. As part of their defense mechanism, some plants contain chemicals with juvenile hormone activity. Plants also have been found that contain chemicals with antijuvenile hormone activity, known as antiallatotropins. Although still not fully understood, it is assumed that the biological control system of the plant distinguishes between the metamorphosis period of an insect (during which time the juvenile hormones would be used as weapons) and the other periods of the insect's life cycle (during which time juvenile hormones are required by the insect, hence use by the plant of the antijuvenile or antiallatotropin compounds). Two antiallatotropins have been isolated from a common bedding plant (*Ageratum houstonianum*). Chemically, these are 7-methoxy-2,2-dimethylchromene and 6,7-dimethoxy-2,2-dimethylchromene.

Phytoalexins. First reported by K. Müller in Germany in 1940, phytoalexins are lipidlike chemicals that are synthesized by some plants. Research indicates that these compounds are toxic to fungi and bacteria, as well as some other pests. It has been found that the chemicals are produced as the result of an attack upon the plant and an analogy between these compounds and inteferon (an antiviral substance produced in humans in response to a viral infection) has been suggested. To date, about 100 phytoalexins have been isolated. One of their roles is believed to be prevention of germination of fungus spores.

Research by K. Uehara at the University of Osaka, Japan, in 1958 produced the concept of elicitors. Since then, at the University of Colorado (Boulder), the first phytoalexin elicitor was isolated. This was obtained from filtrates of cultures of *Phytophthora megasperma* var. *sojae*, a fungus that attacks soybean. This compound stimulates the accumulation of the phytoalexin glycerollin, previously characterized by research at the University of London.

Viruses. There are epidemics caused by viruses, which occur periodically in the insect populations and thus naturally help to check their spread. Entomologists would like to find ways of infecting pest insects before they can cause serious damage. Most insect viruses are specific for a few closely related hosts. The general structure of the viral particles includes DNA plus protein, all imbedded in a protein matrix. They are termed nuclear polyhedrosis virus (NPV). The viruses spread when larvae eat contaminated foliage.

Apparently viral infections in the past have helped to control the population of the Douglas-fir tussock moth. This insect undergoes population explosions at intervals of about 10 years. The outbreaks may last up to 3 years, during which time severe damage results. DDT helped to control the tussock moth population before it was banned. Attempts are now being made to combat a current outbreak of tussock moths with virus. Preliminary experiments in spraying virus on trees have been encouraging.

A virus called NPV is commercially produced and is used for the control of the cotton bollworm, a species closely related to the tobacco budworm. With present technology, the viruses can reproduce only in living cells. The insect viruses are usually grown in the appropriate hosts. Investigators are attempting to develop cell culture systems for propagating insect viruses that will eliminate the inconvenience of contamination of large numbers of insects or insect larvae for virus production.

The possible impact of virus insecticides on other forms of life, including humans, in the long term will obviously require some years of actual experience at a high level of usage. Regulatory agencies at this juncture are understandably extremely cautious in approving more than limited use. There appears to be evidence in support of the safety of the viruses and the negative aspects of this juncture appear to be in the category of theoretical possibilities in the absence of any substantive evidence. One scientist at the U.S. Department of Agriculture, with reference to the case of the cabbage looper caterpillar that succumbs to a virus attack, refers to the so-called coleslaw example. The insect body dissolves and sheds onto the leaf of cabbage large quantities of virus, which are not killed in the preparation of coleslaw. In mid-October, when mortality of the loopers is at the highest level, the average bowl of coleslaw will contain about 4 billion live particles of cabbage looper nuclear polyhedrosis virus. The scientist reasons that if the virus were harmful to people, this would have been long evident.

Microbial Agents. Considerable academic and governmental research has been conducted in this area for many years and is also an area to which industry has made significant contributions. The bacterial agents, *Bacillus thuringiensis* and *B. popilliae* are used commercially. Permission also has been granted for the experimental investigation of NPV (nucleopolyhedrosis virus) of *Heliothis zea* (corn earworm). Although it is not generally believed that microbial agents will replace chemical methods, it is felt that such agents will function importantly in integrated pest management programs of the future.

Insect Adaptability to Climate. Closely related to the foregoing discussion is the concept of genetic suppression of insect populations by their adaptations to climate. Many of the serious insect pests have very broad geographical distributions. For example, the codling moth (*Carpocapsa pomonella* (L.)) is distributed from Canada to Argentina and it occurs in Australia, South Africa, the Mediterranean, and throughout Europe north to the Scandanavian countries. Insects with such broad distributions adapt in various ways to climate.

A number of reports indicate that genetic differences occur between insect populations within a species with regard to: (1) ability to undergo a hibernal diapause; (2) response to diapause-inducing stimuli; (3) duration of diapause; (4) temperature limits of diapause termination; (5) temperature optima for diapause termination; (6) ability to develop cold hardiness; (7) thermal constants and temperature threshold for development; (8) choice of hibernal niches and other behavioral traits associated with surviving inhospitable seasons; and (9) ability for aestival (summer) diapause, its duration and response to conditions that induce or terminate it.

Such genetic differences must exist so that adaptations of insects to climate may be appropriate to their locality. Changes in climate from locality to locality require appropriate changes in adaptations. Insects may synchronize their life cycles with the seasons so that (1) frost-sensitive stages are passed in the frost-free season, (2) feeding stages occur when food is available; and (3) no actively developing stages occur in periods of intense heat or drought. Therefore, insects must be sensitive to stimuli that portend the change in seasons so that they may prepare for adverse periods.

If it is possible to genetically disrupt the seasonal regulations or other climatic adaptations of insects, the insects may not survive. For example, if an insect population at Fargo, North Dakota must respond to a photoperiod of 15 hours in order to enter diapause and be cold-hardy in time for dangerous frosts, and if the population is genetically modified, so that it does not diapause until the day has shortened to 13 hours, then the population may be destroyed by the winter. Further, it may be assumed that this population must remain in diapause until early May, when the danger of killing frost is past and when the host plant has again become available. If the diapause is genetically shortened so that the insects resume development in March, then they would be destroyed either by frost or lack of food.

Inappropriate adaptations to climate are lethal at certain times of the year; they are conditional lethal traits. A conditional lethal trait or combination of conditional lethal traits can be used to suppress or eradicate insect populations. The principle of suppressing insect populations by means of their adaptations to climate has been suggested by a number of investigators.

INSTRUMENTATION (Analytical). See **Analysis (Chemical)**.

INSULATION (Electric). An electrical insulator, when placed between conductors at different potentials, will permit a negligible current (in phase with the applied voltage) to pass through it. In essence, electrical insulators are applied dielectrics. A perfect insulator (dielectric) will pass no current in the foregoing situation. The closest approach to a perfect dielectric is a perfect vacuum. The difference between low-resistance insulators and semiconductors is ill defined. Materials that can be considered as insulators have resistivities greater than 10^{20} ohms down to 10^{6} ohms. Because of varying needs for insulators in the construction and use of electrical and electronic equipment and systems, the wide range of materials available, including a considerable span in cost, provides a convenient selection for the designer.

Relative Dielectric Constant

The capacitance between plane electrodes when in a vacuum, neglecting fringing, may be expressed by

$$C = k_0 A/t = 0.0884 \times 10^{-12} A/t \text{ farads}$$

where k_0 is dielectric constant of a vacuum; A is area, cm^2, t is spacing between plates, cm. If the vacuum is replaced by a dielectric material, the capacitance increases for the same applied voltage. With the dielectric between the plates, the capacitance is

$$C = kk_0 A/t$$

where k is the relative dielectric constant of the material. Capacitance relations change, of course, for other commonly occurring situations, such as coaxial conductors, concentric spheres, and parallel cylindrical conductors. The relative dielectric constant, then, is the key criterion in the functioning of an insulator. Values for several representative materials are given in Table 1. Numerous factors, including temperature, frequency, humidity, age, degree of cure (in case of plastics and polymers), and geometry, affect the relative dielectric constant. For this reason, the term dielectric permittivity is often used instead of relative dielectric constant.

TABLE 1. DIELECTRIC PERMITTIVITY OF REPRESENTATIVE MATERIALS*

Material	k	Material	k
Ceramics and Glasses		*Nonpolar Resins*	
Alumina	8.1–9.5	Polyethylene	2.3
Aluminum silicate	4.8	Polypropylene	2.2
Pyrex (Corning 7740)	5.1	Polystyrene	2.5–2.6
Fused silica	3.8	Polytetrafluoroethylene	2.0
Forsterite	6.2–6.3		
Steatite	5.5–7.0		
High-tension Porcelains		*Polar Resins*	
Beryl	4.5	Cellulose cotton (dry)	5.4
Magnesia	8.2	Cellophane (dry)	6.6
Mica (glass-bonded)	6.4–9.2	Cellulose triacetate	4.7
Titanates	50–10,000	Epoxies (unfilled)	3.0–4.5
Zirconia	8.0–10.5	Nylon	4.0–4.6
		[a]Phenolics (cellulose)	4–15
Crystals		[a]Phenolics (glass)	5–7
Aluminum oxide	10.0	[a]Phenolics (mica)	4.7–7.5
Calcium carbonate	9.2	Polyvinyl chloride	3.2–3.6
Boron nitride	4.2	Polyvinyl acetate	3.2
Barium titanate	4,100	Polyvinyl fluoride	8.5
Mica, synthetic	6.3	Methylmethacrylate	3.6
(fluorophlogopite)		Polycarbonate	2.9–3.0
Mica (muscovite)	7.0–7.3	[a]Silicone (glass)	3.1–4.5
Magnesium oxide	8.2	Polyethylene terephthalate	3.25
Sodium chloride (dry)	5.5		

[a] Filled with material indicated in parentheses.

* Some insulations incorporating organic materials may be carcinogenic when subjected to high temperatures. Regulations on the use of these materials varies from one country to the next. Thus some of these products are not available throughout the world.

Materials Used

With increasing frequency, the permittivity of dielectric decreases. A major factor in the selection of insulation is the ability of the insulation to resist the absorption of moisture. Moisture, of course, can greatly lower resistivity. For wire insulation, synthetic polymers and plastics essentially have replaced the use of natural rubber. Usually, prior to coating a wire with a plastic material, the wire must be treated to assure good contact and adhesion of the insulating material. Copper wire, for example, is treated with hydrogen fluoride, which creates a coating of copper fluoride; in the case of aluminum wire, aluminum fluoride. Thin films of fluoride possess high dielectric strength and resist heat well.

With the possible exception of common line insulators, electrical porcelain is especially formulated and may contain varying percentages of zirconia and beryllia. These ingredients increase both strength (mechanical) and resistance to high temperatures. Hard porcelains are especially formulated to resist thermal shock as well.

Liquid insulators are required for circuit breakers, transformers, and some cable applications. Natural hydrocarbon mineral oils are commonly used, as well as chlorinated aromatic liquids (desirable because of nonflammability). For high-temperature situations, silicone fluids may be used. Permittivities range between 2 and 7. Insulating liquids function both as electrical insulators and heat-transfer media. See also **Dielectric Theory**.

INSULATION (Thermal). Thermal insulation is any substance or configuration of materials that resists the flow of heat. Thermal insulation does not stop heat flow, but retards it to rates that suit particular requirements. For example, in the case of buildings or residences in climates or during seasons when the ambient temperature of the atmosphere is uncomfortably hot or cold, thermal insulation will be used to retain heat within a structure during cold weather and to shield or insulate the structure from the penetration of external heat during hot weather. In the one case, by reducing the flow of heat from structure to atmosphere and near outer space during winter, less energy is required to maintain the desired temperature within the structure. In the other case, by reducing the flow of heat from atmosphere and sun to structure during summer, less energy is required to artificially cool the inside temperature. Many parallel instances occur in industry. By thermally insulating processing vessels, piping, etc., where it is desired to maintain warm or hot conditions, energy is not lost to ambient surroundings. The efficient maintenance of temperature is critical to many industrial situations because temperature affects the physical and chemical properties of materials, such as viscosity, and determines the rate at which chemical reactions occur, among numerous other temperature-sensitive properties. In cryo-processing, as in the liquefaction of gases, the freezing of foods, etc., the objective is the maintenance of low temperatures and thermal insulation in such cases restricts the flow of heat from ambient surroundings and thus reduces the amount of energy required to maintain desirable low temperatures.

Although the principles of heat flow have been understood and treated mathematically since the early 19th century (Fourier, LaPlace, Poisson, Peclet, Lord Kelvin, Riemann, and many others), it was not until nearly

the beginning of the 20th century that major developments of commercial thermal insulating materials and systems were undertaken.

In addition to increasing thermal efficiency (conservation of energy), thermal insulation is frequently used to protect personnel from injury by burns and to shield adjacent structures from overheating, thus assisting in protection against fire. Thermal insulations are not usually suited to fire protection per se once a fire is in progress, but by restricting heat flow in the first place, insulation plays an important role in preventing some kinds of fires from starting. The behavior of thermal insulation once a fire has started is not necessarily positive in all situations and thus requires the attention of equipment and structure designers. A major concern in fires is thermal diffusivity rather than thermal resistance. Thermal insulation may not be suited for protection against high-velocity radiation.

Although not the primary function, the retardation of moisture migration into insulated spaces, where condensation may occur, is an important engineering consideration in the design of thermal insulation systems.

Insulation and Heat-Flow Principles. Heat flows from places of higher temperature to those of lower temperature by one or more of three modes: (1) Conductance through solids; (2) convection by induced motion of fluids carrying heat; and (3) radiation by heat waves emitted from a surface. The rate of heat flow in solids depends upon temperature difference $T_2 - T_1$ and the resistances encountered. The heat flow, under steady state, is expressed by:

$$Q_{\text{heat flow}} = \frac{T_2 - T_1}{R - \text{value}}$$

R-value is a measure of thermal resistance and varies from one insulating material to the next.[1] Q can be expressed Btu/square foot/hour or as Cal/square meter/hour, depending upon the units used in the equation. Helpful relationships between English and metric units are given in Table 1. See also **Heat Transfer**.

While convection may be a significant factor within processes, in general, convection affects thermal insulation primarily at the surface of the insulation or its jacket, where the air film is a resistance to heat flow from (or to) that surface. Wind reduces the air film resistance. To a lesser extent convection can occur within some low-density fibrous insulations, especially in walls, and to a greater extent within cavities and unfilled spaces within constructions. In walls, it is important that insulation that does not fill the space completely be installed so that remaining spaces are uniform, not skewed. Radiant heat flows through space, either vacuum or gaseous, from a higher-temperature surface toward a lower-temperature substance by the difference in absolute temperatures to the fourth power and the surface characteristic called emittance, e, as shown by the Stefan-Boltzman relation:

$$Q_{\text{rad}} = 0.174e\left[\left(\frac{T_2}{100}\right)^4 - \left(\frac{T_1}{100}\right)^4\right] \text{Btu/ft}^2\text{ hr} \quad \text{(on Rankine scale)}$$

$$Q_{\text{rad}} = 5.670e\left[\left(\frac{T_2}{100}\right)^4 - \left(\frac{T_1}{100}\right)^4\right] \text{W/m}^2 \quad \text{(on Kelvin scale)}$$

A common use of low convection with high-reflectance/low-emittance surfaces is in the food and liquid containers (Dewar flask, Thermos™ bottle, etc.). The double glass-wall space is under high vacuum so convection is virtually eliminated, and the surfaces are coated with silver to reduce heat transfer by the low emittance on the outside of the inner wall and the high reflectance on the inside of the outer wall.

Low emittance can be observed if the hand is held close to a very hot silver teapot without feeling much heat despite the high temperature of the surface of the teapot.

In high-temperature process plants, men have been burned on low-emittance hot metal jackets on insulation because the low emittance did not give them a sense of heat. Yet the thermal resistance from the heat conservation standpoint was excellent.

In some materials, especially foams, the spaces may contain gases other than air and the performance in convective and radiative heat transfer in the spaces affects the overall performance of the material. Also, the emittance/reflectance performances of the walls of the spaces affect performance overall.

[1] Resistance, thermal, R-value—the mean temperature difference at equilibrium between two defined surfaces of material, or a construction, that induces unit heat flow rate through unit area. (From ASTM STD. C168-80A)

TABLE 1. CONVERSION FROM U.S. CUSTOMARY UNITS TO METRIC UNITS[1]
(Data are for thermochemical values unless noted. International table values differ slightly.)

W = watt; m = metre; J = joule; kg = kilogram;
C° = temperature difference Celsius

Multiply	By	To Obtain

Therm (100,000 Btu)	$1.055\,056 \times 10^8$	J

[1] Most metric units shown are SI (the universally adopted designation for Le Systéme International d'Unités), except SI uses K (kelvin) for both absolute temperature and for temperature differences even though temperatures are determined on the Celsius scale. Since temperatures will usually be measured on the Celsius scale, the symbols used here are °C for temperature Celsius, as in the past, while C° is Celsius degrees difference. Similarly, °F is temperature Fahrenheit and F° is Fahrenheit degrees difference.

Technically, the performance of materials and systems depends upon all three modes of heat transfer to varying degrees in different materials, so it is the effective or apparent conductance that is to be evaluated. Although such terminology may be correct technically, and is appearing again in the literature, it was discussed many years ago and abandoned because it aroused too many questions by users of insulations with limited technical knowledge. It was felt that those with necessary technical competence would understand that a multimode heat transfer was involved, and the simple thermal conductance would satisfy users so long as the data were correct. R-values are even more readily understood by users, and technical analyses can be made by identifying by subscript that phase of the analysis being evaluated.

Thermal Insulation Systems and Materials

ASTM[2] Committee C-16 on Thermal Insulating Materials defines thermal insulation as a material or assembly of materials used primarily to resist heat flow. The reference to assembly of materials indicates that the concern is thermal insulating systems, because it is not until materials have been designed into systems that performance can be estimated. Thermal insulating systems include not only the basic materials, but also the auxiliary materials and the methods of application and protection in service.

[2] American Society for Testing and Materials, 1916 Race St., Philadelphia, Pa. 19103.

Time of exposure differentiates the needs for insulation performance when used in relatively continuous exposures, in cyclic increases and decreases of temperature, in processes with wide ranges of temperature in the various phases, especially in pipelines carrying fluids that must not fall below critical temperatures lest they solidify and necessitate dismantling and replacement of the lines.

A special short-time performance of thermal insulation is the ablative protection on the bottom of astronautical capsules returning from outer space when they are heated to sudden high temperatures by impact with the atmosphere. As principles stated below indicate, ablation is the process of resisting heat flow by using absorptance in changes of state from solid to liquid and to vapor of the ablative insulation, which is thereby lost, so that a one-time or at most a few times of exposure is practicable.

Classes of Insulating Materials. See Fig. 1. While glass has a high conductance, if it is fiberized and formed into wool-like masses, the high conductance of the fibers is counteracted by the still air that is held within the mass. Still air (no motion) has high thermal resistance, and at one time it was presumed that still air was the best insulator. A few other materials have been found with somewhat greater thermal resistance than still air, but they are so costly that they are suited only to very special applications. Other fiberized materials perform similarly, and rock, slag, and glass wools are collectively called mineral wools, but each has its own temperature limits.

All mass-type thermal insulations rely for their thermal resistance upon dispersion of the solid phase with air, or sometimes with gases. Plastics are reduced in density by foaming them into low-density material (0.5 to 2 lb/ft^3; 8 to 32 kg/m^3). Molten glass is foamed so that it performs as thermal insulation; its advantages are high compressive strength and virtually imperviousness to moisture, although thermal resistance is not as high as in some other materials.

Reacted materials, such as hydrous calcium silicate, are made with the solids dispersed to create density on the order of 12 lb/ft^3 (192 kg/m^3) and still provide high compressive strength. While the reflectance and emittance of the solid phase have an effect on heat transfer, it is the still air within the mass that gives it significant thermal resistance.

Still air is the important factor in dispersed solids, such as wood fibers, exfoliated mica, powdered diatomite, and expanded perlite.

The earliest reacted insulation was so-called 85% magnesium that had wide acceptance for many years, but since it was suited to less than 500°F (260°C), it has been replaced by other insulations with higher *R*-values or more desirable physical properties.

Although metals are good conductors of heat, they can also perform as good thermal insulators when their surface properties are used to advantage. While solid metal conducts heat readily, the emittance and reflectance of some metals are used to provide high overall *R*-values, especially when they are used in multiple sheets with spacers. Moreover, metals have relatively high temperature tolerances but have no absorption, so that all-metal thermal insulation may be suited to higher-temperature services than some other kinds of materials. While silver and gold are the best metals for high reflectance service, their use is limited to special applications where cost is not governing. For long-time exposure, gold surfaces would maintain high reflectance longest. However, aluminum sheets are used effectively when all-metal insulation is required. The first sheet of aluminum spaced about 12 mm (1/2 in.) from the hot surface reflects a large percentage of heat striking it. The unreflected heat passes through the metal rapidly by conductance, but the low emittance of the reverse surface prevents much of the heat leaving to strike the next sheet of aluminum where, again, the reflectance prevents a large portion of the emitted heat to enter that sheet. The number of reflective sheets is designed for the *R*-value desired. If the service temperature is above the working temperature of aluminum, about 1000°F (540°C), the first one or two sheets can be made of polished stainless steel.

Since aluminum is also used for jackets, it should be noted that although the thermal performance may be acceptable, the low emittance of an aluminum surface on the outside may introduce a personnel hazard, mentioned above.

An opposite effect of emittance occurs when an attempt is made to use aluminum jackets on very cold (cryogenic) piping. In this case, heat reaching the surface from surroundings is reflected away so that the metal surface becomes so cold that it will condense and freeze moisture from the air. To overcome this surface condensation and freezing by use of thicker thermal insulation on the lines would require a very great increase in thickness over that needed if the jacket had been made of a heat-absorbing material that would keep the surface above the dew point.

In the high-temperature case, low emittance is desirable from an operating standpoint, whereas in the cryogenic case low emittance is undesirable.

Two general types of heat flow systems exist: one in which it is desired that heat flow as rapidly as practicable, and another in which heat flow must be resisted as much as practicable. The former is a high thermal conductance type of system, whereas the latter is a high thermal resistance, high *R*-value, type. Consequently, in heat conserving systems it is simpler to think in terms of thermal resistances, because resistances are additive whereas conductances are not.

However, sometimes both high and low and low *R*-value materials are needed simultaneously, as in traced lines. See Fig. 2. Although systems are designed with limitation on overall heat loss, high-conductance cements are used for process safety on pipelines carrying hot fluids that would solidify if flow was interrupted or fluids become so viscous that the pumps could not handle the material. In such cases, one or more small pipes called tracers carrying hot fluids are enclosed with the thermal insulation envelope, and high conductance cements are used to improve heat flow from tracers to the main pipe. The size of the pipe insulation must be large enough to enclose the main pipe and the tracers, and also the insulation on fittings.

Importance of Moisture Migration. Heat conservation has been treated from an energy standpoint as if it were an independent subject, whereas great costs and energy losses have been incurred by premature failures, because it was not realized that in many cases thermal insulations cannot be installed without inducing an effect on the migration of moisture. The problems are usually not great from the standpoint of solutions, but are great in getting people to realize that they have created problems that have been overlooked. In most constructions, heat and moisture performance must be considered jointly, because even high-temperature systems are shut down for alterations, maintenance, or repair. For example, in a house wall, adding thermal insulation makes the indoor wall warmer, as desired, but at the same time it makes the outdoor wall colder, and it is well known that when surfaces are colder than the dewpoint, condensation occurs. The old log cabin with its loose construction had no moisture problems, but it was often only the side of the body that faced the fireplace that felt warm while the rest did its best to accommodate the facts.

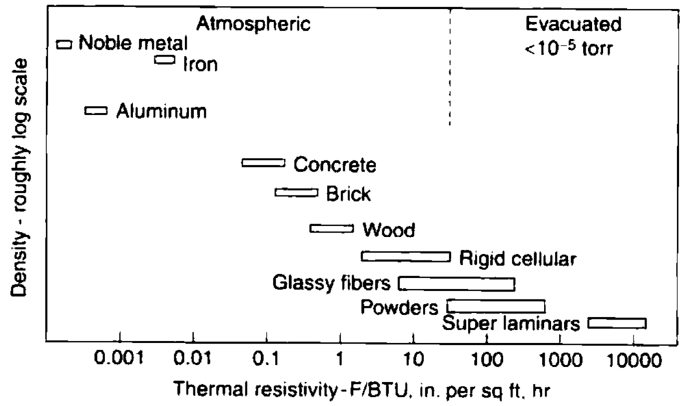

Fig. 1. Thermal resistivity of materials in insulation systems

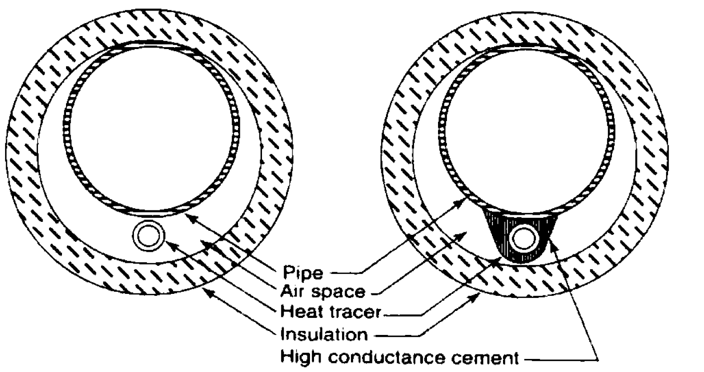

Fig. 2. Pipe insulation over pipe and heat tracer line, with and without high-conductance cement

Economic Considerations. For many years, cost appraisal of insulation was based on a publication by L.B. McMillan in *ASME Proceedings*, December 1926, in which several factors enter into the analysis, as shown in Fig. 3. At present, the cost of money and the costs of materials and labor are so unstable, that such analyses are of little value except that they do indicate the factors that enter into actual costs to plant management.

To presume that thermal insulation is always necessary is false. For example, when cryogenic fluids are transported from a supply source to a vessel, even in bright sunshine, it is usually most economical not to insulate the line at all. The reason for this is twofold: (1) for the short time of transport the area of the pipe exposed to the sun is much smaller than the area that would be exposed if it were insulated; and (2) the heat that would be in the insulation when the transport starts would have to be removed by the cryogenic fluid. The combination of these two factors often makes the use of insulation undesirable for this type of cold fluid transport system. Moreover, the rapid formation of ice crystals from moisture in the air constitutes a thermal insulation.

While thermal insulations are selected first for their resistance to heat flow, their other properties need evaluation for each application. Hence there is no "best" insulation because a material well suited to one service may be poorly suited to another. Economics must be studied in detail because in some services the cost of a highly efficient material per unit of thickness may be overcome by additional thickness of a less efficient material, provided there is room for the greater thickness. All properties of materials must be considered for each exposure, even within the same system. Recognize that when different materials are used on different parts of insulation systems that are close together, the probability of using the wrong material on a particular surface is increased appreciably. Unless there is specific reason for wide use of multiple types of materials, it may be prudent to accept some compromises of properties.

In general, it is desirable to place thermal insulation on or near the outside of constructions, including basement walls, because this location reduces appreciably the temperature stresses in the structure induced by the changes in exposure.

Selection of Thermal Insulation

Test methods, specifications, and some recommended practices are in ASTM Book of Standards, Part 18. Producer's literature gives forms, properties and design data.

1. *Thermal Resistance—R-value*—Thermal data in general Tables, as Table 2, are for dry materials, and for one or two mean temperatures, but most materials are not linear with mean temperature, hence, for specific designs, the whole range of resistance should be obtained.

A factor often overlooked is that space to be occupied by the insulation must be made available; a 3-inch (76-millimeter) iron pipe with 3 inches (76 millimeters) of insulation covered with a protective jacket would have a diameter of about 10 inches (254 millimeters).

2. *Temperature Limit*—Usually the high temperature limit governs because shrinkage then becomes excessive. Generally, high-temperature materials are physically stable at low temperatures but another material may be preferable.

Note that shrinkage data are usually from tests in soaking heat, whereas the field condition is for heat on only one surface. Hence, such data should not be presumed to mean that the insulation will shrink that amount in service; a 1% shrinkage would imply a change of almost 3/8 inch (9.5 millimeters) in a standard 36-inch (914-millimeter) length and leave a wide crack. However, in service such a large shrinkage does not occur; shrinkage would be 1/16–1/8 inch (1.6–3.2 millimeters). Moreover, hot metals expand, and it is this expansion that must be considered in

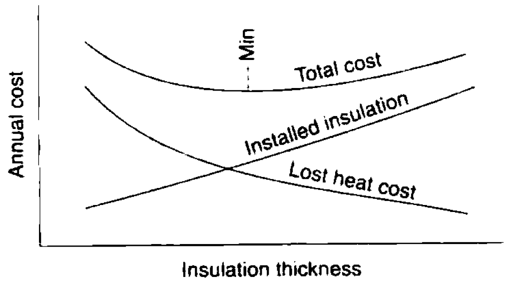

Fig. 3. Relation of incremental cost of Additional thickness of insulation to the resultant savings and total cost. (After *L.B. McMillan*)

compensating for openings between adjacent pieces of insulation, usually by use of double-layer insulation with staggered joints.

For cold-temperature service, moisture ingress is a problem that must be designed against and the material selected for its resistance to moisture and potential freezing.

3. *Corrosion*—While corrosion is usually not a concern on hot surfaces, recognize that all systems have shut down periods, with the probability that moisture will find ingress and condense. Many insulations are alkaline and have little adverse effect on iron and copper, but aluminum is affected adversely. A major concern is stress-corrosion of stainless steel induced by even trace amounts of soluble chlorides; an ASTM Test Method may be used.

4. *Density*—While the density of thermal insulation is low enough not be a problem in most cases, density (or mass-weight) must be considered in airplanes, balloons and other antiterrestrial constructions.

5. *Moisture-Wetting*—If moisture can enter an insulation, the high conductance of water (or ice) reduces the thermal resistance. However, all materials that admit moisture are not affected adversely to the same degree. Some fibrous insulations have a threshold moisture content below which the adverse effect on resistance is not significant; thresholds may be on the order of 8% by weight. The reason is that small droplets adhere to the contact points of one fiber against another so that the volume of relatively still air that provides the thermal resistance is not reduced significantly. Moreover, the temperature difference within the insulation drives the moisture to the cold side, and if it condenses there, the thickness of the wet insulation with decreased resistance is still a small portion of the total resistance.

In materials that readily absorb water, a decrease in thermal resistance will occur, but consideration must be given to the performance after the material is redried.

Caution is needed in interpreting absorption tests by immersion because the internal structure may resist displacement of air or gas so that a low absorption is indicated. However, if moisture is induced to flow through the specimen by vapor pressure differential and a condensing temperature is reached, high absorption may occur in service.

Materials with very high internal surface areas may absorb a measurable amount of moisture; even a monomolecular thickness of moisture on a large area becomes readily measurable. However, exposure to high relative humidity will not "saturate" the material, and as relative humidity changes so will the absorbed moisture. Some materials are tested wet to indicate wet to dry strength ratio.

6. *Handleability*—In the field, materials must have strength properties that enable them to be handled in application by the usual procedures of the industry without excessive breakage. ASTM tests for flexure, impact, and friability are aimed at indicating handling potential. Sometimes vibration tests are indicated if an unusual vibrating condition is to be encountered, although this test is receiving less attention than in the past because vibrations are usually designed against.

7. *Reflectances*—When an all-metal system is desired for temperatures to 1000°F (540°C) usually to avoid absorptions in case of leaks, multilayer sheets of aluminum are spaced on the order of 1/2 inch (13 millimeters). For temperatures to 1400°F (760°C) the first sheets are made of stainless steel.

8. *Fire Behavior*—While thermal insulations are not intended for fire protections (treated elsewhere) their behavior in fire is important, especially from the standpoint of contribution of combustible matter to a fire that has started at the site. Material behavior may be complex, e.g., an absorptive material that would hold a combustible fluid (say, kerosene) would not be a major contribution to fire intensity because the fluid would not flow to the surface to burn as rapidly as it would from a pool of the fluid. Materials that contain organic binders may not be a serious contribution in an open fire, but if they are totally enclosed they may contribute to persistence of fire by smoldering.

While some thermal insulation may not constitute a significant fire hazard, consideration must be given to jackets, coatings, or coverings, and to the methods of attachment, so that even in moderate fires the insulation will not readily fall off the construction they insulate.

Principal Types of Thermal Insulating Materials

Thermal insulations are made from natural or processed materials and combined to provide properties that meet the needs of specific installations. Obviously, all desired properties are not available in any one insulation. Hence, selection of thermal insulation for specific uses involves comparisons for each use, and some high thermal resistance (*R*-value) may

[1] Most high-temperature insulations are usable also at low temperatures, but other materials may be preferable.
[2] Maximum temperatures apply to surface service, not soaking heat.
[3] Thermal resistivity data are approximate and vary widely with density (for specific designs and temperatures, consult current manufacturers' data).
[4] Celsius temperatures are rounded. °C is temperature; C° is temperature difference.

need to be sacrificed in favor of some other property, such as handleability, resistance to compression, thermal diffusivity, avoidance of stress-corrosion, toxicity, or in-fire performance. See Table 2. Based upon ASTM C 168–80a, the principal types of thermal insulation are:

Ablative. Heavy density combination of materials that change state from solid to liquid or vapor in high temperature so that heat absorbed through their change of state reduces substantially the heat transfer rate through the material. Suited to one-time or very few times use.

Calcium Silicate. Composed principally of hydrous calcium silicate, usually containing reinforcing fibers.
Cellular Elastomeric. Composed principally of natural or synthetic elastomers, or both, processed to form flexible, semirigid, or rigid foams which have a predominantly closed-cell structure.
Cellular Glass. Composed of glass processed to form a rigid foam usually having a predominantly closed-cell structure.
Cellular Polystyrene. Composed principally of polymerized styrene resin processed to form rigid foam having a predominantly closed-cell structure.
Cellular Polyurethane. Composed principally of the catalyzed reaction product of polyisocyanate and polyhydroxy compounds, processed usually with fluorocarbon gas to form a rigid foam having a predominantly closed-cell structure. Under investigation by regulators.
Cellulosic Fiber. Composed principally of cellulose fibers usually derived from paper, paperboard stock, or wood, with or without binders.
Diatomaceous Silica. Composed principally of diatomite (diatomaceous earth) with or without binders, usually containing reinforcing fibers.
Gilsonite. A pure form of asphalt processed into powdered form for use as the enclosing insulating mass around pipes or tanks underground.
Mineral Fiber. Composed principally of fibers manufactured from rock, slab, or glass, with or without binders.
Perlite. Composed of natural perlite ore expanded and processed to form particles of various sizes with a cellular structure.
Vermiculite. Composed of natural vermiculite ore expanded and processed to form particles of various sizes with an exfoliated structure.
Wood Fiber. Composed of wood fibers, with or without binders. This is a type of cellulosic fiber insulation.

Principal Forms of Thermal Insulation

Also based upon ASTM C 168–80a, the principal forms of thermal insulation are:

Blanket Insulation. A relatively flat and flexible insulation in coherent form furnished in units of substantial area. Some forms are called batts.
Blanket Insulation, Metal Mesh. Blanket insulation covered by flexible metal-mesh facings attached on one or both sides.
Block Insulation. Rigid insulation preformed into rectangular units.
Board Insulation. Semirigid insulation preformed into rectangular units having a degree of suppleness particularly related to their geometrical dimensions.
Cement, Finishing. A mixture of dry fibrous or powdery materials, or both, that when mixed with water develops a plastic consistency, and when dried in place forms a relatively hard, protective surface.
Cement, Insulating. A mixture of dry granular, flaky, fibrous, or powdery materials that when mixed with water develops a plastic consistency, and when dried in place forms a coherent covering that affords substantial resistance to heat transmission.
Fitting Covers. Manufactured or assembled segments of insulation to form covers for various pipe and vessel fittings such as elbows, tees, crosses, valves, etc. See ASTM Standard C450–76 (or later) for dimensions.
Loose-Fill Insulation. Insulation in granular, nodular, fibrous, powdery, or similar form designed to be installed by pouring, blowing, or hand placement.
Pipe Insulation. Insulation in a form suitable for application to cylindrical surfaces.
Reflective Insulation. Insulation depending for its performance upon reduction of radiant heat transfer across spaces by use of one or more surfaces of high reflectance and low emittance.
Roof Insulation. Rectangular boards or blocks of various thicknesses with properties for use beneath the roofing membrane protected from the weather, or with properties for use above the roofing membrane exposed to the weather.
Underground Systems. Systems that enclose insulated piping in small tunnels that include expansion arrangements and provide drainage. Since accidental general flooding may occur, the insulations should be capable of withstanding "boiling water" effects so that when the system has been dewatered the redried insulation will perform thermally essentially as it did prior to flooding.
Super Insulations. Several insulation systems have been developed that have very higher thermal resistances, such as multi-layer radiation shields, specially selected and matted fibers with small interfiber distances, special powders, ceramic foams, honeycomb composites, often highly evacuated, but they are too costly for usual services with which the general public is familiar.
Insulating Concrete. This should be recognized as relative in performance to usual heavy density concrete, and does not provide thermal resistance in the range of materials understood to be thermal insulations.

INSULIN. A polypeptide hormone having a molecular weight of 5733. It is formed in the isles of Langerhans located in the pancreas and was so named for this reason. Insulin is composed of 16 amino acids arranged in a coiled chain and cross-linked in several places by the disulfide bonds of cystine residues. The sequence of amino acids has been elucidated. The insulin molecule was synthesized in 1963. In 1977, rat insulin was produced in the bacterium *E. coli* by recombinant DNA techniques. A year later human insulin was generated after chemically synthesized genes were added to *E. coli*. This synthetic insulin is now in commercial production and has been approved by the FDA. Insulin regulates carbohydrate metabolism in the body by decreasing the blood glucose level. A systemic deficiency leads to diabetes.

See also **Carbohydrates**.

INTERCALATION COMPOUND. A compound composed of a crystalline lattice that acts as an electron donor, and "foreign" electron acceptor atoms interspersed of diffused between the planes of the lattice. An important group of intercalated compounds are composed of graphite, where bromine, for example, can act as electron acceptor. Graphite is particularly susceptible to this phenomenon because of its orderly stacked layers of crystals. Anhydrous metal nitrates such as copper and zinc nitrates also form intercalated compounds with graphite. A further example is trilithlium nitride, whose structure consists of a series of layers of dilithium nitride, between which is a layer of lithium atoms. This markedly increases the conductivity, so that the material becomes an effective solid electrolyte in batteries. Other substances having this property are sodium β-alumina, titanium disulfide, and some metal dioxides. The phenomenon does not impair the crystalline structure and is reversible. Intercalated compounds are used for superconductors, synthetic lubricants, catalysts, and storage batteries. They are used in biochemical research; an acridine-based compound that can intercalate between stacked pairs of bases in a DNA helix is used in cancer research.

INTERFACE. The area of contact between two immiscible phases of a dispersion which may involve either the same or different states of matter. Five types are possible: (1) solid–solid (carbon black-rubber), (2) liquid–liquid (water-oil), (2) solid–gas (smoke-air), (4) solid–liquid (clay-water), (5) liquid–gas (water-air). At a fresh surface of either liquid or solid the molecular attraction exerts a net inward pull. Hence the characteristic property of a liquid is surface tension and that of

a solid surface is adsorption. Both have the same cause, namely, the inward cohesive forces acting on the molecules at the surface. These phenomena provide to some degree the fundamental mechanism for many industrially important processes (catalysis, emulsification, mixing, alloying) and products (detergents, adhesives, lubricants, paints). Such properties as wettability of solid powders, spreading coefficients of liquids, and protective action of colloidal substances are intimately associated with interfacial behavior.

INTERMEDIATE (Chemical). An intermediate generally is considered to be a material (usually a chemical compound) that occurs somewhere in a chemical manufacturing process between the introduction of the basic raw materials and the creation of the final end products. When two or more separate chemical reactions are involved, the intermediate may be the product of one of the *between reactions* and serve as a charge material for a subsequent reaction. For example, in the manufacture of aromatic polyester, several materials and reactions are required. The fundamental raw materials are nitric acid, xylene, methanol, and ethylene glycol. In one reaction, *p*-xylene and nitric acid yield terephthalic acid. The terephthalic acid then is esterified with methanol using sulfuric acid as a catalyst to yield dimethyl terephthalate. The dimethyl terephthalate then undergoes an ester interchange with ethylene glycol which yields *bis*-(β-hydroxyethyl)terephthalate, later condensed to polyethylene terephthalate. This low-molecular-weight polymer then is polymerized to a high-molecular-weight polyethylene terephthalate. In this operation, terephthalic acid and dimethyl terephthalate can be regarded as intermediates. In some instances, a producer will procure intermediate materials from the outside rather than produce them in-house, particularly in the cases of the pharmaceutical and dye industries. Thus, a number of intermediates are high-tonnage items of commerce. Some intermediates are of low-tonnage requirements and sometimes the economics is in favor of one producer who supplies a number of using firms. A representative list of intermediates would include: *o*-aminophenol-*p*-sulfonic acid; 2,6-dichloro-4-nitroaniline; 4-sulfophthalic acid; *o*-tolidine dihydrochloride; diphenylmethane; diphenylacetaldehyde; methyl cyclopentylphenylglycolate; and 2,3-dichloro-5,6-dicyano-benzoquinone. See also **Synthesis (Chemical)**.

INTERMEDIATE-MOISTURE FOODS. Authorities have various defined intermediate-moisture foods (IMF) as having from 15–40% water at a water activity $a_w = 0.6 - 0.8$. Interest in intermediate-moisture foods for the human diet largely stemmed from the introduction and acceptance of "soft-moist" pet foods, which were first marketed in the 1970s. Research continues at a good pace and considerable progress has been made as, for example, in processed cheese foods with high moisture contents.

More important than moisture content, per se, is the objective of creating a preserved food substance that is stable and can be eaten directly. An idealized IMF system will have (1) a microbial stability at reduced water activity, (2) storage stability without special conditions, (3) reduction of weight and more compactness of product, and (4) can be consumed from the package without rehydration. Some authorities believe that IMF systems represent excellent potential in the development of the snack market.

Two factors have largely delayed expansion of IMF systems: (1) technology and (2) consumer acceptance. Some of the technical problems involved in formulating IMF systems include: (1) rates of lipid oxidation, (2) enzymatic deterioration, and (3) nonenzymatic deterioration. With some products, there are also problems associated with the desired texture.

INTERMETALLIC COMPOUND. In certain alloy systems, distinct intermediate phases occur where the constituent atoms are in fixed integral ratios, e.g., CuZn (β-brass). Such a compound is held together by metallic bonding and may form a very complicated crystal structure. The constitution of such an alloy is often governed by the Hume-Rothery rules. In some cases, if the electron concentration is such as to just fill a band, the material may even be semiconducting (e.g., InAs). See also **Compound (Chemical)**.

INTERSTITIAL. (1) Descriptive of a nonstoichiometric compound of a metal and a nometal whose structure conforms to a simple chemical formula, but exists over a limited range of chemical composition. Interstitial compounds are represented by borides, nitrides, and carbides of the transition metals. (2) Descriptive of an atom of an impurity that causes a defect or dislocation in a crystalline lattice, e.g., an atom of carbon or nitrogen in an iron crystal, or of arsenic in a semiconductor. (3) In a biological sense, the term describes cells located between or within layers of tissue.

IN VITRO. An event or process occurring outside a living organism — in an unnatural environment, as in a test tube.

IN VIVO. An event or process occurring naturally or spontaneously within a living organism.

IODINE. [CAS: 7553-56-2]. Chemical element symbol I, at. no. 53, at. wt. 126.9045, periodic table group 17 (halogens), mp 113.5°C, bp 184.35°C, density 4.94 g/cm^3 (20°C). Iodine has an orthorhombic crystal structure. Solid iodine is a violet-to-black color; vapor is a beautiful violet color. The element sublimes readily and is easily purified in this way. Iodine is insoluble in H_2O, soluble in alcohol, ether, CS_2, or carbon tetrachloride. The element was first identified by Courtois in 1812 when making a study of kelp. There is one stable isotope ^{127}I and fourteen radioactive isotopes ^{122}I through ^{126}I and ^{128}I through ^{136}I. The lengths of half-lives of the isotopes vary widely, the shortest ^{136}I with a half-life of 86 seconds; the longest ^{129}I with a half-life of 1.72×10^7 years. See also **Radioactivity**. In terms of abundance in the crust of the earth, the element ranks 53rd and is about as plentiful as tin, antimony, cesium, and barium. Considerable quantities of iodine have concentrated in the oceans. The average iodine content of a cubic mile of seawater is 230 tons (50 metric tons per cubic kilometer).

First ionization potential 10.44 eV; second, 19.4 eV. Oxidation potentials $I^- \rightarrow \frac{1}{2}I_2 + e^-$, -0.535 V; $I^- + H_2O \rightarrow HIO + H^+ + 2e^-$, -0.99 V; $I^- + 3H_2O \rightarrow IO_3^- + 6H^+ + 6e^-$, -1.085 V; $\frac{1}{2}I_2 + 3H_2O \rightarrow IO_3^- + 6H^+ + 5e^-$, -1.195 V; $\frac{1}{2}I_2 + H_2O \rightarrow HIO + H^+ + e^-$, -1.45 V; $IO_3^- + 3H_2O \rightarrow H_5IO_6 + H^+ + 2e^-$, ca. -1.7 V; $I^- + 6OH^- \rightarrow IO_3^- + 3H_2O + 6e^-$, -0.26 V; $I^- + 2OH^- \rightarrow IO^- + H_2O + 2e^-$, -0.49 V; $IO^- + 4OH^- \rightarrow IO_3^- + 2H_2O + 4e^-$, -0.56 V; $IO_3^- + 3OH^- \rightarrow H_3IO_6^{2-} + 2e^-$, ca. -0.70 V. Other important physical characteristics of iodine are given under **Chemical Elements**.

Sea plants, particularly kelp found in the waters around California and the Bay of Biscay, have been a source of iodine. Because of pollution, the kelp beds in California are no longer a major source. Iodine also is found in the petroleum oil well brine of California and, in small percentages, in sodium nitrate of Chile. The latter was once the primary source of the element. Brines now are the major source.

Uses

For many years, iodine tincture (3% to 7% dissolved in ethyl alcohol) has been an important antiseptic. The commercial tinctures also usually contain 5% potassium iodide to provide stability. This form produces a mild burning of the skin and stains both skin and fabrics. A milder preparation is available in which about 2% iodine is contained in an oil-water emulsion that also contains lecithin. The burning effect of the compound is greatly reduced and the mild stains produced usually wash off easily. There are a number of prepared medicines that contain iodine, although some of these have been removed from the market in recent years. At one time, iodoform CHI_3, a yellow, insoluble, crystalline powder with a very penetrating odor, was a very popular antiseptic and used widely in the preparation of gauzes and packings for infected cavities. Because of possible toxic effects with some individuals, the compound largely has been replaced by other less objectionable, less odorous materials.

The medical use of iodine compounds, particularly organo-iodine substances, has been researched with resultant limited applications. The dietary requirement for iodine was established many years ago as needed for the maintenance of cell growth in humans and animals. The largest concentration of iodine occurs in the thyroid gland where the hormone thyroxine $C_{15}H_{11}O_4I_4N$ is present. The waters and soils of some areas, as in the inland areas of the United States, do not contain the minimal trace quantities of iodine required by the normal diet. Thus for many years so-called iodized table salt with a content of about 0.01% potassium iodide has been available. This preventive practice has been accredited with forestalling goiter and associated glandular disturbances in untold thousands of instances. For health reasons, iodine supplements also are added to cattle feeds.

Iodine tablets provide an easy means for sterilizing drinking water in small portions, usually resulting in less odor and taste objections

than chlorine compounds for the same purpose. Iodine chemicals are widely used in photography and printing reproduction processes. See also **Photography and Imagery**.

The production of vanadium metal essentially is the calcium reduction of vanadium pentoxide in the presence of iodine and is known as the McKechnie-Seybolt process. The reaction is carried out in a steel bomb at about 700°C. The end products are vanadium metal, lime, and calcium iodide. A similar iodide process also is used in the production of high-purity zirconium.

Chemistry and Compounds

Iodine exhibits in common with the other halogens a marked readiness to form singly charged negative ions, as would be expected from the fact that these atoms need only one electron to acquire an inert gas configuration. However, of the four common halogens, iodine has the lowest electron affinity (3.2 eV) due to more effective screening of the nucleus. The iodides range in character from ionic to covalent compounds, many of them, such as hydrogen iodide, having bonds of intermediate nature. Iodine is the most electropositive of the common halogens, functioning as the positive univalent "ion" I^+, as in the compound iodine perchlorate, which, however, is not a salt, as well as in forming trivalent complex radicals, such as IO^+. Iodine also forms essentially covalent linkages with negative elements, in which it has positive valences 1, 3, 5, or 7.

In binary combination with oxygen, however, only one simple compound has been isolated, iodine pentoxide, I_2O_5, a white compound. The yellow I_2O_4, prepared from sulfuric and iodic acids, is considered to be made up of 3+ and 5+ iodine, and the structure iodyl iodate, $(IO^+)(IO_3^-)$, is assigned to it, in which the trivalent state is stabilized by the acid radical. Similarly, yellow tetraiodine enneaoxide, I_4O_9, is considered to have the structure $(I^{3+})(IO_3^-)_3$, in which again the trivalent state is stabilized by the acid radicals.

Hydrogen iodide, HI, is the least stable of the four common hydrogen-halides, and correlatively, the best reducing agent, readily reducing vanadic acid, nitrous oxide to ammonium, nitrous acid to nitric oxide, and HNO_3 to nitrous acid. Because it is so readily oxidized, it cannot be prepared by action of H_2SO_4 on an iodide, but can be made by the action of weak acids, e.g., H_2S, upon iodine, or by hydrolysis of certain iodides. It can be prepared by direct combination of hydrogen and iodine vapor on a platinum catalyst. It is also liberated in many organic iodination reactions, such as the reaction of iodine and refluxing tetralin. The H–I bond is considered to be partly covalent. HI is a monoprotic acid, and is stronger than hydrogen chloride and hydrogen bromide.

The oxyacids of iodine are essentially covalent compounds, the known acids being hypoiodous acid, HIO, iodic acid, HIO_3, and the various periodic acids. Hypoiodous acid is formed, along with iodide ion, by dissolving iodine in dilute alkali, or by action of mercuric oxide upon iodine and water. On standing hypoiodous acid disproportionates to iodic acid and hydriodic acid. Hypoiodous acid is a powerful oxidant. It is also amphiprotic: $H^+ + IO^- \leftrightarrow HIO \leftarrow I^+ + OH^-$, $pK_A = 10.4$, $pK_B = 9.49$. The evidence for the formation of the I^+ ion is the existence of a number of compounds of composition $I(r)_nX$, where r is pyridine or some other nitrogen organic base, n is 1 or 2, and X is hydroxyl, nitrate, or chlorate ion. The conductivity of liquid iodine also indicates ionization into solvated I^+ and I^-.

Hydriodic acid (HI) is a colorless solution formed when hydrogen iodide gas is dissolved in water, commercially of strength 10% HI, frequently colored brown by iodine. There is a maximum constant boiling point 127°C (774 mm) at 57% HI (distillate) for mixtures of hydriodic acid and water. Hydriodic acid is used in the preparation of iodides, and as an important reagent in organic chemistry.

All metallic iodides except silver iodide, mercurous iodide, mercuric iodide, lead iodide, cuprous iodide, thallium iodide, and palladium iodide, are soluble. The iodides of antimony, bismuth, tin require a little free acid to keep them in solution.

Dilute hydriodic acid reacts with hydroxides, oxides, carbonates, sulfides, metals in a manner chemically analogous to dilute HCl; with solutions of some salts, e.g., silver nitrate, to yield the corresponding iodide, e.g., silver iodide, precipitate. Higher strengths of hydriodic acid react with oxygen of the air upon standing to yield free iodine, which imparts a brown color to the solution, thus indicating the reducing character of the acid.

Hydriodic acid is made by the reaction (1) of iodine and hydrosulfuric acid (or sulfurous acid), (2) of phosphorus plus iodine plus water, with subsequent distillation in all cases.

Iodic acid, HIO_3, is commonly prepared by oxidizing iodine with HNO_3. It is a strongly oxidizing acid, oxidizing iodide to iodine, sulfite to sulfate, and H_2S to sulfur. It reacts vigorously even with dry carbon, phosphorus, or organic matter.

Iodate ion in aqueous solution appears to be $I(OH)_6^-$, and the iodine atom in crystalline periodates always is coordinated to six oxygen atoms, three nearest neighbors on one side and three next nearest neighbors on the other side. Thus, potassium iodate, KIO_3, has distorted perovkite structure.

In the broad picture, the iodides, like the other halides, range in character from completely ionic structures to covalent ones. The transition is clearly exhibited by the iodides of the first four groups in the (extended) periodic table, potassium iodide, KI, being ionic and titanium(IV) tetraiodide, TiI_4, essentially covalent. On the right-hand side of the periodic table, even the group I elements form bonds with iodine that exhibit a considerable degree of covalence. In general, the ionic iodides are the most soluble of the halides of the given element, e.g., sodium iodide, NaI, is the most soluble sodium halide, while the covalent (or partly covalent) iodides are the least soluble, e.g., silver iodide, AgI. These effects are correlated with the size and polarizing power of the cation and the increasing size and polarizability of the halogen ion, as is increase of reducing character and stability of coordination complexes. A related fact is the readiness of formation of the complex ion, I_3^-, upon dissolving iodine in an aqueous solution of KI. The variation in character of iodine solutions in various organic solvents as well as water, is also attributed to complex formation.

Because iodine is the least electronegative of the four common halogens, it forms a relatively larger number of compounds with the other three. They include iodine trichloride, iodine chloride, iodine bromide, iodine fluoride, iodine trifluoride, iodine pentafluoride, and iodine heptafluoride. These are reactive compounds, especially the lower ones, which enter into reactions with many organic and some inorganic substances. With ICl and organic substances, the end product is usually an iodine or chlorine substitution product, the solvent being important in determining which is formed. With inorganic compounds, the addition product is often the final product, thus ICl and antimony (V) pentaiodide $SbCl_5$ give a product of composition $ISbCl_6$, which ionizes to I^+ and $SbCl_6^-$.

Several oxyfluorides exist: IOF_3 (iodyl hexafluoridate, $[IO_2][IF_6]$), iodyl fluoride, IO_2F, and periodyl fluoride, IO_3F.

Related to the complex ions, as well as the interhalogen molecules, are their association products, the polyhalide complexes. For iodine they include the alkali (and ammonium) triiodides, along with higher compounds such as that with cesium, Cs_2I_8, ammonium, NH_4I_5, tetraethylammonium iodide, $(C_2H_5)_4NI_7$, tetramethylammonium iodide, $(CH_3)_4NI_9$, and benzene, $KI_9 \cdot 3C_6H_6$. They also include compounds of iodine with alkali metals and one or two other halogens, such as NH_4IBr_2, $KICl_2$, $RbICl_2$, $HICl_4 \cdot 4H_2O$, CsFIBr, RbClIBr, CsClIBr and KIF6. Most of these compounds hydrolyze readily, decompose on heating to give the metal halide of greatest lattice energy, and ionize to give ions such as $ClICl^-$, $BrIBr^-$, and $BrII^-$.

Structural studies show that the complex $HICl_4 \cdot 4H_2O$ contains a positive trivalent iodine atom, and the planar ion ICl_4^- is one of the most stable of the polyhalide anions, as might be expected from consideration of the large size of the iodine atom and the small size of the chlorine atoms.

The difluoroiodate ion, $IO_2F_2^-$, is a trigonal bipyramid with two apical fluorine atoms, two equatorial oxygen atoms and one equatorial nonbonding electron pair surrounding the central iodine atom.

Iodine forms many organic compounds, chiefly by replacement of hydrogen or by addition reactions at double bonds.

Periodic acid H_5IO_6 has been isolated as a colorless solid, mp about 130°C, and at 138°C begins to decompose, metaperiodic acid HIO_4 being formed and at higher temperatures iodine pentoxide plus oxygen plus water. $H_4I_2O_9$ and H_3IO_5 have been reported as fairly well established in identity; in solution the evidence points to the presence of HIO_4. Prepared by reaction of iodine and perchloric acid.

Paraperiodic acid H_5IO_6, is obtained from sodium paraperiodate, formed by action of chlorine upon a NaOH solution containing I_2. On vacuum drying, paraperiodic acid yields metaperiodic acid, HIO_4, and dimesoperiodic acid, $H_4I_2O_9$; which form heteropoly acids with a number of oxides and acids. The periodic acids and their salts are strong oxidizing agents both with inorganic and organic compounds. Although, in general, the iodates do not disproportionate to give periodates, barium iodate, $Ba(IO_3)_2$, on ignition gives barium paraperiodate, $Ba_3(IO_6)_2$, iodine and oxygen.

Sodium periodate $Na_2H_3IO_6$ is formed by reaction of sodium iodate plus sodium hydroxide plus chlorine (sodium chloride also formed), and the periodate separates as crystals from the medium. In solution, it is stated, periodate gradually forms ozone and iodate at the ordinary temperatures.

Metallic periodates are solids, slightly soluble in water. Periodates, when heated, evolve oxygen with simultaneous formation of iodate, which is decomposed at higher temperatures. Periodate in acid solution oxidizes hydrosulfuric acid or sulfurous acid to H_2SO_4, oxalic acid to CO_2, manganous to manganate, and with hydrogen peroxide yields oxygen and iodate.

The biological aspects of iodine are covered in **Iodine (In Biological Systems)**.

IODINE (In Biological Systems). Iodine is not required by plants, but if iodine is present in the soil, it is taken up by most plants and moves on into the diets in forms that are effective in preventing goiter. In areas where the soils are high in iodine, ground water is also high in iodine, but the food supply is still the major source of iodine for people in these areas. Seafoods are good sources of dietary iodine.

Gout is no longer the single target of iodine deficiency concerns. The deficiency is implicated in mental retardation, deaf mutism, short stature, and an increased risk of death during childhood. Iodine deficiency is known to affect development of the central nervous system, particularly during the growing years. Intellectual impairment may range from a mild disorder to one of *cretinism* (significant and abnormal intellectual disturbance). Thus, there is a marked trend today among professionals to group all consequences of iodine deficiency under the category "iodine deficiency disorders."

Uneven Distribution of Iodine

Many of the iodine-deficient regions of the world have been identified. They are generally either mountainous or in the centers of continents, and distant from the oceans in the prevailing wind directions. Studies of the geochemistry of iodine indicate that this element is volatilized from oceans, carried overland by winds, and deposited on the soil by rain. The mountainous areas are low in iodine because little of that volatilized from the seas reaches sufficient altitude to be deposited in high altitudes. In some areas, the younger soils have less iodine than the older ones because of less time for the geochemical processes to build up the iodine level.

Although the amount of iodine in the soil is the primary factor determining iodine levels in food crops from various regions, the level of iodine in plants and the dietary requirements for iodine are modified to some extent by the plants themselves. There are important differences among plant species, and even among varieties of the same species, in their tendency to take up iodine from the soil. Certain plants, especially some of the *Brassica* genus, such as cabbage, contain compounds called *goitrogens*, which interfere with the effect of iodine on the thyroid gland. The amount of iodine required to protect animals, including humans, against goiter and other important iodine-deficiency disorders depends not only upon the kinds of plants in the diet, but also upon the iodine level characteristic of the soils in which the plants are cultivated. Iodine could be increased by adding iodine compounds to the soil, but that is a very inefficient way of insuring adequate dietary levels of the element. Much of the iodine added to the soil would be leached out and returned to the seas before it could be taken up by the crop plants. The use of iodized table salt is such an effective way of supplying this element that there is little need to include iodine in fertilizers.

A more recent method is that of using iodized oil, which has been found to be particularly effective in underdeveloped areas, such as several African countries.

Several comparative regional studies of iodine deficiency have been made. For example, one study shows that 1 of every 12 newborn infants in Freiberg, Germany, had an elevated serum thyrotropin concentration as contrasted with 1 of 1,428 infants born in Stockholm, Sweden, during an equivalent time frame. It has been found that iodine dietary supplementation reduced the incidence of congenital deafness in Switzerland by half. In countries that extend over broad and varied geographical regions, such as the United States, China, and Russia, the iodine content of soil can vary widely from one geographical community to the next. Dietary supplementation of iodine has increased the survival and birth weight of newborns in Zaire, prevented cretinism and decreased the rate of childhood mortality in Papua New Guinea, and advanced educability and economic productivity in China. Inasmuch as the facts leading to past successes have been well established, a meeting of the World Summit for Children in 1990 pledged to eliminate iodine deficiency by the year 2000. The Summit comprised responsible persons from the International Council for the Control of Iodine Deficiency Disorders, the United Nations Children's Fund, and the World Health Organization. Dunn (see reference listed) makes the interesting observation that, in 1923, David Marine wrote that "simple goiter is the easiest of all known diseases to prevent."

Dunn observes, "One intramuscular injection of iodinated vegetable oil containing 480 milligrams of iodine provides adequate amounts of iodine for up to three years. Oral administration of iodized oil is appealing for its simplicity and safety and millions of doses have been given worldwide. Still, the optimal dose and duration of effect have not been fully defined." Tonglet (see reference) and others have reported that as little as 48 milligrams of iodine administered orally as iodized oil is sufficient supplementation for 6 months. See also **Vegetable Oils (Edible)**.

One must be careful in dose determination because excessive doses of iodine can produce harmful effects.

Biochemistry of Iodine

In historical terms, 3,5-diidotyrosine (iodogorgoic acid) had been discovered in sponges and corals long before there was any hint concerning thyroid hormone structure even in mammalian forms. Since this time, iodotyrosines have been demonstrated in algae as well as in many animals possessing a horny skeleton. It has been suggested that iodide in the water is activated by peroxidases due to the presence of oxygen in the water and the resulting iodine is accepted by tyrosine in the protein molecule, similarly to the process in vertebrates. In animals possessing an exoskeleton, the presence of benzoquinones is part of the formation of scleroproteins by a quinone tanning process, and the iodination of tyrosine may be related to this in some way. In rotochordates, the endostyle, a structure secreting mucus, has been found capable of iodination of protein present in the mucus, which is then secreted into the alimentary canal.

The next phylogenetic development takes place in the vertebrates, in the most primitive members of which there is a structure located in the hypopharynx similar to a thyroid capable of collecting iodine and of forming iodinated protein, which is broken down by a protease, liberating iodinated amino acids. In some of these forms, small amounts of thyroxine are actually found in addition to the iodinated tyrosines. In other vertebrates, culminating in the amphibia and higher vertebrates, a thyroid gland is present in which the iodinated protein is held in a storage form known as colloid. In some, but not all, of these forms, hormonal material liberated by action of proteolytic enzymes is secreted into the bloodstream and plays an essential role in the development of the young animal as well as in the behavior and metabolic activity of the adult. Because of the process known as ontogeny, it is not surprising that the development of the thyroid gland in the human embryo commences with a structure located near the alimentary canal, which then separates and develops its peculiar follicular structure. Not until this type of development has occurred can a genuine function for the iodinated substances be demonstrated.

In these discrete glands, a series of specific chemical reactions can be demonstrated. See Fig. 1. Some of these reactions take place in the absence of any apparently specific synthesis of iodotyrosines, and it has not been fully explained how many of these steps require enzymes, even in mammalian forms, although these processes are usually considered as enzymatic. It is possible to iodinate tyrosine in soluble proteins in vitro by addition of elemental iodine and under these circumstances thyroxine and triiodothyroxine will also be formed, in company with small amounts of iodohistidine.

In amphibian vertebrates undergoing metamorphosis, thyroxine is known to be essential for this transition from an immature to a mature animal.

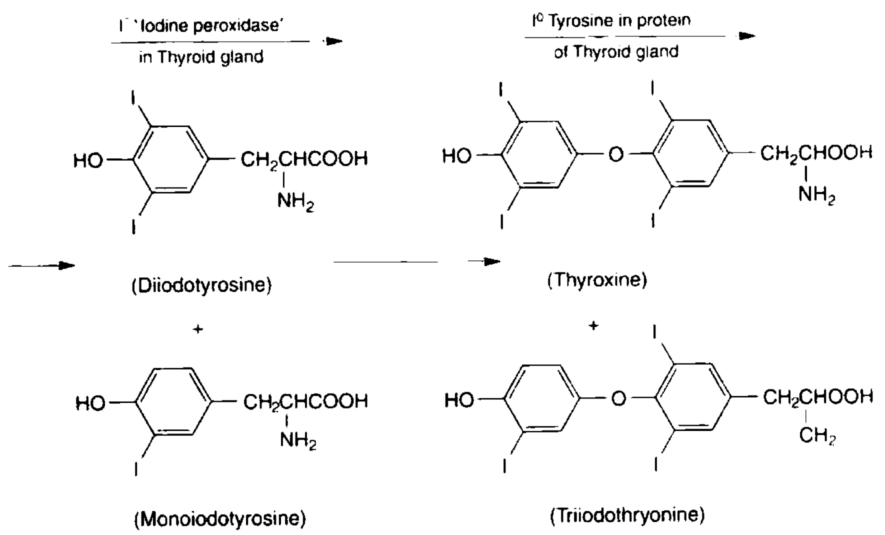

Fig. 1. Series of reactions occurring in thyroid system

There is considerable evidence that after metamorphosis has occurred, the thyroid gland is no longer essential, although it may be involved in seasonal changes, such as molting.

There is no such clear cut differentiation as metamorphosis in the mammal, but development is an extremely complex process and has been shown to depend upon the presence of adequate amounts of thyroid hormones. Deficient development, especially of the central nervous system, is marked in children suffering from thyroid deficiency early in life, and this inadequacy cannot be overcome completely by medication commenced after the first few weeks. In the adult, thyroxine is important in the maintenance of energy turnover in most of the tissues of the body, such as the heart, skeletal muscle, liver, and kidney. Other physiological functions, most notably brain activity and reproduction, are also dependent upon thyroxine, although the metabolic rates of the tissues concerned in these functions do not seem to be altered.

A great deal of work has been done on determining the portions of the thyroxine molecule essential to biological activity. The fact that the hormone is an amino acid is almost certainly due to the widespread existence of the excellent iodine acceptor, tyrosine. Thus, the deaminated and decarboxylated metabolic product of thyroxine, tetraiodothyroacetic acid, has been shown to have appreciable biological activity, although quantitatively less than that of thyroxine itself. As for the halogens present on the diphenyl ether portion of the molecule, bromines and chlorines are also active, although diminishing considerably in that order from iodine.

Assuming there are some quite definite structural requirements for thyroid hormone activity, it is important to inquire into the specific actions of this material. It seems clear that thyroxine does not participate directly in any enzyme system, but rather affects the function of many systems, presumably by some far more general process. One of the earliest of such demonstrated actions was the uncoupling of oxidation from formation of high-energy phosphate compounds, such as adenosine triphosphate. However, such uncoupling is also produced by many other substances not showing thyroid hormone-like effects, and it has been shown that thyroxine is actually capable of accelerating coupled reactions under the proper conditions. From this evidence, it is suggested that the principal role of thyroxine may be the acceleration of enzyme processes ordinarily limiting the level of metabolic turnover. Mitochondria isolated from broken cell preparations by high-speed centrifugation have been shown to swell when placed in contact with thyroxine and similar substances. This may be evidence for a membrane function of the hormone, although it is not fully understood as to how this may alter cellular function in such specific manner as the hormone does *in vivo*.

An acceleration of protein turnover by thyroxine also has been shown, implying that the hormone may alter various processes by a specific effect on synthesis of certain key proteins involved in enzymatic reactions. Thus, not only does thyroxine increase the rate of formation of new protein material, but it also may be responsible for the transformation of non-enzymatically active protein into protein with enzymatic activity. The hormone has also been shown to be capable of acceleration of the synthesis of urea cycle enzymes and probably is essential for the production of a sodium ion transporting mechanism, both of which are essential in the metamorphic transformation of larval forms into mature amphibia.

Steps in the synthesis of thyroid hormone include the following. (1) Active concentration of inorganic iodides within the thyroid epithelial cells. Concentration achieved is approximately 30 times that of plasma concentration. The so-called trapping of iodide is stimulated by thyroid-stimulating hormone (released by the pituitary gland). When present, this step is competitively opposed by thiocyanate and perchlorate ions. (2) Next, the inorganic iodide is oxidized to an organic form, in which peroxidase participates. The iodine becomes part of tyrosine residues in the thyroglobulin molecule. In this way, monoiodotyrosine (MIT) and diiodotyrosine (DIT) are formed. (3) The MIT and DIT are coupled by way of an ether linkage to form tetraiodothyronine (T4) and triiodothyronine (T3).

It has been observed that non-iodinated thyronine is not found in the thyroid gland.

The storage capacity and slow release mechanism of thyroid hormone appear to be unique among the endocrine glands. Usually a reserve of 100 days' needs (about 80,000 micrograms) are stored in the gland. For diseases related to malfunction of the thyroid gland. Sometimes iodides in drugs can cause a condition known as eosinophilia, in which there are reduced counts of eosinophil in the plasma. However, there are many other possible causes of this condition. Eosinophilic granulocytes are components of the blood in which the cytoplasm is filled with coarse acidophilic granules which may be spherical or rod-shaped, and the nucleus is bilobed and stains deeply.

IODINE VALUE (Unsaturates). See **Vegetable Oils (Edible)**

ION. An atom or molecularly bound group of atoms which has gained or lost one or more electrons, and which has thus a negative or positive

electric charge, and sometimes a free electron or other charged subatomic particle. Ions may be produced in gases by the action of radiation of sufficient energy; ionic solids are built up of ions bound together by their electrostatic forces, and when dissolved in a polar liquid, such as water, the salt dissociates into its ions, which have an independent existence.

Ions may be characterized in various ways. When they are described by the sign of their electric charge, they are described as *positive, negative* or *amphoteric* (or *zwitter*), the latter being an ion which carries both a positive and a negative charge, commonly at opposite ends of a long, or fairly long, chain, as in the case of ions of amino acids. See also **Amino Acids**.

Ions may also be described by their atomic structure, when they consist of more than one atom. Thus, a *complex ion* is a complex electrically charged radical or group of atoms such as $Ag(CN)_2^-$ or $Cu(NH_3)_2^{++}$, which may be formed by the addition to an ion of another ion or ions, or of an electrically neutral radical or molecule. When the particle combined with the ion is a large molecule, and the attachment is essentially by an adsorption process, the complex ion is called a *heteroion*. When the complex particle consists of a simpler ion combined with one or more molecules of water, it is known as an *aquoion* or *hydrated ion*. On the other hand, charged molecules, commonly produced by electrical discharges through gases, are often called molecular ions.

In meteorology, there are two special types of "ions" that enter into atmospheric processes: small "ions" and large "ions."

A *small ion* (also called a "light ion" or "fast ion") is the type that has the greatest mobility; hence, collectively, it is the principal agent of atmospheric conduction. The exact physical nature of the small ion has never been fully clarified, but much evidence indicates that each is a singly charged atmospheric molecule (or, rarely, an atom) about which a few other neutral molecules are held by the electrical attraction of the central ionized molecule. Estimates of the number of satellite molecules range as high as twelve. When freshly formed, by any of several atmospheric ionization processes, small ions are probably singly charged molecules; but after a number of collisions with neutral molecules, they acquire (actually, in a fraction of a second) their cluster of satellites.

A *large ion* (also called a "slow ion" or a "heavy ion") is an ion of relatively large mass and low mobility, produced by the attachment of a small ion to an Aitken nucleus.

ION-EXCHANGE RESINS. These materials are insoluble solid acids or bases that have the property of exchanging ions from solutions. During the ion-exchange reaction, the ion-exchange resins are converted into insoluble acids, bases, or salts. Cation-exchange resins contain fixed electronegative charges that interact with mobile counterions having the opposite, or positive, charge. Anion-exchange resins have fixed electropositive charges and exchange negatively charged anions. Ion-exchange resins are three-dimensional macromolecules or insoluble polyelectrolytes having fixed charges distributed uniformly throughout the structure.

Frequently, ion-exchange resins are used in fixed-bed processing equipment for softening and deionizing water. Equations for the removal of sodium chloride from water are as follows.

Exhaustion, or service step:

$$NaCl + RSO_3H \longrightarrow HCl + RSO_3Na \quad (1)$$

Regeneration step:

$$2\ RSO_3Na + H_2SO \longrightarrow Na_2SO_4 + 2\ RSO_3H \quad (2)$$

Equations (1) and (2) illustrate the reversible exchange of sodium ions for the hydrogen ion from the sulfonic cation-exchange resin. When the resin is depleted of hydrogen ions, it is regenerated with a dilute (5%) solution of H_2SO_4 [Eq. (2)]. The duration of the *service step* is usually a matter of hours; the *regeneration step* takes about 30 min.

The removal of NaCl from water (deionization) is completed by passage of the cation-exchanger effluent through a bed of anion-exchange resin.

Exhaustion, or service, step:

$$HCl + ROH \longrightarrow HOH + RCl \quad (3)$$

Regeneration step:

$$RCl + NaOH \longrightarrow ROH + NaCl \quad (4)$$

The effluent [Eq. (3)], which is free of NaCl, is deionized water. The resin is prepared for, the next service cycle by treatment with a 5% NaOH solution [Eq. (4)].

Traditionally, the ion-exchange resins used by industry are manufactured from uniform spheres of copolymers, such as styrene-divinylbenzene (DVB), having diameters 0.3–1.0 mm (20–30 mesh, U.S. standard screen). Such copolymer beads are formed by *pearl polymerization* and converted to ion-exchange resins by a second processing step. Sulfonic-type cation-exchange resins are made by sulfonation of the copolymer beads at elevated temperature. Strong-base anion-exchange resins are produced by means of chloromethylation and amination of the copolymer spheres.

Properties Desired of Ion-Exchange Resins

A well-performing ion-exchange resin should meet the following specifications:

1. Complete insolubility in water and solvents to prevent imparting tastes, odors, or color bodies to the solution being treated; 2. High exchange capacity per volumetric unit, with high regenerate efficiency; 3. Rapid and complete exchange with counter-ions; 4. Good chemical stability to prevent degradation by oxidizing and reducing agents; 5. Resistance to osmotic shock to prevent loss in use by physical breakdown; and 6. Low initial cost. See also Fig. 1.

Early Developments

The first ion-exchange resins were described by Adams and Holmes, a water-treatment expert and polymer chemist respectively, of the British Chemical Research Laboratory (1935). These ion-exchange resins were condensation products of phenol and formaldehyde. The granular-type cation-exchange resin contained sulfonic groups, and the anion exchanger contained aromatic amine groups. They are termed *strong-acid* and *weak-base* ion exchangers. A number of condensation-type ion-exchange resins were manufactured during 1935–1945. The first commercial deionization system was installed in 1939.

The next important step in ion-exchange resin technology was the synthesis of sulfonated styrene-DVB cation exchangers. Commercial quantities of strong-base styrene-DVB anion exchangers appeared in 1948. The first anion exchangers, the weak-base type, removed only strong mineral acids from water, such as HCl and H_2SO_4. The strong-base materials remove all acids, thus paving the way for production of water of

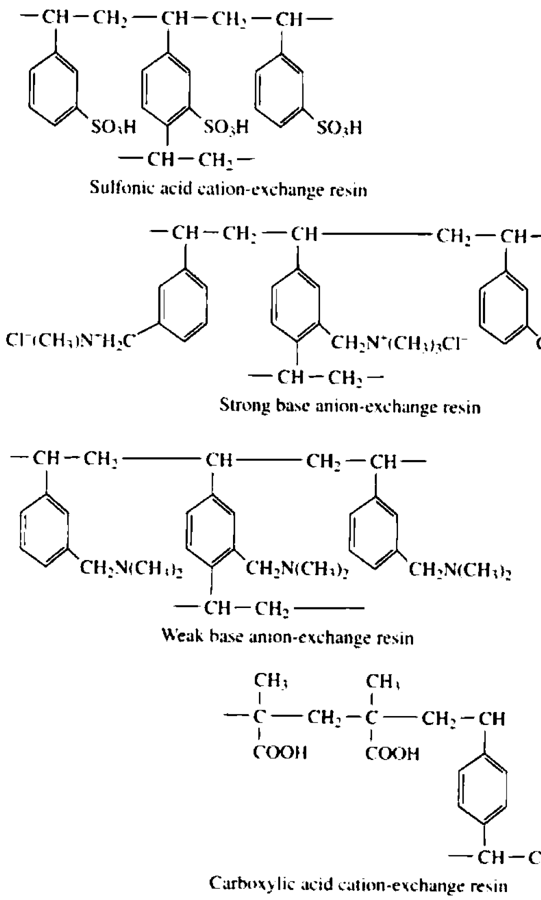

Fig. 1. Examples of ion-exchange resins

TABLE 1. CLASSIFICATION OF ION-EXCHANGE RESINS

Type	Active Group	Typical Configuration
Cation-Exchange Resins		
Strong acid	Sulfonic acid	Weak acid	Carboxylic acid	~~~ CH_2CHCH_2 ~~~ | COOH
Weak acid	Phosphonic acid	Anion-Exchange Resins		
Strong base	Quaternary ammonium	Weak base	Secondary amine	Weak base	Tertiary amine (aliphatic matrix)	Weak base	Tertiary amine (aliphatic matrix)	— $CHCH_2NCH_2$ | | OH CH_2 |

equal or better quality than distilled water and at a much lower cost. The combination of the styrene strong-acid and strong-base exchange resins in a single tank (the mixed-bed deionizer), commercialized in 1949, produces water containing just a few parts per billion of dissolved salts and at a very low operating cost. The mixed-bed process produces ultrapure water from most freshwater supplies at a fraction of the cost of distillation. This is the basic method used for centralization high-pressure boilers (5,500 psig) in the power industry and for applications in the electronics, chemical, and pharmaceutical industries.

Research has continued apace over the years to develop new organic ion-exchange organic polymers—the details of most are proprietary. Both natural and synthetic zeolites also are used in ion-exchange processes, but their extreme importance as catalysts has tended to overshadow their applications for deionizing purposes. See also **Adsorption**; and **Zeolite Group**.

Classification of Ion-Exchange Resins

In Table 1, ion-exchange resins are classified by type, active exchange group, and configuration of the active group on the polymer. Some of the proprietary resins are not included.

Chemical Behavior of Ion-Exchange Resins

This is governed by the nature of the active exchange groups. The acid or basic strength of ion-exchange resins is determined by means of an acid-base titration. Strong-acid and strong-base ion-exchange resins have titration curves similar to H_2SO_4 and NaOH respectively. Weak-acid and weak-base ion-exchanger titration curves are very close to those of CH_3COOH and NH_4OH respectively.

The hydrogen-form strong acid and the hydroxyl-form strong-base anion exchangers convert a solution of a neutral salt into the corresponding acid

TABLE 2. CHEMICALS PURIFIED BY ION EXCHANGE

Chemical	Materials Removed	Ion-Exchange Method*
Formaldehyde	Formic acid	AE
Methanol	Ammonia	CE
Glycerin	Salts, acids, color	MB
Sorbitol	Salts, color	MB
Gelatin	Salts, color	MB
Sugars (sucrose, dextrose, lactose)	Salts, acids, color	MB
Citric acid	Acids, salts, color	CE
		AE
Uranium	Ionic impurities	AE
Chromic acid	Heavy-metal ionic impurities	CE
Copper	Ionic impurities	CE

*AE anion exchange; CE cation exchange; MB multibed ion exchange.

and base, while the ion-exchange resins are converted to the salt form.

$$RSO_3H + NaCl \longrightarrow RSO_3Na + HCl \quad (5)$$

$$ROH + NaCl \longrightarrow RCl + NaOH \quad (6)$$

Weak-acid and weak-base ion exchangers react with strong and weak bases and acids but do not split neutral salts.

$$RCOOH + NaOH \longrightarrow RCOONa + HOH \quad (7)$$

$$RNH_3OH + HCl \longrightarrow RNH_3Cl + HOH \quad (8)$$

Ion-exchange reactions are generally reversible and are analogous to reactions that occur in solution. When a cation-exchange resin with A as its counterion is in a solution containing B cations, the reaction is

$$R^-A^+ + B \longrightarrow R^-B^+ + A^+ \quad (9)$$

where R is the cation-exchange resin.

After equilibrium is established according to the law of mass action, the reaction is

$$K_c = \frac{[\underline{B}^+][A^+]}{[\underline{A}^+][B^+]} \quad (10)$$

A bar under the ion represents the ion in the resin phase; the absence of the bar indicates the ion in solution; the brackets indicate activities. Activity coefficients of ions in the resin phase cannot be precisely determined, and K_c is not constant with change in ionic concentration. The value K_c is considered a *selectivity coefficient* rather than an equilibrium constant. K_c is a useful measure of ion affinity. Values of K_c generally follow this order for strong-acid and strong-base ion exchangers: (1) divalent ions are preferred over monovalent ions, and (2) higher-molecular-weight ions are preferred over lower-molecular-weight ions of equal valence.

Applications of Ion-Exchange Resins

The use of ion-exchange resins fall into five categories: 1. Transformation of ionic constituents; 2. Removal of ionic impurities; 3. Concentration of ionic substances; 4. Fractionation of ionic substances; and 5. A variety of other applications.

Transformation of Ionic Constituent. Softening water with the sodium form of a cation-exchange resin is the prime example of transformation of ionic constituents. Calcium and magnesium ions (hardness) occur in all freshwater supplies, forming objectionable scale and precipitates in boilers, laundries, and home appliances. These ions react with soap to form Ca and Mg stearates and reduce the effectiveness of detergents. The softening process is accomplished by passing the hard water through a vessel containing the Na form of cation-exchange resin. When the Na ions on the resin are depleted by exchange with Ca and Mg ions, the resin is regenerated with a 10% solution of NaCl and rinsed, and the softening cycle is repeated.

Other examples of this type of reaction are the conversion of the antibiotic streptomycin sulfate to its corresponding chloride by means of anion exchange, the exchange of Na ions in milk for the K ion, and the conversion of Na_2CrO_4 to H_2CrO_4 by cation exchange. The latter process is used extensively in the plating industry to concentrate H_2CrO_4 from rinse waters, with subsequent reuse of a toxic chemical and reuse of the rinse water in what might be termed a *closed system*.

Removal of Ionic Impurities. The major use of various combinations of ion-exchange resins under this category is the deionization of water for many purposes. Municipal and industrial water supplies contain dissolved salts, such as Ca, Mg, $NaHCO_3$ chlorides, and sulfates, which must be removed before use. Deionized water must be used in supercritical boilers to prevent scale formation. Deionization is also used to remove dissolved silica from boiler feedwater and condensate. At operating pressures above 1,000 psig, silica is carried over with the steam and condenses on turbine blades in power plants, causing a marked reduction in efficiency. Condensate purification at flow rates of 50 gal/(ft^2)(min) of ion-exchange-resin bed area is used in most power plants having high-pressure boilers to reduce the Na, Fe, Cu, and silica concentrations to less than 50 ppb total contaminants.

A number of aqueous solutions of organic and inorganic chemicals are purified commercially. Dissolved salts, acids, bases, and color bodies are removed by ion-exchange resins.

Concentration of Ionic Constituent. Ion exchange is successfully applied to concentrate electrolytes from dilute solutions with subsequent elution by a more concentrated regenerate solution to obtain a more concentrated solution of the electrolyte. An example is the recovery of H_2CrO_4 from rinse waters in the metal-finishing industry. The rinse waters are passed through a two-bed strong-base deionizer, and the deionized water is recycled to the plating system. The H_2CrO_4 is recovered as Na_2CrO_4, which is converted to H_2CrO_4 by treatment with the hydrogen form of a cation exchanger. Similar exchange processes are used to recover heavy and noble metals, such as Cu, Ni, Pt, and Au.

Fractionation of Electrolyte. Ionic species with opposite charges can be separated with either cation- or anion-exchange resins. The separation of ionic species of the same charge is possible if differences exist in acidic or basic strength, valence of the ion, or ionic radius. Examples of fractionation of electrolytes practiced on a commercial scale include: (1) removal of a strong acid from an organic acid, e.g., sulfuric acid from citric acid; (2) ion-exchange chromatography to produce pure rare earths from a mixture; and (3) concentration of copper and cobalt from dilute solutions and their fractionation by using a carboxylic-type cation exchanger, an example of concentration and fractionation done at the same time.

Miscellaneous Application. In the four categories just discussed the exchange of ions is common to all applications. It should be stressed that ion-exchange resins are reactive but insoluble acids, bases, and salts. These properties are used to advantage on an industrial scale for the adsorption of acidic and basic gases from gas streams. Gases which form an acid or a base with water can be removed by cation- or anion-exchange resins. Examples are SO_2, NH_3, CO_2, and H_2S. Ion-exchange resins have been used as catalysts for a number of years, some of the advantages being: (1) that catalyst-free products are obtained by means of simple filtration; (2) that catalyst can be reused for a number of cycles; (3) that continuous production is possible by passage of the solution through a bed of the material; and (4) that side reactions usually are kept to a minimum. Examples of ion-exchange resin catalysts are (1) sucrose inversion by means of the hydrogen form of a sulfonic-type cation exchanger, (2) ester hydrolysis with sulfonic-type cation exchangers, and (3) epoxidation of fats and oils with RSO_3H-type cation exchangers.

Ion Exclusion. Another process that uses ion exchange resins without exchanging ions is *ion exclusion*. This process uses an ion-exchange resin having high exchange capacity, which excludes free electrolytes from the inner phase. Low-molecular-weight soluble non-electrolytes distribute themselves equally between the resin and solution phases. If the solution of an electrolyte and a nonelectrolyte is passed through a column of a sulfonic-type cation exchanger whose exchangeable ions are the same as in the electrolyte, the nonelectrolyte will not be retarded and the electrolyte, or salt, will be *excluded*. The effluent from such a column can be collected as a relatively pure salt solution, followed by a solution of the mixture and then by a pure product cut. The middle cut usually is recycled. Ion exclusion has the advantage of separating nonionic materials from ionic species without the use of chemicals for regeneration. See Table 3.

TABLE 3. SEPARATIONS MADE POSSIBLE BY ION EXCLUSION

Ionic	Nonionic	Resin
HCl	Acetic acid	RSO_3H
Salt	Ethanol	RSO_3Na
Salt	Glycerin	RSO_3Na
Salt	Sucrose	RSO_3Na

The ion-exclusion process is particularly suited to sugar processing, e.g., sucrose recovery from molasses.

Developed in the early 1980s, tobermorites have selectivity properties intermediate between those of clay minerals and zeolites. They have been considered in catalysis and nuclear and hazardous waste disposal. Tobermorite, $Ca_5Si_6H_2O_{18}\cdot 4H_2O$, occurs naturally as a hydrous calcium silicate in calc-silicate rock. Tobermorites have layer structures similar to those of 2:1 clay minerals, but the structure varies with the chemical composition as well as with the nature of their synthesis. They have been synthesized from a number of starting materials.

ION EXCLUSION. The process in which a synthetic resin of the ion exchange type absorbs nonionized solutes such as glycerine or sugar while it does not absorb ionized solutes that are also present in a solution in contact with the resin. Thus, sodium chloride and glycerine can be separated by passage of their aqueous solution through a bed of particles of an ion exclusion resin.

IONIC CRYSTAL. A crystal that consists effectively of ions bound together by their electrostatic attraction. Examples of such crystals are the alkali halides, including potassium fluoride, potassium chloride, potassium bromide, potassium iodide, sodium fluoride, and the other combinations of sodium, cesium, rubidium or lithium ions with fluoride, chloride, bromide or iodide ions. Many other types of ionic crystals are known.

IONIC EQUILIBRIUM. In a system containing ions, at any particular temperature and pressure, the conditions at which the rate of dissociation of unionized molecules, or other particles to form ions, is equal to the rate of combination of the ions to form the unionized molecules, or other particles so that activities and concentrations remain constant as long as the conditions are unchanged.

IONIC MOBILITY. 1. The ratio of the average drift velocity of an ion in solution to the electric field. It is expressed by the relationship

$$\mu_+ \text{ or } \mu_- = \frac{\lambda_+ \text{ or } \lambda}{F}$$

in which μ_+ or μ_- is the mobility of the ion, λ_- or λ_- is the ion conductance, i.e., the contribution of the particular ion to the equivalent conductance, and F is the Faraday constant.

2. For gaseous ions in an electric field, the quantity k defined by the relationship

$$k = vp/E$$

where v is the drift velocity, p, the gas pressure, and E, the electric field strength.

3. Conduction of electricity in ionic crystals is due to the motion of lattice defects, either of the Schottky or Frenkel type. The mobility is given by

$$\mu = (eD_0/kT)e^{-E/kT}$$

where D_0 is a numerical constant, and E is an activation energy, which depends on the energy required to make a defect and on the height of the energy barrier that must be surmounted in order that the defect may move.

ION IMPLANTATION. A process for introducing alloying elements into a host material by accelerating the ions to a high energy (at least tens of kilovolts) and allowing them to strike the surface of the host. The impinging atoms penetrate into the substrate material to a depth of 0.01 to 1 micrometer, depending on the atomic number and energy of the atom, and create a thin alloyed surface layer on the substrate. The process differs from others, such as electroplating, in that it does not produce a discrete coating, but rather it alters the chemical composition near the surface of the base material.

In recent years, the electronics industry has made increasing use of ion implantation as a method of doping semiconductors. Since the number of ions implanted is determined by the charge transferred to the substrate and their depth distribution by the incident energy, ion implantation has improved the controllability and reproducibility of certain semiconductor device processing operations. Also, ion implantation processes do not require the high temperatures needed to introduce impurities by diffusion. Thus the limitations arising from the changes produced in materials by high temperature are eased. Ion implantation also has been used in electronics to change the magnetic properties of substrates used for magnetic bubble devices.

Ion implantation also has promise in other fields involving surface technology; for example, new metallurgical phases with prior unknown properties can be formed. In some cases, such as heavy implantations of tantalum in copper of phosphorus in iron, amorphous or glassy phases can be formed. Or, if the implanted atoms are mobile, inclusions and precipitates can be formed as, for example, implanted argon and helium atoms are insoluble in metals and may form bubbles. The composition of a surface layer can be changed by differential sputtering caused by the implanted ions.

The damage and high concentrations of lattice defects, resulting from atomic displacements produced by the incident atoms, can change the chemical reactivity and mechanical hardness of a treated surface. Implantation can enhance the diffusion of impurities already deposited in a substrate, presumably through the motion of the high concentrations of lattice defects produced by the incident ions.

One of the most promising nonelectronic applications of ion implantation involves surface treatment to improve the hardness and wear resistance, as well as lowered susceptibility to corrosion, of metals. In some experiments, the benefits of ion implantation on wear may persist to a depth 103 times that of the implanted layer thickness. The implanted atoms are apparently transported into the metal as a tool wears. Thus, the technology is of large interest in connection with improving cutting tools and bearings. Some experiments have suggested that nitrogen implantation increases the fatigue life of carbon steel parts. The results are consistent with present understanding of the mechanisms of fatigue failure. It is well known that fatigue cracks start at the surface and that there is a close connection between surface hardness and fatigue life. Compressive stresses due to the presence of additional implanted ions may also play a role in the suppression of crack initiation.

The production of corrosion-resistant materials by alloying is well established, but the mechanisms are not fully understood. It is known, of course, that elements like chromium, nickel, titanium, and aluminum depend for their corrosion resistance upon a tenacious surface oxide layer (passive film). Alloying elements added for the purpose of passivation must be in solid solution. The potential of ion implantation is promising because restrictions deriving from equilibrium phase diagrams frequently do not apply (i.e., concentrations of elements beyond the limits of equilibrium solid solubility might be incorporated). This can lead to heretofore unknown alloyed surfaces which are very corrosion resistant.

Ion plating is another area of surface treatment. Ion plating is carried out in a gaseous electrical discharge in which the substrate to be plated is the cathode. The discharge is created by an applied potential of 500 to 5000 V. The primary component of the gaseous environment usually is an inert gas, most often argon. Atoms of the material to be plated are introduced into the gas by evaporation from a heated source. A fraction of the atoms injected by evaporation are ionized before striking the substrate. In ion plating, atoms arrive at the surface with energies of only a few hundred volts and penetrate no more than a few lattice constants into the substrate. Thus, ion implantation produces an alloyed surface layer whose composition varies continuously with depth because of the rather broad distribution of the ranges of the implanted ions, while ion plating produces a coating, the composition of which is independent of the nature of the substrate.

Semiconductor Applications

In semiconductor manufacture, the area of the workpiece into which ions are implanted is quite small. High homogeneity is sought in semiconductor applications, that is, the concentration of the implanted species should not vary by more than a few percent over the surface of a wafer. The implantation of ions into semiconductors is usually patterned, that is, some areas of the substrate are covered by a mask that stops the incident ions before they enter the substrate. A doped layer in which the implanted atoms are locally in an equilibrium phase is usually desired. Thus, implantation is usually followed by a high-temperature annealing treatment, which removes radiation damage through diffusion of lattice defects to defect sinks and the recrystallization of disturbed regions. Laser annealing has been used successfully. Laser annealing affects only a surface layer approximately equal to the depth of typical implantations, leaving the bulk of the piece unaltered.

See also **Semiconductors**.

IONIZATION. A process that results in the formation of ions. Such processes occur in water, liquid ammonia, and certain other solvents when polar compounds (such as acids, bases, or salts) are dissolved in them. Dissociation of the compounds occurs, with the formation of positively and negatively charged ions, the charges on the individual ions being due to the gain or loss of one or more electrons from the outermost orbits of one or more of their atoms. The ionization of gases is a process by which atoms in gases similarly gain or lose electrons, usually through the agency of an electrical discharge, or passage of radiation, through the gas.

Ionization by collision is an ionization process occurring by removal of an electron or electrons from an atom as the result of the energy gained in a collision with a particle (or quantum of radiation) possessing sufficient energy.

Specific ionization is the number of ion pairs formed per unit distance along the track of an ion passing through matter. This is sometimes called the total specific ionization to distinguish it from the primary specific ionization, which is the number of ion clusters produced per unit track length. The relative specific ionization is the specific ionization for a particle of a given medium relative either to that for (1) the same particle and energy in a standard medium, such as air at 15°C and 1 atmosphere, or (2) the same particle and medium at a specified energy, such as the energy for which the specific ionization is a maximum.

Total ionization is a term used to denote either the total specific ionization (defined above); or the total electric charge on the ions of one sign when the energetic particle that has produced these ions has lost all of its kinetic energy. For a given gas the total ionization is closely proportional to the initial energy and is nearly independent of the nature of the ionizing particle. It is frequently used as a measure of particle energy.

Minimum ionization is the smallest possible value of the specific ionization that a charged particle can produce in passing through a particular substance. When the specific ionization produced along the path of a charged particle is plotted as a function of the particle energy, minimum ionization appears as a broad dip, bound on one side by a rather sharp rise for decreasing particle energy, and on the other side by a gradual rise for increasing particle energy. For singly charged particles in ordinary air, the minimum ionization is about 50 ion pairs per centimeter of path. In general, it is proportional to the density of the medium and the square of the charge of the particle. It occurs for particles having velocities of 95% of the velocity of light, which corresponds to a kinetic energy of 1 MeV for an electron, 2 BeV for a proton and 8 BeV for an alpha-particle.

Ionization potential is the energy per unit charge, for a particular kind of atom, necessary to remove an electron from the atom to infinite distance. The ionization potential is usually expressed in volts, and is numerically equal to the work done in removing the electron from the atom, expressed in electron-volts. See also **Chemical Elements**.

IONIZED GASES. Various agencies, such as fast-moving electrons, alpha particles, various forms of radiation, and high temperature, are capable of dislodging electrons from atoms or molecules of a gas and thereby leaving them positively charged. Some of the dislodged electrons may attach themselves to other molecules and render them negatively charged. In some cases, two or more electrons may be removed from the same molecule, or a molecule with a double positive charge may unite with a singly charged negative molecule, forming a singly charged complex, etc. Such charged atoms, molecules or molecular groups are called ions, and their production from neutral molecules is called ionization. The complete separation of an electron from a molecule or an atom requires a definite amount of energy. This may be expressed in ergs, but is more commonly given in electron volts (1.59×10^{12} erg), its value being the ionization potential. A lesser amount of energy may excite the atom or molecule to emit radiation, but will not ionize it.

If an ionized gas is left to itself, the ions soon recombine and become neutral. But if it is subjected to an electric field, as in an ionization chamber, the ions pass to the electrodes, such a migration being an "ionization current." Such currents, commonly called electric discharges, are attended by diverse phenomena and vary widely in character from the silent glow discharge to the lightning stroke.

At ordinary pressures, discharges may be classified into four types: (1) If the voltage between two electrodes in open air is gradually increased, the electrodes become surrounded with a luminosity. This "glow" or "corona" gives way, at the negative electrode first, to (2), a "brush," composed of hair-like branches. (3) Finally, the disruptive spark passes. (4) Under other conditions, an arc may be formed. If, however, the electrodes are enclosed in a tube and the pressure reduced, a point is reached at which the tube becomes filled with a beautiful luminosity. Close examination shows this to have structure. Very close to and surrounding the cathode is a thin, luminous layer *c*, the cathode glow (Fig. 1); and outside this, the Crookes dark space *C*. Next, extending toward the anode, is the short negative glow *n*, then the Faraday dark space *F*. From this to the anode extends the long positive column *p*, with its regular, transverse striations. As the pressure is further reduced, the cathode dark space enlarges and the other features dwindle toward the electrodes until they finally disappear at about 0.001 mm pressure. From this point on, the cathode rays are the predominant feature.

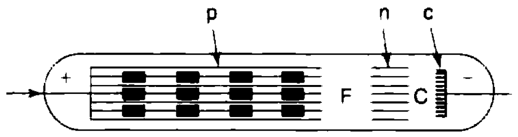

Fig. 1. Elementary gas-discharge tube

Upon exploring the discharge in a Crookes tube with suitable probes, it is found that in certain regions the positive and negative ions are so nearly equal in number as to neutralize each other's effect. Such a region is called a "plasma." The plasma may be surrounded by a "sheath" of ionized gas in which ions of one sign greatly predominate, the effect being that of a space charge.

IONIZING PARTICLE. A particle that produces ion pairs in its passage through a substance. Ionizing particles may be divided into two groups: (1) *directly ionizing particles*—charged particles (electrons, protons, alpha particles, and so on) having sufficient kinetic energy to produce ionization by collision; and (2) *indirectly ionizing particles*—uncharged particles, such as neutrons and photons, which can liberate directly ionizing particles or can initiate a nuclear reaction.

Ionizing radiation is any radiation consisting of directly or indirectly ionizing particles, or a mixture of both. Ionizing radiation, unless controlled, poses a biological and environmental hazard.

ION MICROPROBE MASS ANALYZER. An instrument designed to provide an *in situ* mass analysis of microvolume of the surface of a solid sample. The analysis is accomplished by bombarding the surface with a high-energy beam of ions which causes the atoms at the surface to be sputtered away. A fraction of the sputtered particles is electrostatically charged and these sputtered ions are collected and analyzed according to their mass-to-charge ratio in a mass spectrometer.

Figure 1 represents a schematic diagram of the instrument. The ions used for sample bombardment are generated in a hollow cathode, dual plasmatron ion source capable of producing ions of a wide variety of gases including those of a highly electronegative character. The ions which can be either positively or negatively charged, are accelerated to energies ranging from 5.0 to 22.5 kilovolts and passed through the primary mass spectrometer. The spectrometer permits the analyst to select and purify, by mass separation, a specific chemical species from those produced in the ion source. The purified ion beam is focused to a small probe in an electrostatic lens column and allowed to impinge on the surface of the sample. The diameter of the ion probe may be varied continuously from about 2 to 500 micrometers. The sample and the point being analyzed can be viewed through an optical microscope while under bombardment.

Sputtered ions are collected and their masses analyzed in a double-focusing mass spectrometer in which the velocity dispersions of the magnetic and electric sectors are matched to permit the acceptance of a wide range of initial energies of the sputtered ions. No entrance slit is used and the bombarded area is stigmatically focused directly onto the resolving slit.

The ion beams are then detected with a high gain device that permits single ion counting. Sputtered ions from the sample eject secondary electrons at the conversion electrode and these are accelerated towards the scintillator of a photomultiplier tube where the light produced by their impact is detected. The resolved ion signals can be read as count rates from scalers which can accommodate rates in the megacycle range within significant dead time losses or as direct-currents on chart recorders.

Analytical Method

The analytical method applied with this instrument is based upon the observation that the yields of sputtered ions are greatly affected by the

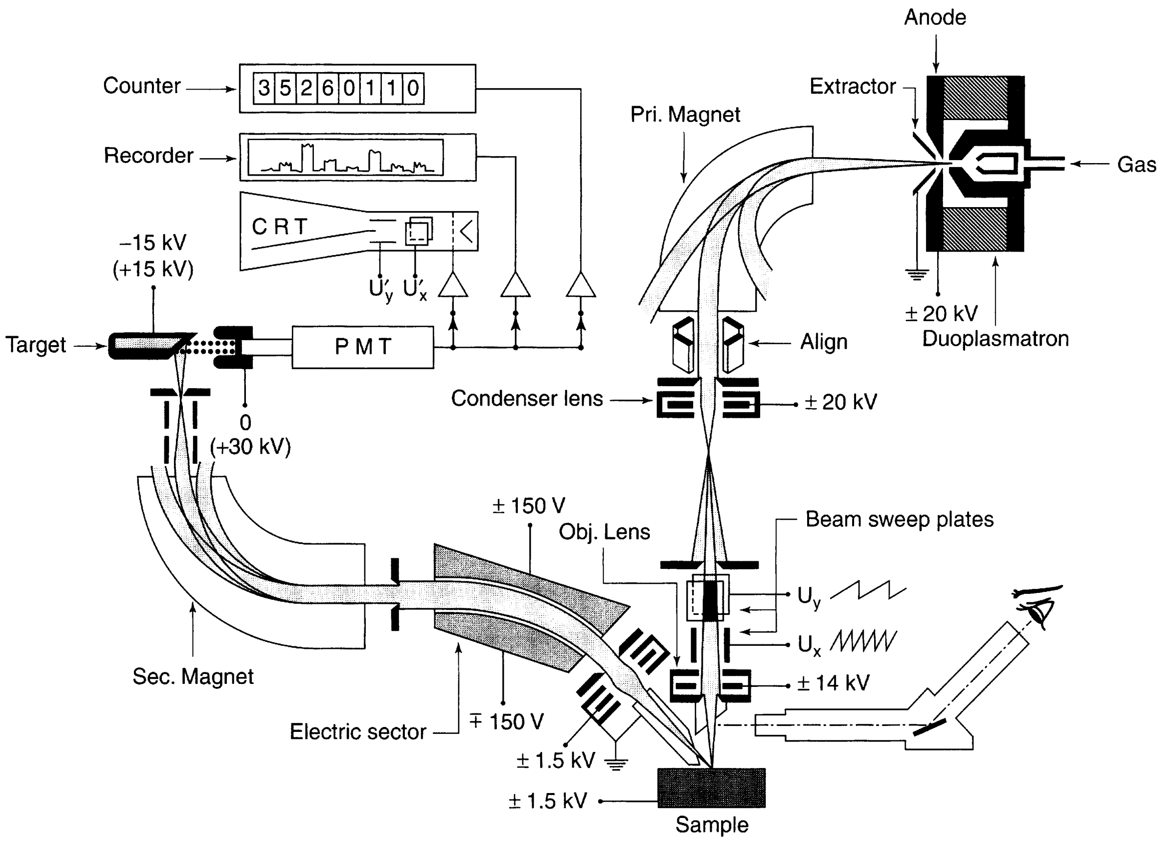

Fig. 1. Schematic representation of the ion microprobe mass analyzer. (*Bausch & Lomb/ARL*)

surface chemistry of the sample. When a metal such as aluminum is bombarded with ions of inert gas such as argon, the yield of positive aluminum ions falls exponentially with time. The ability of the sample to yield positive ions is progressively destroyed by the bombardment. On the basis of the similar behavior of many metals under bombardment by inert gases, it was postulated that the production of sputtered ions is a function of the electronic properties of the surface. The ability to extract positive ions from the sample diminishes as the strongly bonded compounds formed on the surface of the sample through the chemisorption of reactive gases are removed by the eroding action of the bombarding ion beam. It has been shown that the production of positive ions may be maintained at a higher level by controlling the surface chemistry through a proper selection of the species of bombarding ions. Instead of destroying the necessary chemical compounds with an inert gas, it is possible to reconstitute them by bombarding with a reactive gas. Enhanced stable yields of sputtered positive ions of many pure elements have been produced, by bombarding them with beams of carbon, nitrogen, oxygen, chlorine, and iodine ions.

Figure 2 illustrates the relative sputtered ion intensities of some pure elements subjected to bombardment by oxygen ions $^{16}O^-$. The relative intensity for each isotope has been corrected only for its natural abundance.

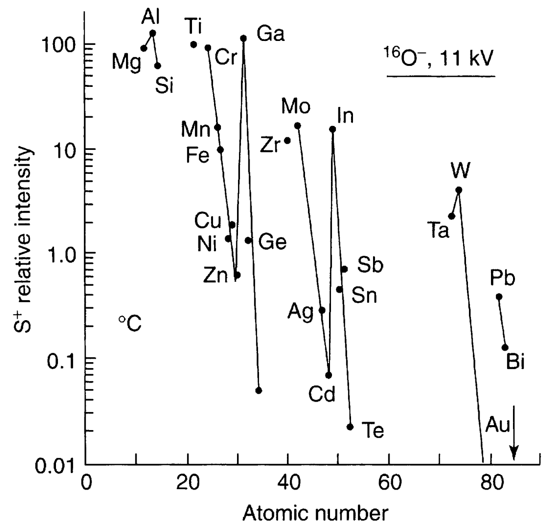

Fig. 2. Relative sputtered ion intensities of some pure elements subjected to bombardment by oxygen ions $^{16}O^-$

Application

Ion sputtering mass spectrometry has been applied to several problems in the analysis of solids with various types of instruments. These include studies of semiconductor devices as shown in Fig. 3, oxygen concentrations and concentration gradients and of processes of oxidation in a variety of metals, some catalytic and corrosion processes on metals, and the chemistry of trace elements in geologic specimens. The distribution of trace elements in lunar rocks has also been studied.

The ion microprobe has also been applied in a preliminary fashion to the rubidium-strontium dating technique. The correlation of the ion microprobe results with the independently determined isochron indicates that it may be possible to obtain useful results for samples on a micrometer scale from this dating technique.

The ion microprobe mass analyzer's unique features permit three dimensional microanalysis of all elements in the periodic table and in addition, the determination of their relative isotopic abundances in a given matrix. Both conductors and insulators may be analyzed. The instrument is applicable in many areas of the science of solid materials analysis. Most elements will have optimum yields in the spectrum of positive sputtered ions and will be detected in concentrations of parts per million in micrometer-sized sampling areas. Electronegative elements will be detected with similar sensitivities in the spectrum of negative sputtered ions but inert gases which are ionized with difficulty and have small electron affinities will be detected with considerably poorer sensitivities. In general, it is possible to measure isotope ratios without chemical separation of the constituent elements of the sample. A controlled sputtering process provides mono-layer resolution of depth profiles and also the ability to make precise in-depth analyses of thick and thin films. Detection efficiency of the instrument can yield quantitative accuracy in the parts per billion

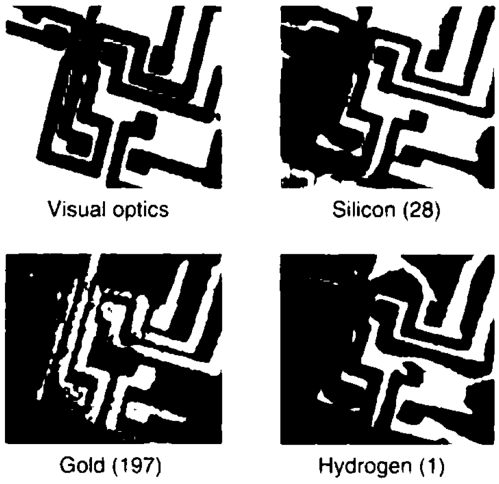

Fig. 3. Ion images of semiconductor device. (*Bausch & Lomb/ARL*)

range in many applications. The precision of an ion microprobe isotope ratio measurement depends basically upon the counting rates involved and its accuracy can approach its precision if auxiliary standards are used.

IONOMERS. The generic term *ionomer* was introduced by DuPont in 1964 in conjunction with the commercialization of the new Surlyn resins to denote a thermoplastic polymer containing both covalent and ionic bonds, and having properties influenced to substantial effect by the ionic bonding. Since that time, the meaning has been expanded to include many compositions such as the glass ionomers used in dentistry which cannot be melt processed. In the interest of clarity and consistency, it is proposed that the term ionomer be reserved for polymers having melt viscosities suitable for conventional melt processing methods. Descriptions such as ion-containing or ion-linked are appropriate for highly viscous or true thermoset materials.

Despite the broad scope of the field and the unusual property combinations obtainable, commercial exploitation has been confined mainly to the original family based on ethylene copolymers. Within certain industries, such as flexible packaging, the word ionomer is understood to mean a copolymer of ethylene with methacrylic or acrylic acid, partly neutralized with sodium or zinc.

Ethylene-Based Ionomers

Physical Properties. The semicrystalline, ethylene-based ionomers of commerce are flexible, transparent polymers notable for high strength and elasticity in both solid and molten states. The ionic bonding is completely reversible and has a strong influence on properties, even at temperatures well above the melting point.

Mechanical Properties. Table 1 shows the general range of mechanical properties available in commercial Surlyn ionomers. The substitution of acrylic acid for methacrylic acid has only minor effects on properties.

The issue of mechanical property changes over time has been addressed and a structural model has been developed. A correlation was established between stiffness and the size of an endotherm (T_i), normally seen in dsc scans of ionomers at about 50°C. This endotherm increases in size with increasing neutralization. The T_i endotherm disappears completely when the dsc measurement is repeated immediately, but then gradually reappears during room-temperature storage.

In addition to time-related effects, the solid-state physical properties are also affected by adsorbed water, which functions as a plasticizer. Water pickup is affected by the nature of the cation, with sodium ionomers absorbing about 10 times the level of the zinc equivalent under the same conditions.

TABLE 1. MECHANICAL PROPERTIES OF SURLYN IONOMERS

Property	Range
stiffness, MPa[a]	90–400
yield point, MPa[a]	8–20
tensile strength, MPa[a]	23–40
elongation at break, %	280–500
Shore D	54–70
brittleness temperature, °C	−100 to −140

[a] To convert MPa to psi, multiply by 145.

Crystallinity of Ionomers. Ionomers are much less hazy than the ethylene acid copolymers from which they are derived. Studies with optical and electron microscopes have shown that this is due to suppression of the spherulitic structure by the metal ions. Surprisingly, x-ray diffraction has shown that polyethylene crystallinity is present in the ionomers. A typical level of crystallinity is 30%.

Rheological Properties. The melt viscosity of an acid copolymer increases dramatically as the fraction of neutralization is increased.

Softening is apparent over a wide range, while the melt is strong and elastic. This gradual melting is beneficial in heat-sealing applications.

Infrared Spectra of Ionomers. Infrared absorption data, first published in 1964, show that partial neutralization of ethylene-methacrylic acid introduced new absorption bands at 1480–1670 cm^{-1} for the ionized carboxylate group while the 1698—cm^{-1} band of the free acid carboxyl diminishes in size. In addition to providing information on structural features, the numerous absorption bands are significant in applications technology, providing rapid warmup of film and sheet under infrared radiation.

Solubility of Ionomers. Ionic bonding with metal ions decreases solubility in organic solvents. At high neutralization levels with alkali metal ions, many ionomers spontaneously form colloidal suspensions in water when stirred vigorously at 100–150°C under pressure. These provide convenient methods for applying thin coatings of ionomers to paper and other substrates.

Electrical Properties. Due to the comparatively low content of polar groups, most commercial ionomers are very good insulating resins.

Permeability. Acid copolymers are less permeable to natural oils than conventional homopolymers, and this difference increases greatly when they are neutralized.

In the area of gas permeability, the low crystallinity of a typical ionomer (~30%) results in relatively high permeability to oxygen. For packaging of fresh meat this is advantageous, but in other packaging areas, combination with a barrier layer may be required.

Manufacture and Processing. Most commercial processes involve copolymerization of ethylene with the acid comonomer followed by partial neutralization, using appropriate metal compounds.

Many methods for the conversion of acid copolymers to ionomers have been described by DuPont. The chemistry involved is simple when cations such as sodium or potassium are involved, but conditions must be controlled to obtain uniform products. Solutions of sodium hydroxide or methoxide can be fed to the acid copolymer melt, using a high shear device such as a two-roll mill to achieve uniformity. All volatile by-products are easily removed during the conversion, which is run at about 150°C.

Economic Aspects. Worldwide production is of the order of 110,000 t.

Health and Safety Factors

During processing at elevated temperatures, normal precautions are needed to prevent accidental burns. Surlyn ionomers have U.S. Food and Drug Administration clearance for food contact.

Uses

Flexible packaging is the largest commercial application area for ethylene ionomers. The unusual resilience and roughness of ionomers have resulted in sporting goods applications, including golf ball covers and bowling pin coatings. Ionomers are easily foamed due to high melt strength, and the foams are durable, leading to uses in construction, skilifts, and softball cores.

Noncommercial Ethylene-Based Ionomers

Noncommercial ethylene-based ionomers include amine-linked and complexed ionomers and ethylene–dicarboxylic acid copolymers.

Ionomers Not Based on Ethylene

Ionomers not based on ethylene include styrene-based ionomers, EPDM-derived ionomers, butadiene–methacrylic acid ionomers, telechelic ionomers, pentenamer ionomers, bitumen ionomers, and polyoxymethylene ionomers.

ION RETARDATION. A process based on amphoteric (bifunctional) ion-exchange resins containing both anion and cation adsorption sites. These sites will associate with mobile anions and cations in solution and thus remove both kinds of ions from solutions. These ions may be eluted by rinsing with water. This process can make clean separations of ionic-nonionic mixtures. It has also been suggested for demineralization of salt solutions.

IPATIEFF, VLADIMIR N. (1890–1952). Born in Russia, Ipatieff was an army officer as well as a chemist. He was a member of the Academy of Science and carried out organic research at the Institute of Chemistry in Leningrad. He left the former U.S.S.R. under the Stalin regime and at the invitation of Gustav Egloff joined the Universal Oil Products Co. He and his close associate, Herman Pines, did basic development on catalytic alkylation and isomerization of hydrocarbons of the greatest importance for high-octane aviation gasoline.

IRIDESCENCE. The exhibition of the colors of the rainbow, commonly by interference of light of the various wavelengths reflected from superficial layers in the surface of a substance.

IRIDIUM. [CAS: 7439-88-5]. Chemical element symbol Ir, at. no. 77, at. wt. 192.22, periodic table group 9 (transition metals), mp 2,410°C, bp 4,130°C, density 22.42 g/cm^3 (solid at 17°C), 22.8 g/cm^3 (single crystal at 20°C). Elemental iridium has a face-centered cubic crystal structure. The two stable isotopes of iridium are ^{191}Ir and ^{193}Ir. The ten unstable isotopes are ^{187}Ir through ^{190}Ir, ^{192}Ir, and ^{194}Ir through ^{198}Ir. In terms of earthly abundance, iridium is one of the scarce elements. Also, in terms of cosmic abundance, the investigation by Harold C. Urey (1952), using a figure of 10,000 for silicon, estimated the figure for iridium at 0.0025. No notable presence of iridium in seawater has been found. The element was identified and named by Tennant (England) in 1804.

Electronic configuration

$$1s^2 2s^2 2p^6 3s^2 3p^6 3d^{10} 4s^2 4p^6 4d^{10} 4f^{14} 5s^2 5p^6 5d^9.$$

Metallic Ir is not attacked by any mineral acid unless it is very finely divided. It can be brought into solution by fusion with indium at 800–1000°C to give a soluble alloy. When fused with Na_2O_2 or an alkaline oxidizing flux, water-soluble irradiates(IV) are formed. The finely divided metal is oxidized by air or O_2 at red heat to the dioxide, which decomposes into its elements at higher temperature. The valences of Ir are 1–6, the 3 and 4 valences being most common.

Iridium black is only slightly soluble in aqua regia. When fused with alkalies and alkaline nitrates or Na_2O_2, the metal is converted to an acid-soluble form. The metal at red heat reacts to a small extent with O_2, S, and P. At elevated temperature, the metal is attacked by Cl_2 and F_2. When fused with NaCl and treated with Cl_2, the water-soluble sodium hexachloroiridate(IV), Na_2IrCl_6, is formed.

Iridium(III) hydroxide is a yellow-green or blue-black compound soluble in alkali and insoluble in water. It is made by adding KOH to a solution of potassium hexachloroiridate(III), K_3IrCl_6, in an inert atmosphere. When the trihydroxide is heated, a mixture of iridium(IV) oxide and the metal is formed. Iridium(III) oxide, Ir_2O_3, is made by fusing potassium hexachloroiridate(IV) with Na_2CO_3 and then leaching the mixture with water. At about 1100°C, both the oxide and the hydroxide decompose into the metal and O_2. When a solution of Ir is heated with $NaBrO_3$ at a pH of approximately 6, the dark-blue precipitate $Ir(OH)_4$ or $IrO_2 \cdot H_2O$ is formed. This water-insoluble compound, when heated to 350°C in N_2, loses its H_2O and is converted to the black oxide, IrO_2.

When iridium(III) chloride is heated in Cl_2 at 773–798°C, iridium(I) chloride is formed. The copper-red crystals are insoluble in acids and alkalies. The compound sublimes in Cl_2 at 790°C and decomposes into Cl_2 and metallic Ir. Iridium(II) chloride is stable from 763 to 773°C. The brown crystals are insoluble in H_2O, acids, and alkalies. Iridium(III) chloride is an insoluble green compound made by reacting the elements at about 600°C. The reaction is catalyzed by CO. Iridium(III) chlorides are prepared by reducing the corresponding iridium(IV) chlorides with oxalate or SO_2. Iridium(III) bromide is made by dissolving iridium(III) hydroxide in HBr. The blue solution yields olive-green crystals of $IrBr_3 \cdot 4H_2O$. When heated, the anhydride is formed. The triiodide is formed in analogous fashion as a trihydrate. Iridium(IV) chloride can be made in solution by the action of Cl_2 or aqua regia on ammonium hexachloroiridate(III). The relative insolubility of ammonium hexachloroiridate(IV), $(NH_4)_2IrCl_6$, makes it useful in the purification of Ir. The compound may be reduced in H_2 to the metal. The analogous sodium salt is very soluble, and the potassium salt is relatively insoluble.

Iridium(VI) fluoride is made from the element at 300–400°C. The bright yellow solid melts at 44°C and boils at 53°C. Potassium hexafluoroiridate(V) also has been prepared. Iridium fluoride can be made by heating the hexafluoride with the metal in a sealed tube at 150°C or heating it with glass above 200°C, at which temperature the glass reduces it to the tetrafluoride. This yellow solid melts at 106–107°C and boils above 300°C. Iridium(III) fluoride is formed by reducing the tetrafluoride with glass for 12–18 hrs. at 430–450°C.

Iridium(II) sulfide is formed by burning the metal in sulfur or by heating a higher sulfide at 700°C in N_2. This black solid is insoluble in H_2O, acids, and aqua regia. Iridium(III) sulfide, Ir_2S_3, is formed as a brown-black insoluble precipitate by passing H_2S through a hot acidic solution of an iridium(III) chloride. The precipitation is usually not quantitative. This amorphous black solid is not attacked by HNO_3 but is slowly dissolved by aqua regia or fuming HNO_3. The brown insoluble iridium(IV) sulfide, IrS_2, is partly formed by treating a tetravalent Ir solution with H_2S; when it is prepared in this way, some iridium(III) sulfide also is formed by reduction. Iridium(III) sulfate can be formed by dissolving iridium(III) hydroxide in H_2SO_4 in the absence of air. Trivalent iridium forms numerous cationic and anionic complexes in which it has a coordination number of 6. The amines are extremely stable and, once formed, difficult to destroy. Tetravalent Ir also forms complex ions, but to a lesser extent.

Iridium As a Key to Mass Extinctions

Airborne particles from the January 1983 eruption of Kilauea (Hawaii) volcano indicated exceptionally large concentrations of selenium, arsenic, indium, gold, and sulfur, as expected from a volcanic eruption. Unexpected were exceptionally high levels of iridium. Investigators found that the ratio of Ir to Al was about 17,000 times its value in the associated Hawaiian basalt. Inasmuch as Ir enrichments had not previously been detected in volcanic eruptions, Zoller et al. (1983) suggested that the Kilauea volcano may be part of an unusual volcanic system which may be fed by magma from the mantle. The researchers further suggested that the Ir enrichment may be linked with the high fluorine content of the volcanic gases, indicating that the Ir was released as volatile IrF_6.

In recent years, Zoller and associates (University of Maryland) have studied six active volcanoes (Augustine, Mount St. Helens, El Chichón, Arenal, Poas, and Colima) and have found no evidence of Ir enrichment. The new Kilauea evidence of volcanic action as an Ir source tends to conflict with that of other researchers who have generally attributed the Ir anomaly to an extraterrestrial source, such as resulting from a cataclysmic meteorite or asteroid impact, notably in connection with the Cretaceous-Tertiary (K-T) boundary layer.

Much of the theorizing pertaining to mass extinctions of flora and fauna during the past history of the earth has been based upon finding

Ir anomalies. Currently, scientists are attempting to establish the order of mass extinctions. Present opinions seem to suggest that the extinction of terrestrial fauna, including the dinosaurs, was an event that followed rather than occurring concurrently with the catastrophe met by many marine species. See also **Chemical Elements**; and **Platinum and Platinum Group**.

IRON. [CAS: 7439-89-6]. Chemical element symbol Fe, at. no. 26, at. wt. 55.847, periodic table group 8 (transition metals), mp 1,535°C, bp approximately 2,750°C, density 7.874 g/cm3 for the pure solid (20°C); 7.92 for a single crystal of a-iron. Iron has a body-centered cubic crystal structure (a-iron).

Iron is a silver-white metal, capable of taking a high polish; ductile; malleable; can be welded when hot. Pure iron is attracted by a magnet, but does not retain the magnetism. Silicon steel is preferred for electromagnets because it retains magnetism even less than pure iron. See also **Magnetism**. The discovery of iron was prehistoric. There are nine isotopes of iron, 52Fe through 60Fe Isotopes 54, 56, 57, and 58 are fully stable, whereas four others have fairly short half-lives, ranging from 8.9 minutes (53) to 2.94 years (55). The half-life of 60Fe is approximately 3 × 105 years. Iron has valence numbers of 2+ (ferrous) and 3+ (ferric). The hardest of the ductile metals, iron is surpassed only by cobalt and nickel in tenacity. Iron is an extremely versatile construction and engineering material and serves both in relatively pure forms, such as malleable and wrought iron, and in many hundreds of iron-base alloys of major importance, including the numerous types of steel.

Electronic configuration is 1s 22s 22p 63s 23p 63d 64s 2. First ionization potential is 7.896 eV; second 16.5 eV. Oxidation potentials: $Fe \rightarrow Fe^{2+} + 2e^-$, 0.441 V; $Fe \rightarrow Fe^{3+} + 3e^-$, 0.036 V; $Fe^{2+} \rightarrow Fe^{3+} + e^-$, −0.771 V; $Fe + 2OH^- \rightarrow Fe(OH)_2 + 2e^-$, 0.877 V; $Fe(OH)_2 + OH^- \rightarrow Fe(OH)_3 + e^-$, 0.56 V; $Fe(OH)_4^- + 4OH^- \rightarrow FeO_4^{2-} + 4H_2O + 3e^-$; E = 0.55 V (80°C; 40% NaOH). Metallic radius, 1.2412 Å; ionic radius Fe 2+, 0.80 Å, Fe3+, 0.67 Å. Other important physical properties of iron are given under **Chemical Elements**. See also Table 1.

Three allotropic forms of iron are known: (1) *alpha iron*, which is present below 769°C; (2) *gamma iron*, which exists between 906° and 1,404°C, and (3) *delta iron*, which occurs between 1,404° and 1,536°C. On slow cooling, the reverse changes occur, but may be slowed or partly or entirely prevented in the presence of alloying elements.

In terms of abundance in the earth's crust, iron ranks fourth, being estimated as comprising about 5% of the weight of igneous rocks. Of course, only a very small portion of this large amount of the element in the earth's crust is obtainable as iron ore. In terms of cosmic abundance, the estimate of Harold C. Urey made in 1952 put iron as number 9 among the elements, having a figure of 7,250 related to a base for silicon of 10,000. Iron is ranked number 23 among the elements in terms of its presence in seawater, an estimated 47–48 tons per cubic mile (10.2–10.4 metric tons per cubic kilometer) of seawater. In this regard, it is approximately equal with aluminum, molybdenum, and zinc.

TABLE 1. SELECTED PHYSICAL PROPERTIES OF IRON

Electrical Properties	
Electrical conductivity, volume, % of annealed copper at 20°C	17.75
Electrical resistivity, microohm-cm,	
at 0°C	8.9
at 2s0°C	9.7
Temperature coefficient of electrical resistance (0–100°C)	0.65×10^{-4}
Electrode potential (standard hydrogen scale), at 25°C, volts	−0.44
Electrochemical equivalent, milligrams/second-absolute amperes	
Fe^{2+}–Fe	0.1929
Fe^{3+}–Fe	0.2893
Magnetic susceptibility, at 820°C	1.000 × 106
Thermal Properties	
Emissivity, at 0.65 micrometers, %	40
Heat of combustion, cal/gram atom	88,355
Latent heat of fusion, cal/gram	65.5
Latent heat of vaporization, cal/gram	1.598
Specific heat, at 25°C, cal/(°C)(gram atom)	6.55
Thermal conductivity, at 0°C, (cal)(cm)/(second)(cm^2)(°C)	0.18
Thermal expansion, linear coefficient,	
cm/(cm)(°C)	11.76×10^{-6}
in/(in)(°F)	6.53×10^{-6}
Average coefficient of linear expansion, at 77°F,	
cm/(cm)(°C)	12.3×10^{-6}
in/(in)(°F)	6.83×10^{-6}
Mechanical Properties	
Brinell hardness, at 25°C, 99.9% Fe	82–100
Percent elongation, at 25°C, 99.9% Fe	30–40
Yield strength, psi, at 25°C, 99.9% Fe	10,000–20,000
Tensile strength, psi, at 25°C, 99.9% Fe	30,000–40,000
Modulus of elasticity, psi	28.5×10^6
Modulus of rigidity, psi	11.64×10^6
Poisson's ratio	0.28
Other Properties	
Density, liquid, at 1564°C,	
g/cm^3	7.00

2,500 Å	38
10,000 Å	65
Surface tension, at 1,550°C, dynes/cm	1,835 1,865
Thermal-neutron-absorption cross section, barns	2.53
Viscosity, cP,	
at 1,743°C	4.45
at 1,390°C	7.85

Iron Ores

Iron occurs abundantly in several materials, mainly in the form of oxides, carbonate, silicates, and sulfides. These are shown in Table 2. Most of the ores shown in the table are described under separate alphabetical listings in this volume. Briefly, the major iron-bearing materials are:

Magnetite, Fe_3O_4, corresponding to 72.4% Fe and 27.6% O_2, dark gray to black, sp gr 5.16–5.18, strongly magnetic, permitting magnetic exploration methods. Some ores contain small amounts of titanium whereupon they are referred to as titaniferous magnetite.

Hematite, Fe_2O_3, corresponding to 69.94% Fe and 30.06% O_2, steel gray to dull red or bright red, earthy to compact or crystalline, sp gr 5.26, most important of iron ores, occurs widely in many types of rocks of varying origin.

Ilmenite, $FeTiO_3$, corresponding to 36.8% Fe, 31.6% Ti, and 31.6% O_2, iron-black, opaque, generally mined for titanium with iron as a byproduct, also called iron titanate.

Limonite, mineralogically composed of various mixtures of the minerals *goethite* and *lepidocrocite*, $HFeO_2$ and FeO(OH), respectively. Goethite contains 62.9% Fe, 27% O_2, and 10.1% H_2O, sp gr 3.6–4.0, commonly yellow or brown to nearly black, compact to earthy and ocherous. Limonites are important sources of iron throughout the world.

Siderite, $FeCO_3$, corresponding to 48.2% Fe, 51.8% CO_2, sp gr 3.83 3.88, white to greenish-gray and brown, contains variable amounts of calcium, magnesium, and manganese, varies from dense, fine-grained and compact to crystalline, sometimes referred to as spathic iron ore, or black-band ore. The carbonate ores are calcined

TABLE 2. PRINCIPAL IRON-BEARING MINERALS

Class and mineralogical name	Chemical composition of pure mineral	Common designation
Oxides		
Magnetite	Fe_3O_4	Ferrous-ferric oxide
Hematite	Fe_2O_3	Ferric oxide
Ilmenite	$FeTiO_3$	Iron-titanium oxide
(Goethite)	$HFeO_2$	
Limonite		Hydrous iron oxides
(Lepidocrocite)	$FeO(OH)$	
Carbonate		
Siderite	$FeCO_3$	Iron carbonate
Silicates		
Chamosite		
Stilpnomelane		
Greenalite	Various: often complex	Iron silicates
Minnesotaite		
Grunerite		
Sulfides		
Pyrite (iron pyrites)	FeS_2	
Marcasite (white iron pyrites)	FeS_2	(Iron sulfides)
Pyrrhotite (magnetic iron pyrites)	FeS	

before they are charged into the blast furnace: frequently contain sufficient lime and magnesite to be self-fluxing.

Silicate Group Ores. There are comparatively few silicates with iron as the principal base. Often they have a rather complex chemical formula, with sp gr higher than 2.8, occurring in various shades of green or black tones. Important iron-silicate minerals are *chamosite, stilpnomelane, greenalite, minnesotaite,* and *grunerite*. Presently of minor importance as a source of iron.

Sulfide Group Ores. The principal materials in this group are *pyrite, pyrrhotite,* and *marcasite*. Pyrite, FeS_2, corresponding to 46.6% Fe, 53.4% S, sp gr 4.95–5.10, is pale brass yellow, and the most widespread of the iron sulfides. Pyrrhotite (magnetic pyrite), varies in composition from FeS to FeS +S, typically contains 59.4% Fe, 40.6% S, bronze yellow to copper red, frequently tarnished, and is often considered an indicator of nickel deposits because of common association with pentlandite. Marcasite (white iron pyrites), FeS_2, corresponding to 46.6% Fe, 53.4% S, is pale brass yellow, commonly associated with limestones, clays, and lignite deposits. It differs from pyrite only in its crystal structure and greater chemical instability. Iron sulfides sometimes are mined for their sulfur content: more commonly because of their association with other valuable metallic elements, such as copper, nickel, zinc, gold, and silver. Iron sometimes is recovered as a byproduct.

Geology and Genesis of Iron Deposits. Iron ores have a wide range of formation in geologic time as well as a wide geographic distribution. They are found in the oldest known rocks of the earth's crust, with an age in excess of 2.5 billion years, as well as in rock units formed in various subsequent ages. Iron ores are forming presently where iron oxides are being precipitated in marshy areas, and where magnetite placers are being formed on certain beaches. Thousands of iron deposits are known throughout the world. The deposits range in size from a few tons to many hundreds of millions of tons. Many of the world's largest deposits of iron ore are located in the oldest geologic series, the Pre-Cambrian.

Iron ores occur in igneous, metamorphic or sedimentary rocks, or as weathering products of various primary iron-bearing materials. For convenience of analysis, iron ores are grouped into (1) igneous ores, (2) contact ores, (3) hydrothermal ores, (4) sedimentary ores, with several subclassifications of the latter ores. Brief definitions follow:

Igneous Ores. These were formed by crystallization from liquid rock materials, either as layered-type deposits that possibly are the result of crystals of heavy iron-bearing minerals settling as they crystallize to form iron-rich concentrations, or as bodies which show intrusive relationship with their wall rocks. These ore bodies may be tabular or irregular and are composed largely of magnetite with varying amounts of hematite.

Contact Ores. Iron-ore deposits formed at or near the contact between igneous rocks and sedimentary rocks, the latter usually limestones, are commonly composed of magnetite and hematite with associated carbonates and pyrite. The ore deposits are commonly in the sedimentary rocks as irregular or tabular replacement bodies.

Hydrothermal Ores. Iron-ore deposits formed by hot solutions which transported iron and replaced rocks of favorable chemical composition with iron minerals to form irregular ore bodies, commonly in limestones, are termed hydrothermal deposits. The iron often occurs as siderite, or sometimes as oxides.

Sedimentary Ores. There are six subclassifications:

Bedded Ores. These often are composed of oölites of hematite, siderite, iron silicate, or less commonly, limonite in a matrix of siderite, calcite, or silicate. They have a wide geographic distribution associated with other sedimentary rocks. They sometimes contain fossils and fine grains of sand. They often have a fairly high phosphorus content and may be self-fluxing.

Siderite Ores. These ores consist of beds of siderite or siderite nodules associated with shales. They are common in coal-associated beds and commonly contain associated sulfides, with a fairly high sulfur and phosphorus content.

Placer Ores. Iron oxides, when compact, are rather resistant to weathering and erosion, and under favorable conditions may form placer deposits, which, in relatively few instances, constitute iron ores. Generally they are of rather minor importance as sources of iron.

Bog Iron Ores. Bog ores occur in many swampy areas, particularly in glaciated areas in Europe, Asia, and North America. They occur commonly as dark-brown, cellular masses, or granular or fine particles of limonite. Once important when iron furnaces were local and small, they have ceased to be of commercial importance.

Metamorphic Ores. These ores include sedimentary iron-ore deposits, which have been metamorphosed, as well as ores associated with metamorphic rocks, in which the origin of the ore is obscured by recrystallization. Essentially all of the Pre-Cambrian sedimentary iron formations are of this type.

Residual Ores. These ores are commonly products of the surficial weathering of rocks, but may include ores formed by hydrothermal oxidation and leaching. Ores of this kind were formed extensively in Pre-Cambrian iron formations by leaching of silica, which commonly constituted in excess of 50% of the rock. Oxidation changes iron carbonate, silicate minerals, and magnetite to hematite or limonite.

Principal World Iron Deposits

Name and/or Type of Ore	Location
Kerchoölitic limonite	Crimea, Russia
Salzgitter limonite and hematite	Germany
Minette limonite and hematite	France, Germany, Luxembourg
Blackband ironstones	British Isles
Siegerland siderite	Germany
Clinton hematites	Alabama (U.S.A.)
Wabana oölitic hematites	Newfoundland
Minas Gerais hematite	Brazil
Krivoi Rog hematites	Ukraine, Russia
Bihar, Orissa, and Bastar hermatites	India
Labrador hematite	Quebec, Labrador (Canada)
Lake Superior taconites, jaspilites, hematites, and magnetites	Michigan, Wisconsin, Minnesota (U.S.A.) Ontario (Canada)
Cerro Bolivar and El Pao hematites	Venezuela
Kirunavaara magnetite	Sweden
Hematites	Australia

Iron Ore Processing. Two major developments have occurred during recent years because of the increasing needs for iron: (1) increased search for new supplies of high-grade iron ores, and (2) expansion of iron-ore pellet-plant production, particularly in those industrial nations where supplies of high-grade ores have diminished. More recently, iron ore has

been shipped in slurry form in ocean-going tankers. Once the slurry, containing about 75% solids, settles, the excess water is pumped off, leaving a nonshifting cargo in the hold of about 92% solids. Upon arrival at the receiving port, the cargo is reslurried with high-pressure water jets. Considerable savings in dockside loading and unloading expense are thus effected.

Beneficiation. This is a term that describes all processes used to improve the chemical and physical characteristics of ore (not limited to iron ore) for later use. In the case of iron ore, beneficiation makes the ore better for handling by the blast furnace. The principal methods include crushing, screening, blending, grinding, concentrating, classifying, and agglomerating. Concentration operations include jigging, flotation, and magnetic separation. A blast furnace operates best with a permeable burden, which permits not only a high rate of gas flow, but also a uniform gas flow with minimum channeling of the gas. Agglomeration improves burden permeability and thus the gas-solid contact in the furnace. This reduces blast-furnace coke rates and increases the rate of reduction. Agglomeration also decreases the amount of fines blown out of the blast furnace, thus reducing the load on the gas-recovery system.

Practice has shown that the best agglomerate for a blast furnace will contain about 60% or more of iron, a very minimum of undesirable constituents, and a minimum of material larger than 1 inch. However, the agglomerate must have sufficient strength to withstand degradation while in stockpiles and during transportation and handling. The target is to have the material arrive at the blast furnace, after prior handling, with about 85–90% of the material over 1/4 inch. The agglomerate must be able to withstand the high temperature and the degradation forces within the furnace without slumping or decrepitating. Further, the agglomerate should be reasonably reducible so that a satisfactory reduction rate can be maintained in the furnace.

There are four major types of agglomerating processes: (1) sintering, (2) pelletizing, (3) briquetting, and (4) nodulizing. The first two processes have been most popular.

Sinter consists of small particles of iron-bearing materials, which are fused or fritted together at high temperature. The latter is achieved by burning carbon in the form of coke breeze in a sintering-machine feed mix. Optionally, fluxing material may be added to eliminate later additions to the blast furnace. A number of materials can be converted by sintering, such as flue dust, naturally fine ores, ore fines from screening operations, and other iron-bearing material of small particle size. A continuous sintering process is shown in Fig. 1.

A traveling grate conveys a bed of ore fines or other finely divided iron-bearing material intimately mixed with approximately 5% of a finely divided fuel, such as coke breeze or anthracite. Near the head or feed end of the grate, the bed is ignited on the surface by gas burners and, as the mixture moves along the traveling grate, air is pulled down through the mixture to burn the fuel by downdraft combustion. As the grates move continuously over the windboxes toward the discharge end of the strand, the combustion front in the bed moves progressively downward. This creates sufficient heat and temperature (1,310–1,480°C) to sinter the fine ore particles together into porous, coherent lumps. Sinter plants with a suction area of up to 5,200 square feet (483 square meters) a strand width of 17 feet (5.2 meters) and a production capacity of about 20,000 tons per day have been built.

In the pelletizing process, the agglomeration of material is effected prior to heat treatment. A green, unbaked pellet or ball (glomerule) is formed and hardened by heating. The iron ores to be pelletized are ground finely to present an adequate surface area for the formation of green balls and mixed with water and a binding agent, such as bentonite clay. A small amount of fine solid fuel may be added to the pellet mix or coated on the pellets to furnish part of the heat required. Oxidation of a pelletized magnetite concentrate to hematite during the firing step may also furnish a substantial portion of the heat requirements. The optimum moisture content for pellets is a function of fineness and use of additives, but usually ranges from 9–12%. To improve pellet strength, soda ash, limestone, or dolomite may be added. Hardening of pellets is effected in several ways, including a traveling-grate, as shown in Fig. 2, a combined grate and rotary kiln, or a shaft furnace. As illustrated by Fig. 3, ore beneficiation operations usually require large amounts of water.

Chemistry of Iron

Reduction of iron ores in preparation of iron and steel making is described under **Iron Metals, Alloys, and Steels**.

With its $3d^64s^2$ electron configuration, iron forms Fe^{2+} and Fe^{3+} ions, the latter, involving the removal of one 3d electron. The ferrate ion, FeO_4^{2-}, containing hexavalent iron, is unstable in acidic solution, being a very strong oxidizing agent.

Three oxides of iron are known, FeO, Fe_3O_4, and Fe_2O_3 although pure FeO does not exist. The actual composition of iron(II) oxide may be

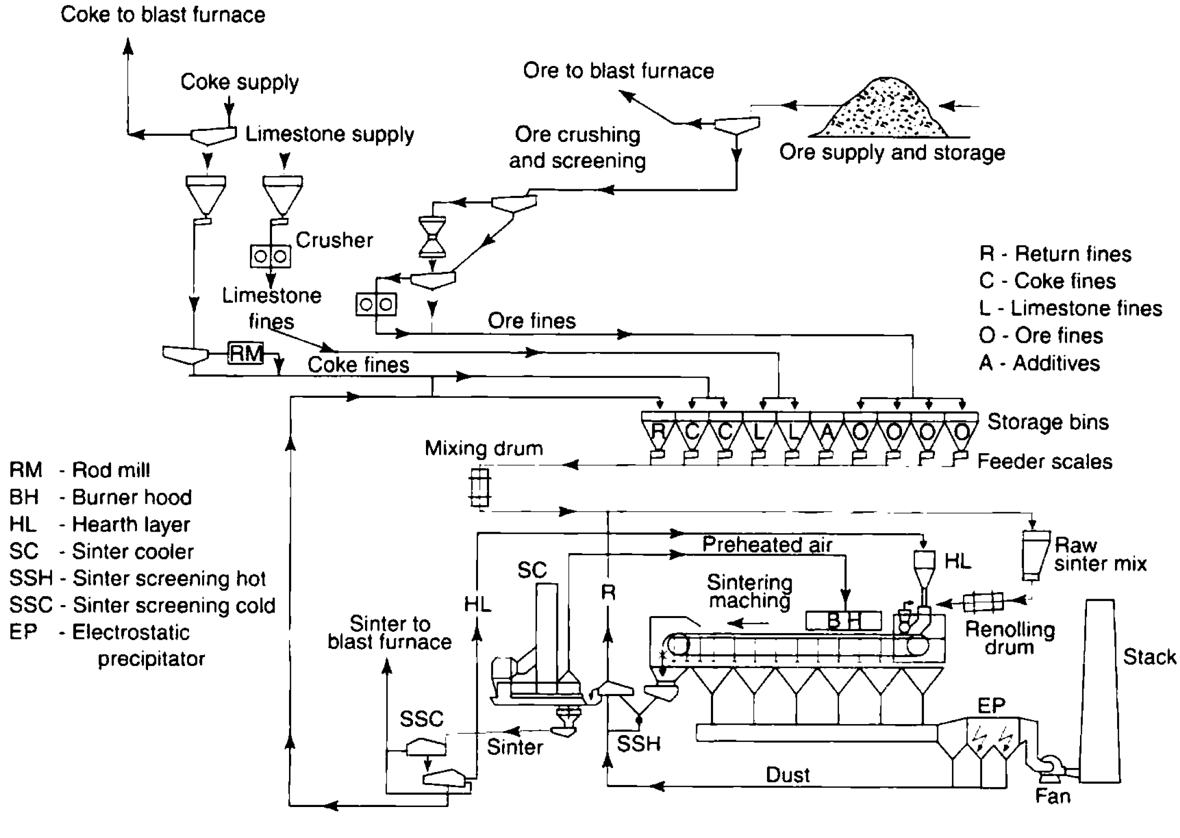

Fig. 1. Schematic flow diagram of continuous iron-ore sintering process. (*Metallgessellschaft A.G.*)

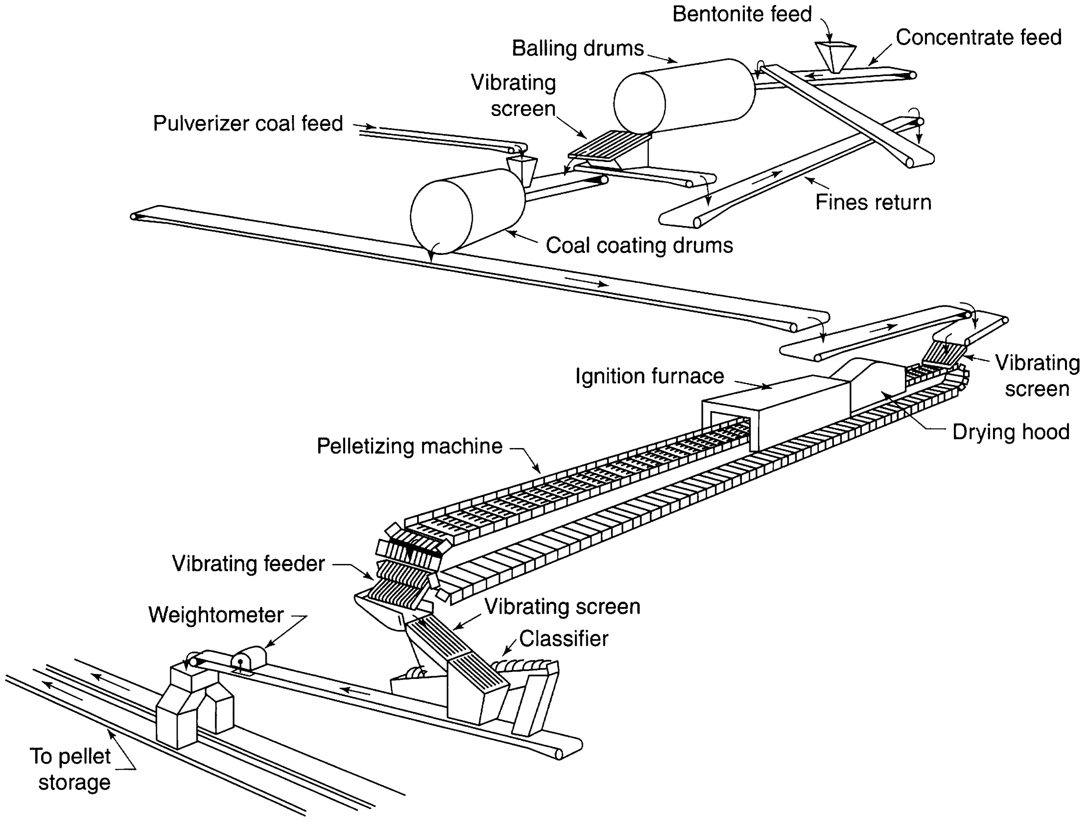

Fig. 2. Pelletizing process in which a traveling grate is used

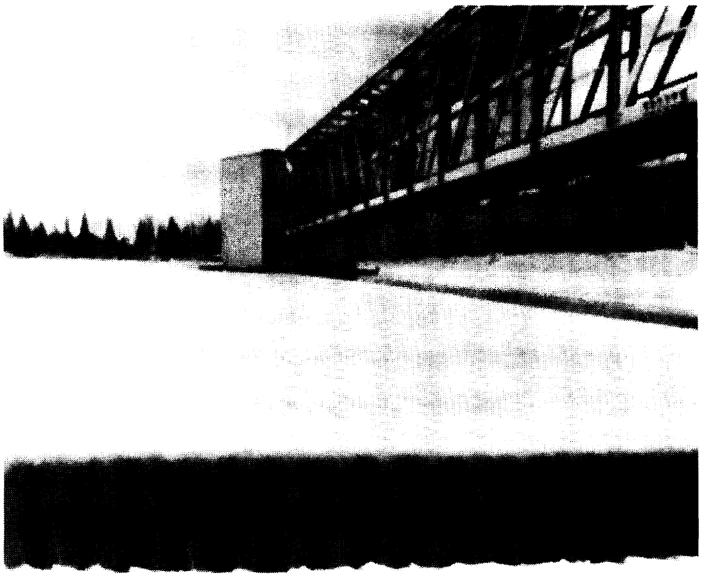

Fig. 3. The beneficiation of taconite ore on the iron range requires large volumes of water in concentrating by magnetic separation. To eliminate massive waste-disposal problems, huge thickeners, such as the 300-foot (91.5-meter) diameter caisson unit shown here, are used. This system will handle over 70 million gallons (265 million liters) per day or 50,000 gallons (189,250 liters) per minute of liquid and 250 tons per day of suspended solids. Clarifying the waste tailing stream permits reclamation of water on a large scale for plant reuse

approximated by replacement of a small proportion of the Fe(II) atoms by two-thirds their number of Fe(III) atoms. If the operation is continued until three-quarters of the Fe(II) atoms have been replaced, then the composition Fe_3O_4 is reached, which may thus be described by the formula $Fe^{2+}(Fe^{3+}O^{2-}O^{2-})_2$. Continuation of the replacement until all the Fe(II) atoms have been replaced yields α-Fe_2O_3. The γ-allotrope of Fe_2O_3 and the compound Fe_3O_4 are both ferromagnetic.

Iron(II) sulfide, FeS, also may show considerable departure from stoichiometric proportions, exhibiting an electrical conductivity when in large crystals that resembles an alloy rather than a sulfide. Iron(III) sulfide, Fe_2S_3, cannot be prepared in solution in pure form, because of the oxidizing action of Fe^{3+} upon H_2S, and even upon S^{2-} ions in alkaline solution, and when Fe_2S_3 is prepared by reaction of dry H_2S and the hydrated Fe_2O_3, it breaks up into FeS and FeS_2. The latter is made up of Fe^{2+} and $S_2{}^{2-}$ ions, and the mineral, pyrites, it has a cubical structure composed of these ions.

Iron forms dihalides with all four of the common halogens, and trihalides with all but iodine. FeF_2 and $FeCl_2$ are readily formed in anhydrous state by action of the hydrogen halide upon the heated metal, and the others can be made directly from the elements. The iron(III) halides, like iron(III) salts generally, are more readily hydrolyzed than the corresponding ferrous compounds, due to the smaller size and greater change of the Fe^{3+} than the Fe^{2+} ion.

Other elements with which iron forms binary compounds, especially at higher temperatures, are boron, carbon, nitrogen, silicon, and phosphorus. Like FeO, these compounds often depart slightly or even considerably from daltonide composition, frequently being interstitial compounds, and in higher elements of groups VB and VIB, merging into the interstitial compound-solid solution picture which iron exhibits with the transition metals.

The oxyacid salts of iron(III) are more numerous than those of iron(II). Among the former, the sulfates are of interest because of the readiness with which iron(III) sulfate replaces aluminum sulfate in the alums, which are hydrated double sulfates formed by certain trivalent and alkali metal (and other monovalent) sulfates. Iron(III) sulfate, $Fe_2(SO_4)_3$, is isomorphous with aluminum sulfate, $Al_2(SO_4)_3$, because the radius of the Fe^{3+} ion is so close to that of the Al^{3+} ion (0.57 Å). For that reason, the isomorphous relationship extends to other salts, i.e., the fluorides and some of the nitrates.

Like the neighboring elements of group 8, iron forms large numbers of complexes. This is due to the availability of two $3d$ orbitals in Fe^{2+} and Fe^{3+} to form hybrid orbitals with the $4s$ and $4p$ orbitals to yield spin-paired complexes (the so-called "covalent" or "inner" complexes).

Many ions contain iron combined with oxygen atoms or hydroxyl groups and are known, respectively, as ferrates or hydroxyferrates. Those of iron(II) include $FeO_2{}^{2-}$, $Fe(OH)_4{}^{2-}$, and $Fe(OH)_6{}^{4-}$, while those of iron(III) include $FeO_2{}^{-}$, $Fe_2O_4{}^{4-}$, and $Fe(OH)_8{}^{5-}$. Their compounds are also called ferrates, except that the name ferrite is used for such compounds of iron(III) as MFe_2O_4, in which M is a divalent metal, this last type of

compound being used to form magnetic cores because of their low core losses when properly fabricated. See also **Ferrites**.

The complexes of iron(II) are commonly octahedral (formed by d^2sp^3 hybridization), and include chelate and other cyclic compounds as well as monocyclic ones. The most stable of the latter are the ferrocyanides, or hexacyanoferrates(II), containing the $Fe(CN)_6^{4-}$ ion, which is a spinpaired, diamagnetic complex. It is produced by reaction of cyanides with Fe^{2+} solutions. The Fe^{2+} diammine ion, $Fe(H_2O)_4(NH_3)_2^{2+}$ is a spin-free complex, and is paramagnetic. Divalent iron forms several pentacyano complexes, which contain an ion (such as NO_2^- or Cl^-) or a molecule (NH^3, CO, or H_2O) besides the five cyano groups. Examples are $[Fe(CN)_5NO_2]^{4-}$ and $[Fe(NH_3)_5Cl]^+$. A complex with a single nitroso group in addition to H_2O occurs in $Fe(NO)^{2+}$, formed by reaction of Fe^{2+} and NO.

The ferric ion also forms many octahedral complexes. A spin-paired type is the ferricyanide (hexacyanoferrate(III)) ion, $Fe(CN_6)^{3-}$, while a spin-free type is the hexafluoroferrate ion, FeF_6^{3-}.

The effect of coordination in stabilizing higher states of oxidation is seen in the occurrence of iron(IV) in certain cationic complexes, such as $[Fe(Cl)_2 \bullet 2C_6H_4(As(CH_3)_2)_2](FeCl_4)_2$ (cf. the corresponding nickel(IV), Ni(IV), complex).

Iron forms polydentate chelate compounds with a number of organic substances, including the oxalates, dipyridyl and orthophenanthroline. Such a structure is found in hemoglobin.

Iron forms a number of carbonyls in which its atomic charge number is zero, $Fe(CO)_5$ being produced by heating iron powder with carbon monoxide under pressure, and $Fe_2(CO)_9$ and $Fe(CO)_{12}$ being prepared from it. These iron carbonyls are reactive, yielding hydrogen compounds, e.g., $H_2Fe(CO)_4$ with alcoholic potassium hydroxide; halogen compounds, $Fe(CO)_4X_2$, with halogens; amino or substituted-amino compounds $Fe(CO_2)_n(Am)_{5-n}$, where Am is an amino group, with ammonia, pyridine or ethylenediamine. Iron carbonyls form compounds with R_3P, R_3As, R_3Sb, or diphosphines, etc., such as *o*-phenylenediarsine. They also form nitroso derivatives; such as $Fe(CO)_2(NO)_2$, and mercaptides, such as $Fe_2(C)_6(SC_2H_5)_2$. In strong acids (e.g., liquid hydrofluoric acid), $Fe(CO)_5$ gives $Fe(CO)_5H^+$ with the proton attached directly to the iron atom.

Iron also forms a series of similar nitrosyls, such as $Fe(NO)_4$, which is probably $[NO^+][Fe(NO)_3^-]$, $Fe_2(NO)_4I_3$, $Fe(NO)_2I$, $Fe(NO)I$, $Fe(NO)_3Cl$, $Fe_2(NO)_4(SA)_2$, where A=H, a metal, a sulfonate group, an alkyl or aryl group. $M^I[Fe(NO)_2S]$ (Roussin's red salt), $M^I(Fe_4(NO)_7S_3]$ (Roussin's black salt), obtained by treating the red salts with alkali. $Fe(NO)_2SR$, where $R=C_2H_5$ or C_6H_5, $M^I(Fe(NO)\ SSO_3]$ and others described under hexacyanoferrates.

By heating powdered iron with cyclopentadiene

$$\overline{CH=CH-CH=CH-CH_2}$$

the compound ferrocene, insoluble in water, soluble in organic solvents, consisting of two cyclopentadienyl radicals connected to an iron atom, C_5H_5-Fe-C_5H_5 is prepared. It is of great interest because the iron atom is sandwiched between the two parallel and symmetrical rings with delocalized bonding. Alkali metals produce salts of the type $M^IFe(C_6H_5)_2]$, powerful reductants. Halogens produce water-soluble ferrocenium salts, such as $[Fe(C_5H_5)_2]Cl$. From both of these, sigma-bonded alkyl and aryl derivatives, such as $Fe(C_5H_5)_2CH_3$, can be obtained in which the alkyl group is attached directly to the iron atom.

IRON (In Biological Systems). Iron plays a number of vital roles in plants and animals. Unlike some of the minerals, research on the functions of iron have been studied for several decades.

Iron and Crops

Iron deficiency is a serious problem in crop production in certain regions of the world and some nutritionists consider iron deficiency anemia to be one of the most frequently observed mineral element deficiency conditions in humans. But iron fertilization of soils is not likely to be effective in decreasing the incidence of this deficiency. The reasons for this apparent contradiction are based upon the behavior of iron at several stages in the food chain.

In the United States, severe iron deficiency in crop plants occurs most frequently on the alkaline soils of the western states and on very sandy soils, although some plants, especially broad-leaved evergreens, are sometimes iron deficient on many other kinds of soils. Iron deficiency is rarely due to a total lack of iron in the soil. It is nearly always due to the low solubility of the iron that is present. For example, some soils that are red from iron compounds may contain too little available iron for normal plant growth. The relative susceptibilities of cultivated crops to iron deficiency are listed in Table 1.

To correct iron deficiency in plants, it is usually necessary to add a soluble form of iron to the soil or to spray the foliage. Since soluble iron

added generally will revert to insoluble forms, these procedures for plants are only temporarily effective. Soil treatments that make alkaline soils more acid, such as incorporating large amounts of sulfur, may offer a more lasting correction. Incorporating large amounts of manure into soil makes the iron more soluble and may be effective in correcting iron deficiency, particularly in fine-textured alkaline soils.

Iron-deficient plants are generally stunted and chlorotic, i.e., normally green leaves are yellow or streaked with yellow. When the iron deficiency is treated by adding soluble iron to the soil, the plants turn green, grow larger and yield more, but sometimes the concentration of iron unit weight of plant material may be no higher than in the stunted, iron-deficient plants. Thus, in terms of forage plants, correction of iron deficiency in the plant does not necessarily improve the plant as a source of dietary iron. The iron-treated plants, however, may contain a higher concentration of carotene or provitamin A than the yellow, stunted, deficient plants. Thus, iron fertilization can be more useful in improving the vitamin A than the iron level in diets.

In livestock, iron deficiency is most common in young pigs raised in confinement on concrete floors. Injecting iron compounds and painting the sow's udder with iron compounds are measures used to prevent this deficiency. Grazing animals seldom suffer from iron deficiency unless they are heavily parasitized.

Synthetic chelates and some natural organic complexes tend to resist the adverse effects of soil reactions, climate, and management practices that change available iron into unavailable forms. Natural organic complexes, including some lignin sulfonates and polyflavonoids, or synthetic chelates of iron tend to remain in an available form during most of the growing season. Synthetic chelates are mobile, however, and may be lost from the root zone if subjected to excessive leaching due to overirrigation or high rainfall. Not all iron chelates behave the same in soils, since some are differentially fixed onto clay particles. Fixed chelates do not function in delivering iron to plants. Stability or resistance to decomposition of metal chelates is related to soil pH. Some chelates tend to release their iron more readily than others. For application to calcareous soils of pH 7.5 or higher, the principal iron chelate that will correct iron deficiency for most dicotyledonous plants is FeEDDHA or other similar compounds which have high metal chelate stability. Commercial sources of iron for agricultural application include:

Inorganic Sources: Ferrous sulfate; ferric sulfate; ferrous carbonate; ferrous ammonium sulfate; iron frits.

Chelates: FeEDTA (ethylenediaminetertraacetic acid); FeHEDTA (hydroxyethylethylenediaminetriacetic acid)

Organic Complexes: Lignin sulfonate; methoxy phenylpropane complex; polyflavonoid

During recent years, more emphasis has been placed on testing soils for iron deficiency. A commonly used test, developed at Colorado State University, employs a solution of the chelating agent DTPA (diethylenetriaminepentaacetate) and calcium chloride buffered at pH 7.3 for extracting the soil under test. For testing larger areas, a new method of detection and visual assessment of iron chlorosis or deficiency symptoms in growing crops has been developed. This involves aerial infrared photography which records distinctive color differences between chlorotic and normal green plants. Assessment of a spotty chlorotic field by proportion (percent) and three-dimensional projection makes possible economic evaluation of the iron deficiency problem existing in any given field on a large-scale basis. See also **Fertilizer**.

Iron in Human Physiology

The bioavailability of iron has been researched extensively. Investigators have found this to be quite variable because numerous factors influence absorption of iron, including the consumer's needs and the composition of the diet. Chemical factors that affect iron availability include the valence, solubility, and degree of chelation or complex formation of the iron. Researchers have shown that the ferrous valence is considerably more available than the ferric valence. Others have shown that prior to absorption in the gut, iron must be in solution. Further, it has been demonstrated that chelation may augment iron absorption by maintaining the iron in solution under conditions where it would otherwise be insoluble. Because of more ready availability, ferrous sulfate is used in bread and flour enrichment even though it has a greater reactivity with foods. Ascorbic acid has been shown to increase iron availability when in the diet.

Iron Absorption. The iron content of the normal adult human is dependent on the size of the individual and the hemoglobin concentration. The distribution of iron in a male weighing 155 pounds (~70 kilograms) has been estimated at just under 3.5 grams. About 64% of this iron is in hemoglobin as part of the peripheral blood; and 2.5% as hemoglobin in the bone marrow. Another 4% is present as myoglobin which also participates in oxygen transport and storage. Another 13% is present as ferritin and 16% as hemosiderin, which are storage forms. Extremely small amounts are found in cellular cytochrome and in the enzyme catalase.

It is generally agreed that iron is absorbed from the most part in its ferrous form directly into the bloodstream. Radioactive iron has been shown to be absorbed from any portion of the intestinal tract, but its uptake appears greatest in the duodenum. On the basis of experiments done on the absorption of iron from the intestinal tract of guinea pigs, it was earlier postulated that iron is taken into the mucosa cells and ferritin is formed by a combination of a protein, *apoferritin*, with iron. After the cell is saturated with ferritin, absorption no longer takes place until the iron of ferritin is transferred to plasma. For a number of years, this concept of a mucosal block was the accepted explanation for iron absorption. However, later research showed that there is no absolute block to iron absorption. It is found that the absorption of iron in patients and in experimental animals is greater than normal in iron deficiency and in cases where erythropoiesis is accelerated, even when the body iron reserves are elevated. Later evidence indicated that the ferritin concentration in the intestinal mucosa neither controls nor blocks absorption. An active transport mechanism requiring energy is concerned with iron transfer across the intestinal mucosa.

The factors involved in the absorption of iron in food are more complex than those involving inorganic iron. To obtain Fe^{59}-marked foods, radioactive iron has been injected into hens to obtain labeled eggs and meat; plants have been grown in media containing Fe^{59}, and Fe^{59}-enriched bread has been prepared. It has been shown that iron-deficient subjects absorb more food iron than normal subjects. Absorption from liver, hemoglobin, muscle, and "enriched" bread is greater than from eggs or plants. Most probably, the low absorption from egg yolk derives from the presence of a ferric iron-phosphate complex. In such research, large variations in results have been obtained.

In the presence of a large amount of ascorbic acid (vitamin C), the absorption of iron is appreciably enhanced, because of the reduction of Fe^{3+} to the Fe^{2+} form. In the presence of phosphates, carbonates, and phytates, insoluble iron compounds are formed, thus reducing absorption.

It has been estimated that normal subjects ingesting a mixed diet containing 12–15 milligrams of iron retain 5–10% (0.6–1.5 milligram), whereas iron-deficient patients retain 10–20% (1.2–3 milligrams) iron.

Iron Transportation. After iron enters the bloodstream, it is immediately bound by a specific plasma protein that is a β_1-globulin. This protein, *transferrin* (siderophilin), has a molecular weight of about 90,000 and binds two atoms of ferric iron. About 0.25 gram of transferrin in 100 milliliters of plasma is capable of binding about 300 micrograms Fe^{3+}, but normally it is only one-third saturated while the remaining two-thirds are unbound reserve. If a small amount of ionized iron is injected intravenously, it is bound by the transferrin, which may be completely saturated. If the binding limit is exceeded, ionized iron exhibits toxic effects. The transferrin concentration is increased in iron deficiency and during the latter half of pregnancy; it is decreased during infection and a variety of other disorders.

Electrophoretic studies show there are several genetically controlled variants of human transferrins. They all deliver iron in an equivalent manner for utilization and storage. Evidence indicates that iron may be transferred directly to the developing erythroblast. It has been demonstrated that transferrin-bound iron is utilized by reticulocytes for hemoglobin formation. The transfer of iron is not maximal until 25% of the transferrin is saturated.

Excretion. The total loss of iron from an adult is about 1 milligram daily and is distributed in sweat, feces, hair, and urine. Since approximately 1 milligram of iron is normally absorbed daily, the organism is in iron balance. The loss of red cells from the body in normal menstruation would account for 16–32 milligrams of iron, which would amount to an average daily loss of from 0.5–1.0 milligram during the 28-day menstrual cycle. Pregnancy would also represent a loss of iron from the body, but this is compensated by the absence of menstruation. During normal hemoglobin catabolism, about 20–25 milligrams of iron are released per

day. The excretion of minute amounts of iron allows the body to conserve and reutilize the iron for the synthesis of hemoglobin. This tenacious conservation has been demonstrated repeatedly by radioactive techniques.

Enzymes. Heme serves as the prosthetic group for catalase, peroxidase, cytochrome oxidase, and the related cytochromes. Catalase and peroxidase iron are presumably present in the ferric form while the iron of the cytochromes may exist in the reduced or oxidized form. A number of flavoproteins, including succinic dehydrogenase, contain iron in the molecule. Iron appears to act as coenzyme for aconitase. A number of other enzymes require the presence of iron for their activities.

Storage Iron. Ferritin and hemosiderin represent practically all the iron present in the reticulo-endothelial cells of the liver, spleen, and bone marrow and in the parenchymal cells of the liver. Ferritin is an iron protein complex containing up to 23% iron. It is composed of a protein, which has a molecular weight of 450,000 and a colloidal ferric-hydroxide-phosphate complex. Preparations of hemosiderin granules contain up to 40% iron and are insoluble in water. It appears to be an iron-loaded organelle, such as mitochondrion. The granule contains a small amount of ferritin, but the remaining material is composed of heterogenous proteins.

Hemoglobin. The approximate formula (molecular weight >52,000) is $(C_{738}H_{1166}FeN_{208}S_2)_4$. Hemoglobin is the respiratory protein of the red blood cells. It transfers oxygen from the lungs to the tissues and carbon dioxide from the tissues to the lungs. Its affinity for carbon monoxide is over 200 times that for oxygen. Hemoglobin is a conjugated protein consisting of approximately 94% globin (protein portion) and 6% heme. Each molecule can combine with one molecule of oxygen to form oxyhemoglobin. The iron (in the heme portion) must be in the reduced (ferrous) state to enable the hemoglobin to combine with oxygen. Heme $(C_{34}H_{32}FeN_4O_4)$ is the nonprotein portion of hemoglobin and myoglobin, consisting of reduced (ferrous) iron bound to protoporphyrin. See also **Hemoglobin**.

Iron Deficiency Disorders

Iron deficiency may occur from several causes, including loss of blood through hemorrhage, an iron-poor diet, or an inability to metabolize iron in a normal fashion. There are a few more complex disorders, some of which have hereditary vectors.

Nutritional Anemias. These disorders may result from nutritional deficiencies or decreased bone marrow function, both of which cause defective blood formation. The least severe but most common of these anemias results from an inadequate amount of iron required for red cell formation. The result is *microcytic hypochromic anemia*. About 100 milligrams of iron per day are needed for hemoglobin manufacture. About 85% of this iron may be obtained from the iron released by breakdown of older red cells. However, some iron is always lost in the excretions and thus must be made up by the diet. Where there is chronic blood loss, as in cases of ulcers or hemorrhoids, or where the iron may not be properly absorbed from foods, the need for iron may be greater. Milk, cereals, and many refined foods, unless artificially supplemented, do not contain much iron. Better sources of iron include meat and leafy vegetables. Iron deficiency is not uncommon.

A common form of iron-deficiency anemia frequently seen in young women during the last century was sometimes called chlorosis, or "green sickness" because of the peculiar hue of the skin. With the discovery that iron salts can effect a cure, the disease almost completely disappeared. Idiopathic hypochromic anemia is another iron-deficiency anemia associated with a lack of proper stomach acidity. When hydrochloric acid in the stomach is lacking, iron cannot be liberated from foods and converted into a form that can be absorbed. Administration of iron in proper form also alleviates this condition.

Iron in Pregnancy. During pregnancy, the mother must furnish greater volumes of blood to support herself and the developing baby. Blood volume is increased and causes dilution unless sufficient iron is available. Vomiting in early pregnancy may increase the danger of an iron deficiency. Usually, babies are born with adequate supplies of iron in their tissues to last several months. However, infants born of a mother with an iron deficiency have low reserve stores of iron and will require a diet that is supplemented with the proper amounts of iron. Milk is a poor source of iron, and infants strictly on a diet of milk almost invariably develop hypochromic anemias. Anemic babies are much more subject to infections, which may in turn further increase the anemia. Thus, such children should be treated early.

Infants with Iron Deficiency. B. Lozoff (Case Western Reserve University) and associates reported that "Several consistent results have emerged from five studies of the behavior and development of infant with iron-deficiency anemia, a condition that affects at least 20 to 25 percent of the world's babies." All five studies used careful definitions of iron status and included comparison groups without anemia. All showed that infants with anemia scored lower on tests of mental development administered before treatment than infants without anemia did.

Iron Overload. An inborn error of metabolism leads to the absorption of excess iron from a normal diet. Hereditary *hemachromatosis* is found mainly within the white population. Black people who live in sub-Saharan Africa, however, show a high incidence of this disorder. At one time, this was attributed to the high content of iron in a home-brewed beer. Recent studies show that it is a combination of a high-iron diet and hereditary disposition.

Thalassemia Major. Transfusion-dependent thalassemia major patients have abnormal growth and sexual maturation at puberty, presumably as a result of pituitary iron overload. Still poorly understood, this disorder is reported to respond well to deferoxamine iron chelation therapy, particularly if administered before the age of maturity.

Mitochondrial Myopathy. A general deficiency of iron may be implicated in mitochondrial myopathy, which is a complex disorder that affects muscular activity. It has been suspected for a number of years that the disorder is caused by a defect of mitochondrial-protein transport. H.H.V. Scharpa and a team of researchers (Royal Free Hospital, London) postulate that a deficiency of an iron-sulfur protein in muscle dehydrogenase may be the specific cause.

Iron Chelation Therapy in Cerebral Malaria. It is estimated that over 1 million children die from severe forms of malaria annually, notably in sub-Saharan Africa. Cerebral malaria is one of the most severe complications of malaria infection (*Plasmodium falciparum*). It is known that iron is an essential nutrient for promoting the growth of the infectious agent. Victor Gordeuk and a team of investigators report that the iron-chelating agent deferoxamine enhances the clearance of the *P. falciparum* parasitemia. Iron chelation inhibits peroxidant damage to the central nervous system, as previously tested in animals. Iron also serves as a redox agent in the generation of free radicals that mediate ischemic and hemorrhagic tissue energy. A report issued in November 1992 concludes: "Iron chelation therapy may hasten the clearance of parasitemia and enhance recovery from deep coma in cerebral malaria."

IRON METALS, ALLOYS, AND STEELS. Chemically pure iron is used essentially in powder metallurgy and for chemical applications where the element serves as a catalyst, or as a base ingredient for ferrous and ferric chemicals. Iron principally is used as the dominant ingredient of cast irons and steels. Iron-base alloys notably are known for their physical strength and toughness and, when compared with most other metals for similar applications, reasonable cost. The following properties depend upon the nature and extent of the ingredients, such as carbon, present in the alloys and also upon the mechanical and heat treatments given to the formed metals: (1) impact strength or brittleness, (2) cohesive strength, (3) compressive strength, (4) creep, (5) fatigue, (6) ductility, (7) hardness, (8) malleability, (9) shear strength, (10) yield strength, (11) torsional strength, (12) electrical conductivity, (13) thermal conductivity, (14) thermal stability, (15) thermal expansion, (16) corrosion resistance, (17) magnetic properties, and (18) heat treatability.

The iron metals family of products may be classified into: (1) *the pure irons*, such as ingot iron and wrought iron, which have only traces of carbon (see Table 1) and other elements, and are very ductile; (2) *cast irons*, which are alloys of iron and carbon, with or without other elements, and normally containing from 2.4 to 4.5% carbon; (3) *steels*, which are alloys of iron and carbon, with or without other elements, in which the carbon content seldom exceeds 1.7%; (4) *alloy steels* whose properties mainly are attributed to the presence of one or more elements other than carbon. There are other groups and numerous subgroups in the total iron metals family.

Ironmaking

The starting ingredients for the numerous iron metals are obtained in three major ways: (1) by smelting run-of-mine or beneficiated iron ore in a blast furnace, low-shaft furnace, or electric smelter to yield a liquid, molten product; (2) by reducing run-of-mine or beneficiated iron ore via direct reduction processes to produce sponge iron; and (3) by melting ferrous scrap in a cupola, electric furnace, or fuel-fired furnace. Inasmuch as the majority of iron ores are in the form of oxides of iron, the iron is obtained by employing suitable reducing agents to reduce the oxides. Reducing agents most often used are carbon, carbon monoxide, hydrogen, and hydrocarbons, such as methane. With carbon monoxide, the reduction is exothermic; with the other reductants, it is endothermic.

TABLE 1. TYPICAL ANALYSES OF PURE IRONS

Ingredient	Ingot iron	Electrolytic iron	Carbonyl iron	Hydrogen-purified iron
	PERCENT OF TOTAL			
Carbon	<0.020	0.006	0.0004	0.005
Manganese	<0.020	—	—	0.028
Phosphorus	0.005±	0.005	—	0.004
Sulfur	0.020±	0.004	—	0.003
Silicon	Trace	0.005	—	0.001
Copper	0.04±	—	—	—
Oxygen	Some	Some	<0.01	0.003
Nitrogen	0.004±	—	—	0.0001

Blast Furnace. For several decades, the blast furnace was the unchallenged producer of iron (pig iron) from iron ore. With the growing availability of steel scrap over the last several years, scrap as a source of iron for steelmaking became increasingly important, a fact which made electric furnace steel production, to be described later, very attractive. Blast furnaces are large, bulky structures that have been part of the integrated mill concept, a concept that has been threatened economically for several years. Blast furnaces are high-capacity producers and, consequently, essentially unsuited to the current philosophy of spreading steel production geographically (nearer the consumers). It is much easier to commence with scrap than to have to make pig iron. A number of the older style blast furnaces have been dismantled in recent years because of the growing dependability of scrap as a starting material. But, as pointed out later, all steel products do not represent potential usable scrap and, consequently, the iron ore reduction processes, including the blast furnace, will continue to be used in a number of locations.

A typical, traditional blast furnace is shown in Fig. 1. The furnace is a tall, refractory-lined vessel. Raw materials including iron ore (sinter or pellets), coke (the reducing and thermal agent), and limestone (for fluxing the gangue material) are charged into the top of the furnace. A blast of hot air is introduced at the bottom of the furnace to burn the coke and thus to heat, reduce, and melt the charge as it descends toward the bottom of the furnace. Liquid iron and slag collect in the furnace hearth. These materials are tapped at regular intervals. Although the furnace can be damped down for short periods, the process essentially is continuous. The waste gas contains about 28% carbon monoxide with a calorific value of about 90 Btu/cubic foot (800 kcal/cubic meter). After collection at the top of the furnace, dust is removed, and the gas is used as a fuel for heating the hot-blast stoves. Blast furnaces range from 100 to 10,000 tons/day in capacity; the hearth diameter may range from 9 to 46 feet (2.7 to 13.8 meters); the height from 50 to 150 feet (15 to 45 meters).

Air required for combustion is furnished by turboblowers and preheated in hot-blast stoves lined with refractory-brick checker-work. Commonly,

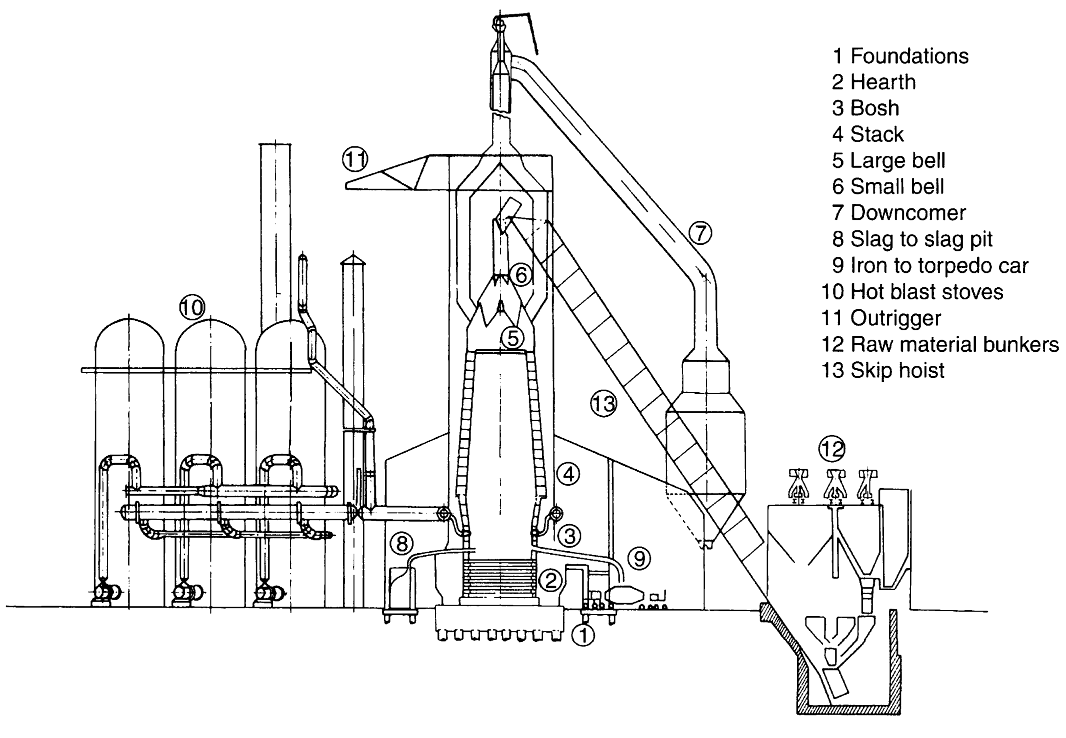

Fig. 1. Cross section of a traditional blast furnace plant

three stoves are used per furnace. The stoves are operated alternatively on a regenerative principle, one stove normally providing the hot blast while the other two stoves are heating up to temperature. The checkerwork provides the means for temporarily storing the rather large quantities of heat required. Fuel for the stoves includes the blast-furnace off-gas previously mentioned, augmented by coke-oven gas from a nearby coke-producing facility. The exact fuel-supply arrangement varies with local conditions. The hot blast is supplied by a gas main to a bustle pipe, which encircles the bosh and distributes it to water-cooled tuyeres located below the bosh for injection into the furnace. The metal is tapped into refractory-lined, open-top torpedo or kling-type ladles and thence transported to the pig-casting machine; or directly to the steel plant. A comparatively few blast furnaces are operated with charcoal instead of coke, but these are limited to a capacity of about 300 tons/day because of the low crushing strength of charcoal. Improvements in blast furnace operations over the last several years have resulted from better preparation of the charge, fuel injection through tuyeres, reducing-gas injection in bosh, and oxygen enrichment of blast.

Low-Shaft Furnace. These furnaces are circular or oval in cross section. The oval shape permits greater hearth area without increasing the required depth of penetration of the blast supplied through the tuyeres. Such furnaces are designed for finer raw materials and low-grade coke or lignite. Once considered ideal for small-scale iron production, only a limited number have been installed. The operating principles are essentially similar to those of a blast furnace.

Electric Smelter. Electric energy provides the heat in these designs. Low-grade coke can be used as the reducing agent. Electric smelters are generally limited to areas of low-cost electric power. The most commonly used furnaces of this type employ a submerged arc, using the Söderberg continuous self-baking electrodes. Developed by Tysland and Hole in Norway, the furnace is circular or rectangular in cross section with transformer ratings of up to 60,000 kVA. Production capacity can be increased and power and coke requirements lowered by preheating and prereducing the iron-ore charge.

Direct Reduction Process. Numerous schemes over the years have been attempted as an alternative to the blast furnace. These include rotary and stationary kilns and furnaces, reverberatory furnaces, retorts, fluid-bed reactors, pot furnaces, and jet smelting. Similarly a variety of reductants have been used, including lignite, coal, char, fuel oil, tar, and various gases. The direct reduction approach is essentially useful for producing a highly reduced product containing mostly metallic iron and little gangue material, thus providing a substitute for ferrous scrap for steelmaking operations.

SL/RN Process. In this process, using a rotary kiln and solid reductant, high-grade pellets or lump ores and anthracite are used. The ore or pellets, anthracite, dolomite or limestone, and return coal are fed to the rotary kiln. The temperature is controlled by means of shell burners which are furnished with air and gas or oil. A uniform temperature of about 1,100°C is maintained over about 60% of the kiln length. After leaving the reduction kiln, the charge is passed through a gastight seal into a water-cooled drum, whereupon it is cooled to a temperature below 100°C to prevent reoxidation of the sponge iron. Most of the sponge iron can be separated by screening, which is augmented by magnetic separators.

HyL Process. This batch-cyclic process reduces rich lump-iron ores by flowing a reducing gas in a fixed-bed reactor. The reducing gas may be prepared by steam reforming of natural gas or other hydrocarbons. A typical reducing gas may contain 74% hydrogen, 13% carbon monoxide, 8% carbon dioxide, and 5% methane (all volume percent). The process requires four reactors, each reactor following four steps in a 12-hour cycle: (1) removal of cold sponge iron and loading with fresh iron ore or pellets; (2) preheating and secondary reduction with partially spent reducing gas from another reactor; (3) primary reduction to sponge iron; and (4) cooling the sponge iron with fresh, cool reducing gas and controlled deposition of carbon where required.

Purofer, Midrex, and Armco Processes. These are continuous processes in which shaft furnaces are used. Iron ore or pellets are charged from the top and the reduced product is withdrawn from the bottom. The reducing gas may be generated by reforming natural gas, or methane rich gas from naphtha may be used. The hot reducing gas flows counter-current to the descending charge.

Fior and U.S. Steel Processes. Similar reducing gases are used in connection with a fluid-bed reactor. The iron ore may require further grinding and drying before introduction into the fluid bed. The reduced ore may be briquetted or used as fines.

Cupola. This type of furnace is widely used for making iron for casting in foundries and sometimes may be used to augment the iron required by steelmaking operations. A cupola may be operated for just a few hours/day, or up to 2 to 3 months continuously. A cupola is a vertical cylindrical shaft furnace that uses the countercurrent-flow principle to heat and melt the charge as it descends. Cupola capacity may range from 2 to 75 tons/hour. Unlike a blast furnace, a cupola is not a reducing unit, but is essentially used to melt ferrous scrap and cold pig iron or previously reduced sponge iron. The heat required is supplied by nearly complete combustion of coke. Air is injected through tuyeres near the hearth zone. Some cupolas are equipped for hot-blast supply through recuperators. The iron raw material is charged in alternate layers with coke. Limestone is added to flux the ash from the coke and form slag. The molten iron collects in the hearth and may be removed continuously or intermittently through a taphole.

Steelmaking

Raw materials for steelmaking include liquid iron, steel scrap, preproduced sponge iron, or mixtures of the foregoing ingredients. During the past quarter century, steelmaking has undergone numerous changes, essentially motivated by marked increases in energy costs, by the need for better production flexibility, and by the impact of worldwide competition, particularly by nations that could essentially commence serious production with modern technology rather than engaging in tremendously costly modernization of decades-old, large, and sprawling integrated mills. Essentially since the turn of this century, the traditional steelmaking countries such as the United States, United Kingdom, and Germany depended upon the integrated mill concept to produce vast tonnages of steel, largely a system that served them well during two world wars. The basic economics of the steel industry today are strikingly different, and altered economics, even more than the availability of technology, have brought about steel production changes. The competition of other metals and materials also has adversely affected the once-exclusive market for steels. The greater availability of steel scrap has also been a factor.

Historical Open-Hearth Process. For well over a century prior to the 1960s, the open-hearth process was the principal means for making steel. As of the late 1980s, open-hearth steels had dropped from well over 90% of total steel production to less than 10% of steel production. The attraction of the basic open-hearth system over many decades was versatility in handling a variety of raw materials required for most grades of steel. Raw material charges could be 100% scrap, 100% hot metal, or scrap and hot metal in all intermediate ratios.

In the open-hearth process, the iron is kept molten with gas burners for as long a period as needed for reaction of carbon in the metal with oxygen. Oxygen is added along with the gas fuel above the molten material. Oxygen can be added to the melt in the form of iron oxides, the latter sometimes derived from iron ore or rusty steel scrap. In the open-hearths still operating, the percentage of scrap has generally increased. In its many decades of use, the open-hearth process became a mature technology, having benefited from numerous technical improvements. But, these improvements were not sufficient to permit the open-hearth process to compete with other basic steelmaking processes.

Steel was also made for many years in Bessemer converters, wherein liquid iron was refined in a bottom-air-blown converter—a refractory-lined, pear-shaped, cylindrical vessel open at the top to permit charging of materials and to allow the escape of gases. In this process, a considerable amount of heat was wasted in heating the nitrogen in the air. The Bessemer process could melt only 5 to 10% scrap. The nitrogen content of Bessemer steels was high and oxygen-steam or oxygen-carbon dioxide mixtures were used instead of air to produce low-nitrogen steels.

Basic Oxygen Process (BOP). In this process, almost pure oxygen is blown at high velocity onto the surface of the molten iron. Conversion to steel occurs roughly ten times faster than with the open hearth. The BOP produces heat as the oxygen combines with the carbon in the molten metal, which occurs at a very fast reaction rate. Thus, supplemental fuel is not required to keep the melt from solidifying during its conversion to steel. In 1960, only 3% of steels produced in the United States were by BOP. A basic oxygen steel plant is shown in Fig. 2.

In this process, molten iron is refined to steel by top-blowing oxygen at high pressure onto the surface of the metal through a water-cooled lance contained in a tilting furnace. The oxidation of carbon, silicon, manganese,

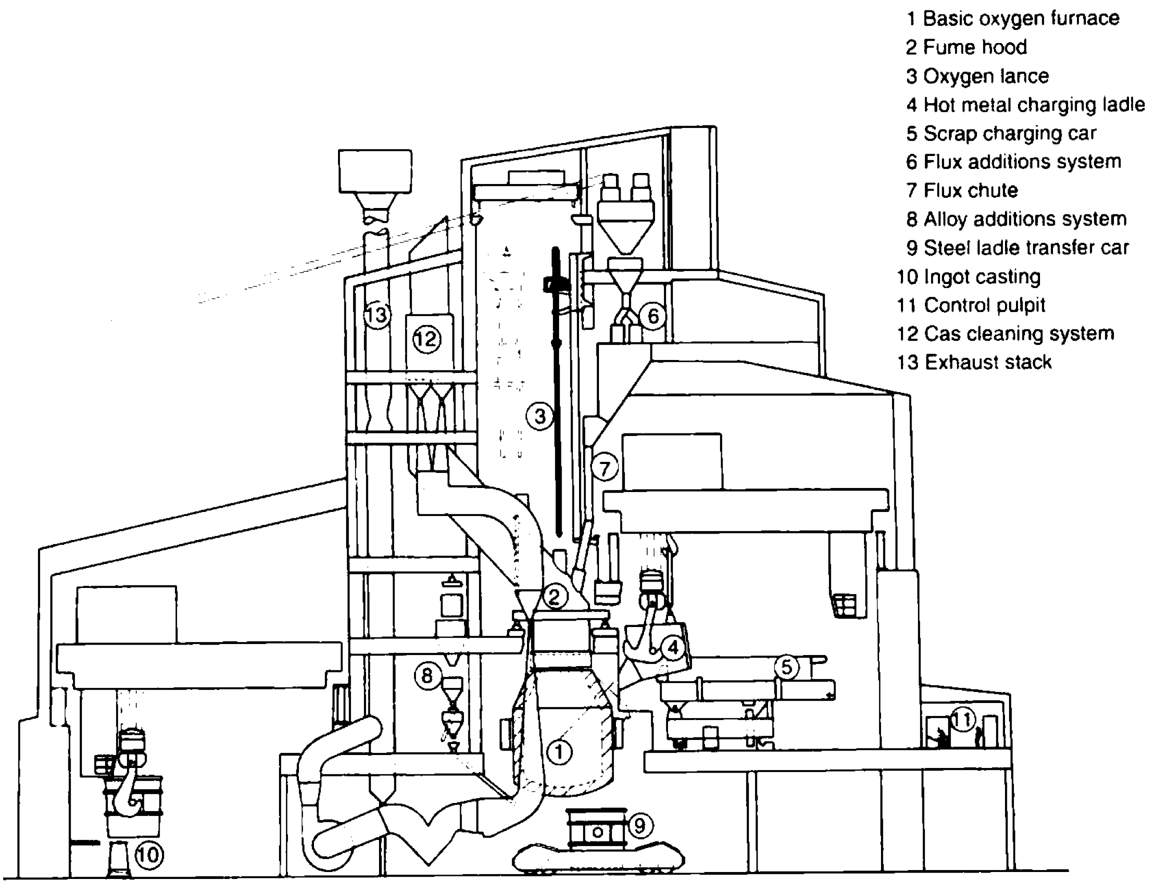

Fig. 2. Section through basic oxygen steelplant

and phosphorus provides sufficient heat for converting molten iron into steel. Because of the excess heat generated, up to about 30% scrap can be charged. A conventional basic oxygen process can refine iron containing up to 0.3% phosphorus into most grades of steel. Where the phosphorus content is higher, a modified process uses injection of powdered lime with the oxygen stream, or double slagging is required. A basic oxygen furnace with 300-ton capacity is shown in Fig. 3.

Numerous modifications of the BOP have appeared during recent years. For example, the OBM/Q-BOP, LWS, and SIP processes have been developed which use bottom blowing of oxygen and a shielding hydrocarbon through tuyeres in the bottom of the converter vessel. The endothermic dissociation of hydrocarbon by its cooling effect prevents excessive refractory wear in the tuyere area. The result is a substantial increase in the life of the bottom refractory plug. The OBM process was initially developed in Germany. The designation Q-BOP, introduced in the United States after further development work, is intended to emphasize the advantages of the new process compared with the Basic Oxygen Process (BOP). The letter, Q, stands for "quiet, quick, quality." Natural gas, propane, or liquefied petroleum gas are used as the gaseous hydrocarbon shield injected through an outer concentric gap around the central oxygen tuyere. A similar development, preferably using fuel oil as a hydrocarbon shield, is termed the LWS process. The OBM tuyere is successfully inserted in the bottom of an open hearth furnace for injecting oxygen into the metal bath for refining. This relatively new steelmaking technique is known as SIP (submerged injection process).

In the Kaldo process developed in Sweden, the refining of molten iron to steel is carried out in a titled pear-shaped basic-lined converter. Oxygen is blown at an oblique angle to the metal bath through a water-cooled lance. Much of the carbon monoxide produced by the carbon/oxygen reaction is burned inside the converter. The heat generated is absorbed by the rotating vessel and transferred to the bath, thus providing a high thermal efficiency and allowing up to 40% scrap in the charge. Both low- and high-phosphorus irons can be handled. Refractory consumption is high, tending to reduce the availability of the furnace.

In the Rotor process, a long cylindrical horizontal vessel, rotating at 1 to 5 rpm, is used. Oxygen is injected by two lances, one carrying high-purity oxygen into the bath, the other carrying low-purity oxygen for burning the carbon monoxide evolved by the refining reaction. While the configuration differs, the operating principle is essentially similar to the Kaldo process.

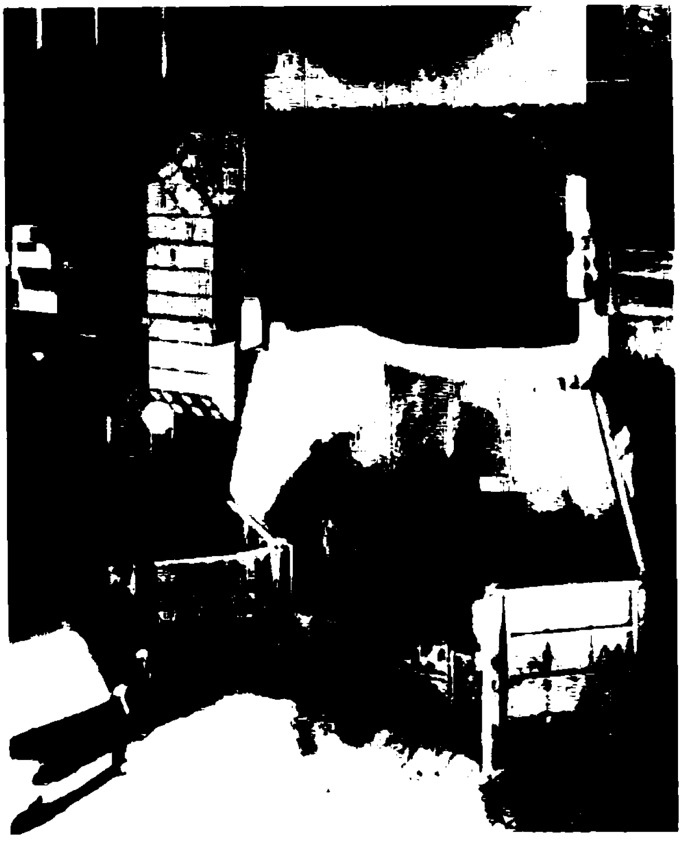

Fig. 3. A basic oxygen furnace of 300-ton capacity. (*Davy McKee Iron & Steel Division, Stockton-on-Tees, England*)

A drawback of the basic oxygen process is its limitation of about 30% scrap in its charge. This amount of scrap in the steel mix is often barely adequate to utilize the scrap produced at the manufacturing plant per se. As a result, other sources of scrap are recycled in electric furnaces. These other sources include scrap from industrial operations (i.e., arising from the manufacture of finished products such as automobile body parts), and scrap reclaimed from discarded or obsolete steel-containing equipment such as automobiles and rail cars. Thus, basic oxygen steel production, primarily from pig iron, and electric steel production from scrap complement each other in utilizing different raw material resources.

Electric Furnace Processes. Electric furnaces have been used for several decades to produce special steels for which the open-hearth process was not suitable.

Direct-arc electric furnaces are widely used. Essentially, the furnace is a tilting cylindrical bowl-shaped hearth with three graphite electrodes inserted vertically through the roof. The electrodes are supplied with three-phase current via a transformer. Heat is supplied by the arc struck between the charge and the electrodes. The arc temperature is approximately 3,400 C. The furnace is highly versatile, in that operation may be under oxidizing, reducing, or neutral conditions. The versatility is comparable to that of the open-hearth process. Some electric furnaces operate with liquid iron in the charge, but the majority use steel scrap and prereduced pellets.

With very high power input operation and transformer ratings of up to 100,000 kVA, common grades of steel, requiring single slag practice only, can be produced in up to 300-ton heats in less than 3 hours. Special steels also are made in induction furnaces where a current of high or medium frequency is passed through a coil surrounding a refractory crucible containing the charge.

Spray Steelmaking Process. In this process, liquid iron is poured through a tundish and refined continuously by injecting powdered lime and oxygen tangentially from a ring onto the surface of the metal stream.

FOS Process. In the fuel-oxygen-scrap process, a vessel similar in shape to an electric-arc furnace is used, but having a greater height-to-diameter ratio. There is a removable roof to permit rapid charging of scrap. Heat is supplied by an oxyfuel burner inserted through a central opening in the roof.

Additional processes include the Wocra and the Irsid processes which are based upon continuous melting and/or refining techniques. The cyclosteel and jet-smelting processes make liquid iron by flash smelting of iron ore.

TABLE 2. AVERAGE ENERGY REQUIREMENTS FOR PROCESSING STEPS IN THE PRODUCTION OF RAW STEEL

Operation	Energy requirement (MBtu Ton)**
Ore beneficiation	1.7
Ore transport	0.5
Blast furnace	14.6
Steel production	
open hearth	4.1
basic oxygen process	1.3
electric process	5.3
Scrap processing and transport	0.6

* Use of electricity counted at 10,600 Btu/kWh.
** 1 Btu = 0.252 kilogram-calorie or 1055 joules.

TABLE 3. ENERGY REQUIRED PER TON OF RAW STEEL PRODUCED*

Steel process	Energy use, MBtu per Ton of raw steel**
Open hearth	14.9
Basic oxygen process	15.1
Electric process	6.3

* By taking into account the actual amounts of pig iron and raw steel used in each process, and the energy associated with those inputs, the total energy required to produce steel by the various methods can be computed.
** 1 Btu = 0.252 kilogram-calorie or 1055 joules.
Source: Electric Power Research Institute, Palo Alto, California, August 1986.

Comparison of Process Energy Requirements. Energy requirements for the various steps in raw steel production are shown in Table 2. When the energy requirement for each step is weighted according to the different proportions of raw materials used in the three basic processes just described, the total amount of energy per ton of raw steel is determined to be about 15 MBtu per ton for the open hearth and basic oxygen processes, compared to about 6.3 MBtu per ton for electric melting. See Table 3. Note that the value given for electric steel includes the energy required to generate the electricity. Part of the reason for the large difference in energy requirements is that electric steel is made from scrap and, therefore, little energy is required to reduce iron oxide to elemental iron. In this sense, stockpiles of iron and steel scrap represent a significant source of stored energy.

It is, of course, important to observe that currently about 30% of the output of steel products made is not recoverable as scrap. Examples include reinforcing bars incorporated within concrete structures, wire products, such as nails and fencing, and buried piping, such as oil well casings. Other products, such as "tin" cans, may someday be recovered on a large scale from municipal wastes. Presently, much of this steel is wasted. It is this unrecoverable quantity of material that in any long-term equilibrium sense ultimately must be derived from the mining and reduction of iron ore. Consequently, the reduction of ore to iron, as in a blast furnace, and the need for the basic oxygen process or equivalent is self-evident.

Minimill Concept

The switchover from open-hearth to basic oxygen processes for steel production created an opportunity for new producers of electric steel to enter the competition. Small "minimills" using electric furnaces are not tied to the logistical problems of coal, ore, and limestone supply or the economies of scale associated with blast furnace and coking operations. Small minimills can be built with a relatively modest investment. These mills are well suited to take advantage of the greater availability of local scrap and, because of their relatively small size, can be located virtually anywhere, thus avoiding the costs associated with transportation.

Casting Steel

Although steelmaking processes vary considerably, the liquid steel resulting is tapped from the furnace into a ladle. This is a refractory-lined cylindrical container with trunnion attachment for crane lifting to transport the steel. Generally, the bottom of the ladle is fitted with a stopper-rod nozzle or a sliding-gate nozzle for pouring. Lip-poured ladles are occasionally used. Additions of deoxidants, recarburizers, and alloying materials may be made to the ladle during tapping from the furnace so that final composition of the steel may be adjusted. Sometimes, vacuum or gas-stirring treatment is used prior to casting steel.

Treatment of liquid steel under vacuum makes it possible to reduce the amounts of hydrogen, nitrogen, and oxygen and some harmful non-metallic inclusions, thus improving the properties and qualities of the steel. Lengthy heat treatments of up to 2 and 3 weeks can be eliminated by the effective removal of hydrogen from certain forging steels. Vacuum degassing of steel prior to casting includes: (1) ladle degassing in a chamber; (2) stream degassing by pouring from ladle to ladle or ladle to ingot; (3) vacuum-lifter or circulation degassing; (4) mold degassing; (5) a combination of arc heating and degassing; (6) vacuum-furnace degassing; and (7) employing a consumable electrode under vacuum. To equalize temperature and improve steel quality, sometimes inert gases, such as argon or nitrogen, are bubbled through liquid steel.

Once tapped from the furnace, vacuum degassing, or stirring treatment, the liquid steel is teemed into molds as ingots, continuously cast or pressure-poured into semifinished shapes, or poured into molds as steel casting. In conventional casting-pit practice, steel is teemed from the ladle into iron ingot molds of square, rectangular, polygonal, or round cross section where it solidifies as blocks. The ingots can be top-poured directly into individual molds, or bottom-poured simultaneously into a cluster through a trumpet-and-runner arrangement. To counteract shrinkage during solidification of killed steels, hot tops are used on molds. Once teemed, the molds are stripped and the ingots charged into soaking pits for heating for subsequent processing; or allowed to go cold for placement in the stockyard.

Continuous Casting. This process, wherein liquid steel is poured directly into semifinished shapes, such as slabs, blooms, blanks, or billets,

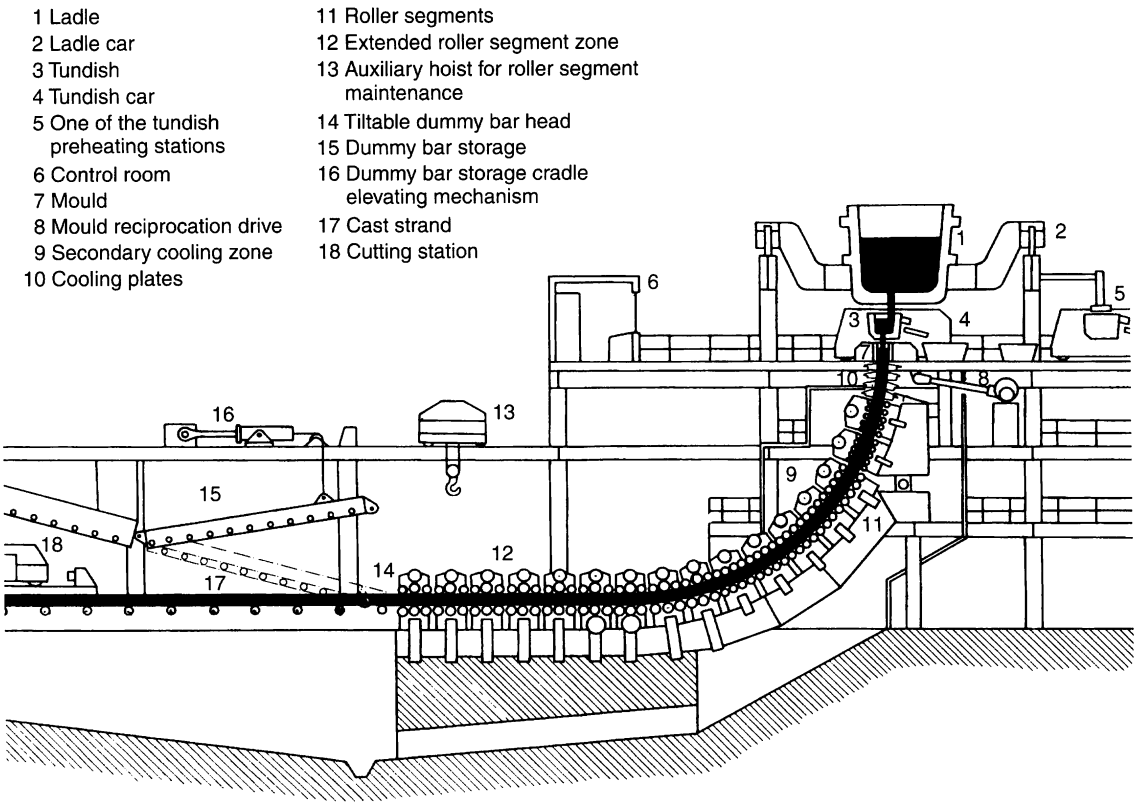

Fig. 4. Continuous slab casting machine. (*Concast A.G. Zurich*)

is growing in use, mainly because it eliminates the need for heavy rolling-mill equipment.

In continuous casting, 90% or more of the molten steel ends up as finished product. This represents an enormous productivity gain compared with traditional practice. This gain is the result of converting steel finishing from a batch operation (with the ingot removed for reheating at several stages) to a continuous operation (with reheating applied as needed as the ingot moves along).

In principle, all steel could be delivered to finishing operations via continuous casting regardless of the process used to produce the steel. In practice, however, continuous casting operations are most easily and economically introduced in conjunction with new steelmaking facilities where the capacity and design of the steelmaking equipment can be matched with the capacity and layout of the finishing section and with the line of products planned for the operation. This is precisely the situation for the regional minimill specializing in the production of a small variety of high-volume simple shapes. In Japan, where more than 70% of the steelmaking capacity came on line after 1963, more than 80% of steel production was continuously cast by 1982. In that year, the United States by comparison continuously cast only about 25% of its steel production.

A continuous casting line is shown in Fig. 4. Steel is poured via a tundish into a water-cooled copper mold. As casting commences, the bottom of the mold is sealed with a dummy bar onto which the steel solidifies.

The solidified cast product is removed continuously by way of a direct spray-cooling withdrawal roll and cutoff system, maintaining a desired molten metal level in the copper mold. Once cut off, the cast product is discharged onto a cooling bank. Principal types of single or multistrand continuous-casting machines available include: (1) vertical mold with vertical cutoff; (2) vertical mold with blending rolls and horizontal cutoff; (3) curved mold with bending and horizontal cutoff; and (4) machines with direct strand-reduction units to reduce cross section by rolling before cutoff.

Pressure-Pouring Process. In the system shown in Fig. 5, the molten metal is forced up through a refractory tube into a mold by means of compressed air. To cast a number of molds in succession, two systems are used. The ladle may be placed in a stationary airtight pressure chamber and the molds moved over the chamber; or the molds may be stationary and the pressure chamber incorporating the ladle may be transported underneath the molds. The rate of pouring is determined by the rate of air-pressure

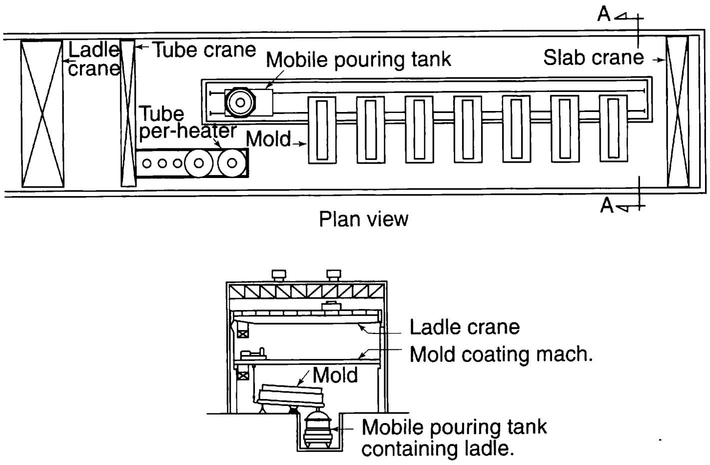

Fig. 5. Pressure pouring plant showing fixed mold and moving pouring tank layout. (*Davy McKee Iron & Steel Division, Stockton-on-Tees, England*)

increase; the height to which the liquid steel is raised is a function of the pressure applied.

Steel Castings. Where intricate shapes are involved or where mechanical working from standard shapes is not possible, the liquid steel can be poured into a mold of desired shape. Sand molds are commonly used.

Shaping Steel

With exception of a small tonnage of steel castings, most steel products are made from steel that is cast first as ingots or semifinished products, followed by mechanical working into desired sizes and shapes. This working processing reforms the cast structure, generally improving the physical properties of the steel.

There are three main ways for forming steel by hot working: (1) forging; (2) extrusion; and (3) rolling. For these processes, the steel must be heated until it is plastic. Soaking pits are used for heating ingots; reheating furnaces are used for heating semifinished products. Generally, the heating temperature is in the range of 1,150 to 1,350°C.

Forging. The operations performed in forging are hammering or pressing. Commonly forged products include crankshafts, rolling-mill rolls, boiler drums, turbine rotors, axles, and many other components of cars and machinery. *Hammer forging* involves the deformation of the red-hot steel block, resting on an anvil, by a series of repeated blows of the heavy part of the hammer, called the ram. Where intricate shapes are required, the ram and the anvil may be fitted with detachable dies having the shape of the desired final product in each half. This latter method is termed *drop forging* or *stamping* and used where precise dimensions are required and a large quantity of items of one pattern are to be made. *Press forging* involves forming the heated steel block into shape in a hydraulic press. A steady squeeze is applied which penetrates through the entire thickness of the forging.

Extrusion. The hot-extrusion process involves placing the heated piece of metal in a chamber, whereupon high pressure is applied from one end by means of a hydraulically operated ram, thus causing the metal to flow through a restricted orifice at the other end. Desired shapes (cross sections) may include rounds, squares, and hexagons. For producing tubes, a die and a mandrel are required. The process normally is limited to stainless and high-alloy steel products because of cost.

Rolling. In excess of 90% of steel production is processed by rolling. A rolling mill is used to produce a variety of semifinished and finished products, notably blooms, slabs, billets, rails, beams, angles, channels, rounds, squares, sheets, plates, and strip. Essentially, the process consists of passing the metal through (between) two rolls which are revolving at the same peripheral speed, but in opposite directions. The rolls may have smooth or grooved surfaces. The tap between the rolls is less than the height (thickness) of the material being rolled. While gripping the material during its passage through them, the rolls effect a reduction in cross-sectional area, with a corresponding increase in length. A final shape can be produced from a large block by making multiple passes between the rolls in a reversing action.

Rolling mills for processing large steel ingots are termed *blooming* or *slabbing* mills and the resulting forms are termed blooms or slabs. Blooms range from 5 × 5 inches (12.5 × 12.5 centimeters) upward. Products which commence with blooms are numerous, including: rails, structural shapes for bridges and building construction, window framing, steel partitions, bars of a variety of cross sections (ultimately made into nuts, bolts, shafts, and machinery parts, etc.), rod that ultimately may become wire, and narrow strip, which may become razor blades, tubes, pipes, wheel rims, etc.

Billet mills produce a product of 2 to 5 inches (5 to 12.5 centimeters) square in cross section. Heavy plates are produced in *plate mills*.

Steel sheets, widely used in thousands of products, are produced from slabs from a slabbing mill, continuous casting machine, or pressure-poured molds. These pieces are hot-rolled in a hot strip mill, descaled by pickling in an acid solution, and then cold-rolled and tempered in a cold-reduction and temper mill. The cold-rolled strip may be marketed in coil form, or carried to a side-trimming and sheet-shearing line, where it is customized for specific user needs.

Tin cans used as containers are made from tin plate, that is, a sheet steel thinly coated on each side by hot-dipping or the electrolytic process.

The hot strip is pickled and passed through cold and temper mills, after which it is passed through annealing and tinning lines. Further, zinc, terne, aluminum, or plastic coating can be applied for additional corrosion resistance.

Summary of Production Operations

The flow sheet of Fig. 6 indicates the principal processes and processing routes encountered in iron- and steelmaking, including major classes of products made. Traditionally, prior to the 1960s, these processes generally were effected in a huge central facility, referred to as an *integrated* iron and steelworks.

Metallurgy of Iron and Steel

The physical properties of ferrous products can be altered by cold working or heat treatment, both processes that affect the microstructure. The role of carbon in ferrous products is explained to some degree by the *iron-carbon diagram*. See Fig. 7. This diagram shows the relationship between carbon content and temperature and includes key information on microstructure and heat treatment.

When cooled, pure iron solidifies at about 1,536°C as delta iron, having a body-centered cubic lattice structure. This form changes allotropically to gamma iron with a face-centered cubic lattice structure below 1,404°C, and is nonmagnetic. When cooled further, gamma iron changes to alpha iron, with a body-centered cubic lattice structure. At a temperature of 768°C, a nonallotropic change occurs, making the alpha iron strongly magnetic, accompanied by marked changes in electrical resistance, rate of thermal expansion, and specific heat. The foregoing changes occur in reverse order if pure iron is heated instead of cooled.

Carbon dissolves in molten iron to form iron carbide. When the carbon content is increased, the liquids temperature (melting point of iron) is lowered. The eutectic point (lowest melting temperature) is 1,130°C when the carbon content is 4.3%. Similarly, the solidus temperature is lowered to 1,130°C up to a carbon content of 1.7%. The resulting transformations and the products formed after cooling the iron-carbon alloy below the solidus temperature depend on the carbon content, the temperature, and the rate of cooling. Some of these substances are defined briefly below:

Austenite. This is an allotropic form of gamma iron with carbon in solid solution. Austenite transforms to other products on cooling below 723°C. The products depend on the rate of cooling. At ordinary temperatures, austenite containing only carbide is not stable and thus cannot be completely retained by quenching. The stability can be increased by adding certain alloying elements.

Ferrite. This is practically pure iron and can exist in magnetic alpha-iron form in iron, with up to 0.83% carbon. Ferrite exists at room temperature and up to about 910°C in the absence of carbon. Its upper limit of existence is lowered progressively to about 723°C as the carbon content increases up to 0.83%. Ferrite cannot dissolve carbon, is soft and ductile, and has poor abrasive resistance.

Cementite. This is iron carbide, Fe_3C, containing 6.67% carbon. The substance is hard, brittle, and crystalline. Cementite is precipitated when austenite cools.

Pearlite. This is a eutectoid comprised of a laminated structure of ferrite and cementite. Pearlite is formed by transformation of austenite upon cooling. The fineness or coarseness of the laminated structure is determined by the rate of cooling. The lamellar arrangement of ferrite and cementite produces a very tough structure. It is responsible for the mechanical properties of steels.

Graphite. This is the free or uncombined carbon usually found in cast irons. Because graphite occurs as flakes, cast irons are easily machinable even though they have a high resistance to abrasion.

Mystery of Damascus Steels Solved. The legendary steel used in Damascus swords, probably first used as early as 320 B.C., has puzzled historians and metallurgists for many centuries. Probably the first serious attempt to explain the superiority of Damascus steel was made by Anosoff in 1841. A two-volume monograph (*On the Bulat*) was published by Anosoff, who proclaimed, "Our warriors will soon be armed with bulat blades, our laborers will till the soil with bulat plowshares, our artisans will use tools fashioned of bulat, and bulat will supersede all steel employed for the manufacture of articles of special sharpness and endurance." This forecast was not realized. BrÉant and Faraday also had investigated the secret of making Damascus steel. The most recent and very serious study of the topic was made by Sherby and Wadsworth (Stanford University), who reported in 1985 their concept as just how the Damascus steel was processed. In outlining a typical manufacturing procedure, the investigators claim that a Damascus sword commenced with the casting of an ultrahigh-carbon steel, called *wootz*, in Indian foundries. (Damascus steels contained more carbon than most modern steels.) Iron ore and charcoal were mixed and heated to about 1200°C in a shallow stone hearth. The iron was reduced, that is, stripped of oxygen by virtue of reactions with carbon present in the charcoal. At this point, the metal had a spongy consistency. To remove impurities, the sponge iron was hammered, to produce bits of wrought iron with a low carbon content. To increase the carbon content, the investigators envision that pieces of the wrought iron were heated in a clay crucible along with charcoal. To prevent oxidation of the iron, the crucible was sealed. When there was indication of melting within the crucible, the latter was cooled slowly within the furnace. The product was wootz, which incidentally during the period was traded in the form of cakes. A Damascus blade was forged from an individual cake of wootz, which is estimated to have been heated to a temperature of 650–850°C. (Modern ultrahigh-carbon steels are ductile within that temperature range.) The finished blades were hardened, by reheating them and then quenching them in water, brine, or some other liquid. The investigators attribute their postulations to a study

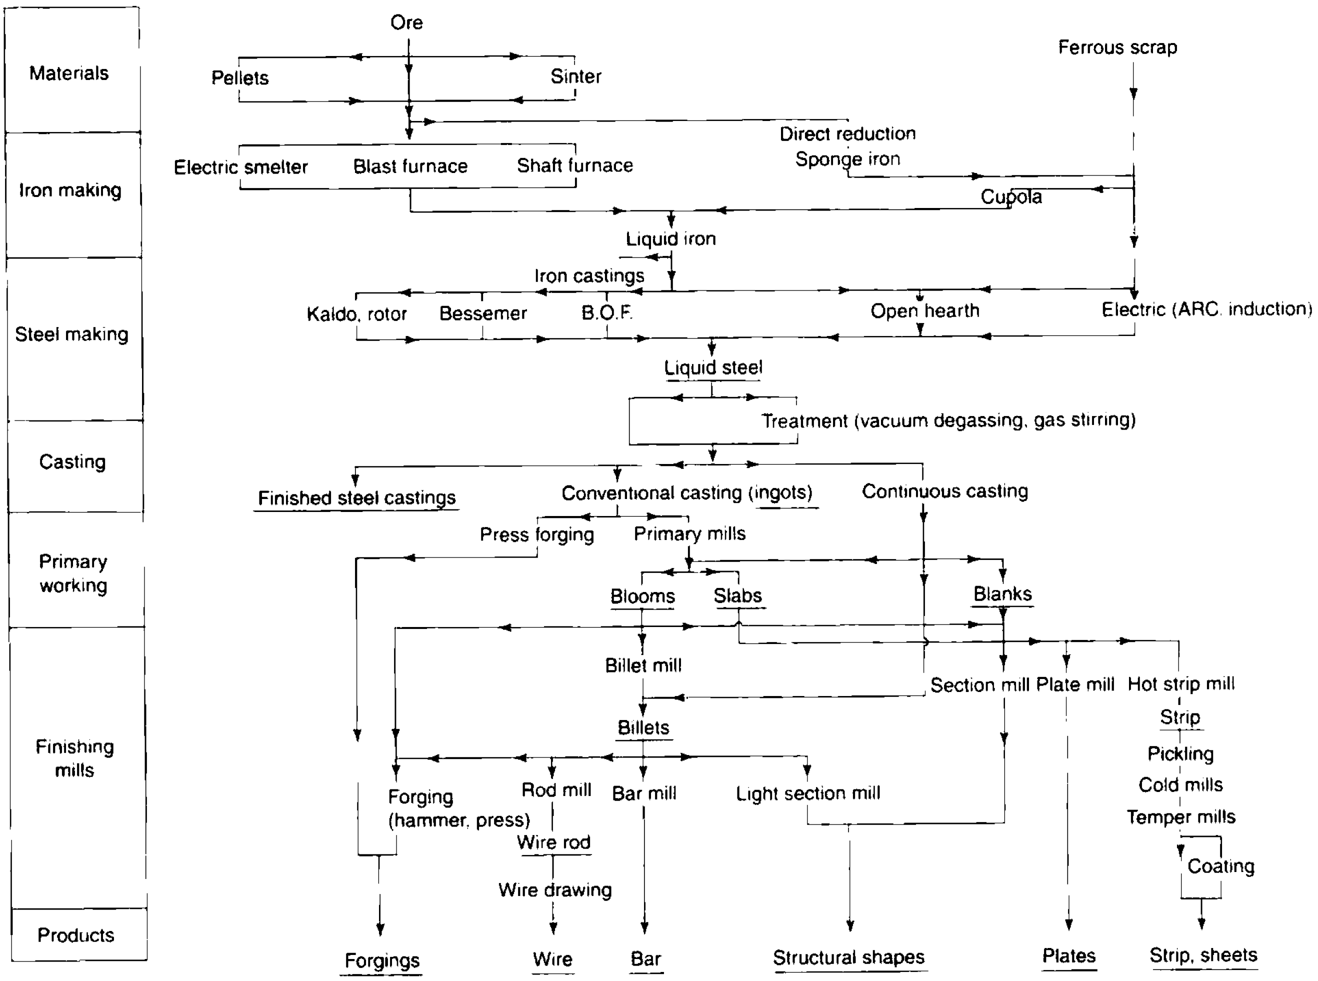

Fig. 6. Principal processes and processing routes in iron- and steelmaking, indicating major classes of products made

of the iron phase diagram (previously shown in Fig. 7.). Quoting from their report. "When wrought iron and charcoal were heated to 1200°C in a crucible, the iron converted into face-centered *austenite*. Carbon from the charcoal could then dissolve in the iron, decreasing its melting temperature. Molten cast iron formed at the surface of the iron particles when the carbon content of the surface layer exceeded 2%. Slow cooling allowed the carbon to diffuse through the metal, producing a steel with an average carbon content between 1.5 and 2%. Slow cooling also allowed the austenite grains to grow to a coarse size. When the temperature fell below about 1000°C, carbon precipitated out of solution as cementite at the grain boundaries. The coarse *cementite* network was the source of the whitish damask markings. As the temperature fell below 727°C, face-centered austenite converted into alternating layers of cementite and carbon-poor, body-centered *ferrite*. The blades were hardened by being reheated above 727°C and then quenched, which converted austenite into martensite." It is assumed that medieval smiths estimated the metal's temperature from its color.

It is interesting to note that a description of the hardening procedure for Damascus steel (*bulat*) was located in the Balgala Temple in Asia Minor. "The bulat must be heated until it does not shine, just like the sun rising in the desert, after which it must be cooled down to the color of the king's purple then dropped into the body of a muscular slave.... the strength of the slave was transferred to the blade and is the one that gave the metal its strength."

Types of Steel

The carbon content of steels usually does not exceed 1.7%. In addition to carbon, *plain carbon steels* contain small amounts of silicon, manganese, phosphorus, and sulfur—derived from the raw materials and fuel used in the steelmaking process. Within limitations, silicon and manganese are beneficial and often are purposely added, mainly because they are deoxidants. Except in free-cutting steels, where sulfur is purposely added, sulfur and phosphorus are deleterious and their content is kept as low as possible. Some of these terms are rooted in steelmaking technology prior to the growing adoption of continuous casting processes.

Killed Steel. Deoxidizing elements are used to remove oxygen by forming solid oxides. Thus the reaction to form carbon and oxygen gas is suppressed and the killed steel lies quiet in mold when poured, shrinking upon solidification, usually with formation of a conical cavity known as a pipe. The most commonly used deoxidizers are silicon and aluminum. Killed steels are used for forging, carburizing, heat treating, and other applications because of their superior uniformity and soundness.

Rimming Steel. This is produced by leaving sufficient oxygen to react with carbon to evolve bubbles of carbon monoxide, conditions best achieved in steels with low carbon and manganese contents through the controlled addition of deoxidants. The effervescing action of carbon monoxide evolution causes a pure outer skin of ferrite and a tougher inner core containing carbon, impurities, and inclusions on solidification of the poured block. The sandwich like macrostructure is retained during subsequent shaping operations. Thin sheets intended for deep drawing or deep pressing, as used in the manufacture of auto bodies and domestic appliances, are made from rimming steel because they provide a smooth surface with adequate strength. Rimming steels also are used for forgings requiring smooth surfaces.

When the top end of the ingot is sealed after pouring, the term *capped steel* is applied. Big-end-down bottle-top molds are used and, after a small addition of aluminum, are sealed by using a heavy metal cap. Steels of this type are used for sheet, strip, skelp, tin plate, wire, and bars.

Semikilled or Balanced Steel. This is produced by adjustment of the silicon and aluminum added to low-carbon steel before teeming. The character is intermediate between the killed and rimming steels. The steel is deoxidized less than the killed steel, leaving sufficient oxygen to react with carbon and form blowholes to compensate in all or in part for the shrinkage that accompanies solidification. Semikilled steels are used for less severe drawing and pressing than rimming steels and for structural shapes, plates, and merchant bar.

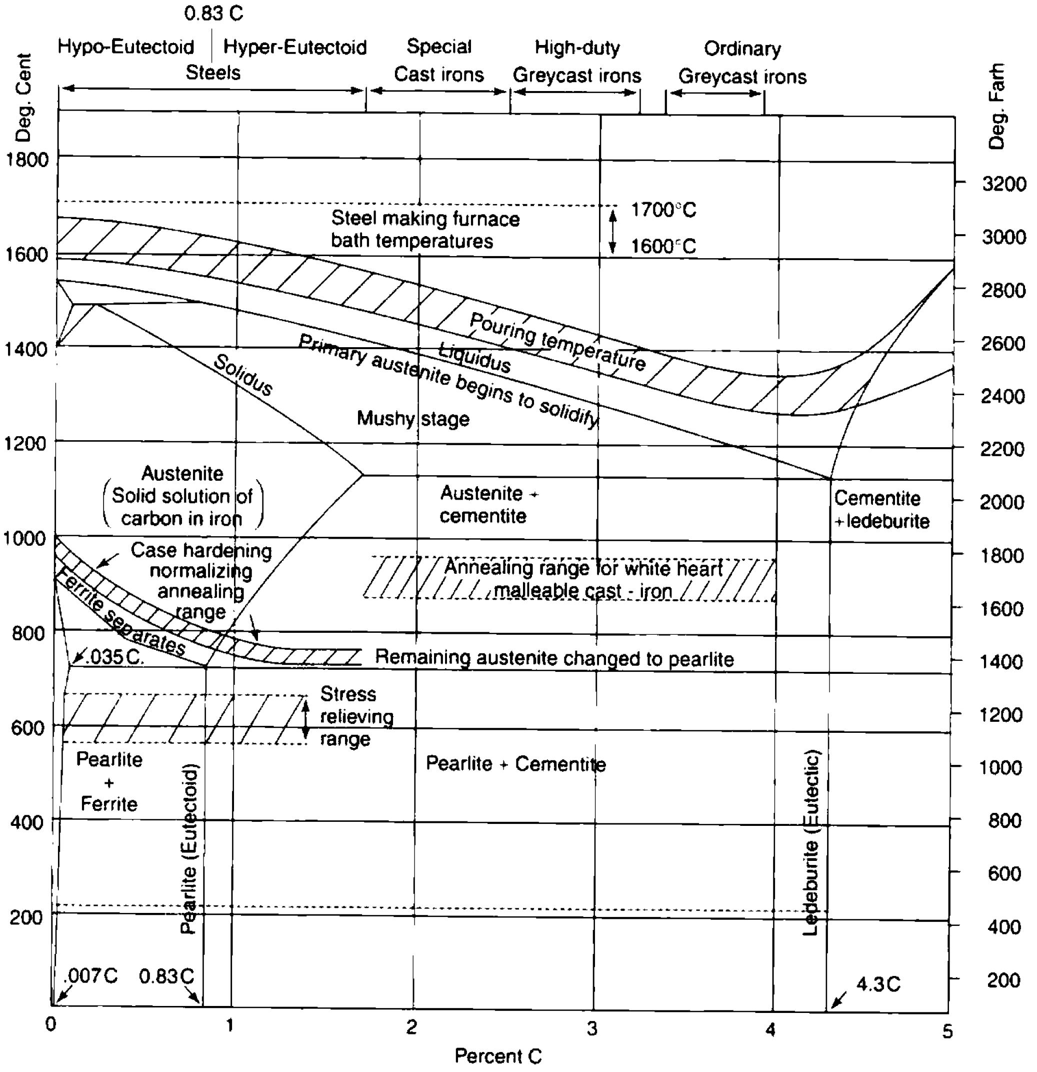

Fig. 7. Iron-carbon equilibrium diagram

Effect of Ingredients on Steels

The iron-carbon diagram (Fig. 7) shows the effects of carbon in steel. Steels containing less than 0.83% carbon are known as *hypoeutectoid steels*. When cooled slowly, the microstructure of these steels consists of pearlite and ferrite. *Eutectoid steel* containing 0.83% carbon consists entirely of pearlite. Steels containing more than 0.83% carbon are known as *hypereutectoid steels*. When cooled slowly, their microstructure is comprised of pearlite and cementite. Each increase in the carbon content of the steel increases the hardness and tensile strength of the steel in the *as-rolled* or *normalized* condition up to 0.83% carbon. The effect is less pronounced above this figure. The maximum hardness attainable after quenching also increases with the carbon content up to about 0.60% carbon. The strength of quenched and tempered steels depends upon the tempering temperature. Ductility decreases as the carbon content increases, and weldability is impaired above certain levels.

Manganese. This element is generally added to bring the amount to between 0.5 and 1.0%. Normally some manganese is present since it occurs in so many iron ores. Manganese contributes to strength and hardness, but the effect is less than like additions of carbon. Manganese lowers difficulty, but again to an extent less than carbon. Surface quality improves with manganese in all carbon ranges, notably in resulfurized steels. Manganese also increases the rate of carbon penetration during carburizing.

A steel qualifies as an alloy steel when the manganese specified is within the limits of 1.65–2.10%. Manganese is of major importance in increasing hardenability—the depth of hardness penetration after quenching. Thirteen percent manganese steel is widely used as a wear-resistant steel.

Phosphorus. A high phosphorus content in some types of steel is undesirable because it decreases ductility and impact toughness. Because of large loss of ductility, phosphorus is notably undesirable in the higher-carbon steels. In lower-carbon steels, phosphorus promotes machinability and, with copper, improves resistance to atmospheric corrosion.

Sulfur. This element is detrimental to surface quality, but beneficial to machinability, particularly in low-carbon and low-manganese steels. Sulfur decreases transverse ductility and impact resistance, but has only a small effect on longitudinal properties. As sulfur content increases, weldability decreases. Sulfur is added to the extent of 0.2–0.4% in free-cutting steels to improve machinability.

Silicon. Rimmed and capped steels contain no significant amounts of silicon. When specified within the limits of 0.60–5.00%, silicon qualifies a steel as an alloy steel. The resiliency of steel for spring applications is increased with silicon content. The element also raises the critical temperature for heat treatment. Silicon promotes the susceptibility of steel to decarburization. Because they have a low hysteresis loss and a high electrical resistance, very low carbon steels with 0.6–5.00% silicon are used as transformer steels. Silicon promotes the adherence of zinc coating on hot-dipped galvanized wire. Silicon is less effective than manganese in increasing strength and hardness.

Aluminum. The main use for this element is to deoxidize steels and to obtain a fine grain size. Aluminum also is used to obtain nonaging characteristics and to prevent the recurrence of stretcher strains in sheets and strip. When added in amounts of about 1%, aluminum promotes nitriding properties, that is, surface hardening by means of nitrogen-bearing gases at high temperatures.

Copper. This element is beneficial to atmospheric corrosion resistance if present in amounts in excess of 0.20%. Appreciable amounts of copper are detrimental to hot-working operations. Copper also adversely affects forge welding and is detrimental to surface quality. However, copper does

not seriously affect arc or acetylene welding. Copper is not removed in the conventional steelmaking processes and hence, because of increasing accumulation in scrap, it is becoming increasingly difficult to control copper within low limits.

Nickel. Aside from manganese, nickel is the most common alloying element for steel. Nickel is used in amounts up to 5% to increase strength and improve shock resistance. The element counteracts the brittleness that develops in most pearlite steels at subnormal temperatures, lowers the critical temperature of steel, widens the temperature range for successful heat treatment, and promotes corrosion resistance. When nickel is used in quantities greater than 5%, the steels fall into the stainless and heat-resistant steel categories. These are described shortly.

Niobium. By addition of amounts of up to 1%, niobium stabilizes chromium and stainless steels. Additions of only about 0.02% increase the yield point of medium-carbon steels by about 50% without any loss of weldability.

Tungsten. When added to steels in amounts up to 20%, tungsten greatly improves the hardness of a steel, a hardness that is maintained at high temperature and very important to high-speed tool steels. Smaller amounts of tungsten are added to hot-working steels.

Zirconium. Small amounts of this element, when added to high-chromium steels, improve their machinability.

Cobalt. This element provides cutting efficiency to high-speed steels and also is a constituent of heat-resisting steels because it conveys a resistance to creep and scaling.

Chromium. This element increases hardness, improves hardenability, and promotes the formation of carbides and for these reasons is used in constructional steels. Chrome steels are relatively stable at elevated temperatures and have outstanding wear resistance. Chromium is an important constituent of stainless and heat-resistant steels to be described shortly.

Molybdenum. Steels with molybdenum are usually less susceptible to temper brittleness. Molybdenum has a major effect on increasing hardenability and a notable effect on increasing the high-temperature tensile and creep strengths of alloy steels, that is, the steels have less tendency toward deformation under stress at elevated temperatures.

Vanadium. A strong deoxidizing agent, vanadium promotes a fine austenitic grain size. Constructional steels contain about 0.03–0.25% vanadium. Larger quantities are used in tool steels. Vanadium additions of about 0.04–0.05% increase the hardenability of medium-carbon steels with a minimum effect on grain size. Further additions, however, decrease the hardenability with normal quenching temperatures. Where the austenizing temperatures are increased, however, the hardenability can be increased with higher vanadium contents.

Titanium. This element acts as a deoxidizer in pearlitic steels. The yield point of plain-carbon steels is increased with titanium in amounts of 0.02–0.05%. Titanium promotes weldability without the need for normalizing.

Boron. This element is added to increase hardenability, but is effective only when added to fully killed steels. Since only a few thousandths of 1% of boron usually remains in the steel, evaluation of boron steels is by increased hardenability rather than chemical content. The hardenability characteristics of elements already present in the steel are intensified by boron, making possible alloy ingredient conservation. Although effective with low-carbon steels, the effectiveness of the element decreases as the carbon content increases.

Industrial Classification of Steels

Numerous systems are used for classifying steels—some based on composition, others on physical properties, special properties, and so on. For convenience, there are two broad categories: (1) plain carbon steels; and (2) alloy steels. Plain carbon steels account for about 95% of all steel production. As described earlier, plain carbon steels are classed as hypoeutectoid or hypereutectoid steels, depending on whether the carbon content is above or below 0.83% (the eutectoid composition). *Low-carbon* steels have a carbon content below 0.20%. *Medium-carbon* steels have a carbon content in the range between 0.20 and 0.50%. *High-carbon* steels have a carbon content in excess of 0.50%.

Alloy Steels. An alloy steel as defined by The American Iron and Steel Institute is: "By common custom alloy steel is considered to be alloy steel when the maximum of the range given for the content of alloying elements exceeds one or more of the following limits: manganese, 1.65%; silicon, 0.60%; copper, 0.60%; or in which a definite range or a definite minimum quantity of any one of the following elements is specified or required within the limits of recognized field of constructional alloy steels: aluminum, boron, chromium up to 3.99%, cobalt, columbium (niobium), molybdenum, nickel, titanium, tungsten, vanadium, zirconium, or any other alloying element added to obtain a desired alloying effect."

High-strength, low-alloy steels have a twofold objective: (1) higher mechanical properties, and (2) greater resistance to atmospheric corrosion than achievable with structural-grade carbon- or copper-bearing steels. Often, these are proprietary steels with specific trade names. A representative steel in this class will have a tensile strength of about 70,000 psi (483 MPa) for a 1/2-inch ($\sim$1.3-centimeter) thick section and have a yield point of about 50,000 psi (345 MPa).

Constructional alloy steels are a major part of the tonnage of alloy steels and are used mostly in the automotive and aircraft industries. These steels usually are quench-hardened and tempered with or without carburizing.

Stainless steels have a large degree of resistance to chemical attack. This property sometimes is referred to as *passivity*. This property results when iron is alloyed with at least 11% chromium. The corrosion resistance is further enhanced by higher chromium additions and by the addition of nickel. A steel with 12% chromium will stain, but will not exhibit progressive rusting in normal atmospheres. Under normal circumstances, a steel with 18% chromium will not stain, but may discolor, particularly in heavy industrial areas. When 8% nickel is added to an 18% chromium steel, the metal will be stain-resistant in all but the very worst of atmospheres. Even further enhancement of corrosion and heat resistance results with the addition of molybdenum.

Iron-chromium alloys and their general corrosion-resistant properties were known in England and France nearly 150 years ago, but the phenomenon of passivity was not formally recognized until 1910 (Borchers and Monnartz in Germany). This discovery led to rapid development of a series of commercial stainless steels. Stainless steels fall into three broad categories: (1) *martensitic types*—chromium-iron alloys with chromium in the lower range (12 to 17%) and with a wide range of carbon. A main characteristic is an ability to harden by heat treatment in a manner similar to carbon steels. Tensile strengths range from 70,000 to 105,000 psi (483 to 725 MPa) for annealed steels and 125,000 to 200,000 psi (863 to 1380 MPa) for hardened steels. They are particularly well suited for hot working and forging; the lower-carbon types can be cold-worked. (2) *ferritic types*—chromium-iron alloys with higher chromium in a range of 18 to 30% and with a lower carbon content. They have a microstructure that is predominantly ferritic. The steels are not hardenable by heat treatment. They are ferromagnetic. They have a relatively low coefficient of thermal expansion. These steels exhibit good resistance to oxidation and corrosion; they are frequently selected for high-temperature service, notably for applications involving intermittent heating and cooling, because of their ability to retain the oxide scale that has formed. (3) *austenitic types*—iron-chromium-nickel alloys, with a chromium content ranging from 8 to 30% and a nickel content ranging from 6 to 20%. They retain austenite at room temperature. They are characterized by high ductility of the austenite, work-hardening ability, good corrosion resistance, and superior high-temperature properties. Austenitic stainless steels are inherently tough; well adapted for fabrication by deep drawing. They are easily welded and soldered. Their tensile strength (annealed) approximates 90,000 psi (621 MPa) with a yield strength of about 35,000 psi (242 MPa).

Heat-Resisting Steels, as may be required for steam-generating boilers, pressure vessels, furnaces, distillation equipment, and internal-combustion engines must retain their specified physical properties at elevated temperatures. Where temperatures exceed 540°C, molybdenum is used along with chromium as an alloying ingredient. Only 2% chromium provides oxidation protection up to about 620°C. A chromium content of 10 to 14% is required for temperatures up to about 760°C. For higher temperatures, stainless steels are used. For service in the temperature range of about 815° to 1,095°C, steels containing 25% chromium and from 20% to 27% nickel are frequently used.

Electrical Steels. The properties required of a good electrical steel include high electrical resistance, high permeability, and low hysteresis loss. These properties are provided by the addition of 0.6–5.0% silicon to a relatively carbon-free steel. Such steels are used in power transformers, motor and generator rotors and stators, and communications equipment.

Cold Working and Heat Treating Steels

When steel is cold-drawn or cold-rolled, it is said to be *cold-worked*. This process significantly improves mechanical properties, such as increasing the tensile strength, yield strength, torsional strength, hardness, and wear resistance. By suitably combining chemical composition, cross section, method of steel production, and thermal treatment with cold-working, distinctive properties in steels can be achieved. Cold working can impart properties to some steels comparable to those of heat-treated bars. In low-carbon steels, cold-worked steel bars show greatly improved machinability. The ratio of yield strength to tensile strength influences machinability. A high yield-strength ratio, resulting from cold drawing, minimizes plastic flow during machining, thus permitting better utilization of machine tool energy.

Heat Treating Steels. Heat treatment enables the modification of mechanical properties of steels. Three fundamental operations are involved: (1) heating the steel above the critical range, to approach a uniform solid solution of austenite; (2) hardening by quenching in oil, water, or air, to induce the formation of martensite (the hardest micro-constituent of steel); and (3) tempering by reheating to a temperature below the critical range, to secure the desired combination of strength and ductility. Three types of steel generally do not respond to this form of heat treatment: (1) steels which contain very low amounts of carbon; (2) austenitic steels for which the critical ranges are below room temperature; and (3) ferritic stainless steels. Products which normally can be furnished in the quenched and tempered condition include carbon and alloy steel plates; carbon, alloy, and martensitic stainless steel bars; hot-rolled alloy steel sheets; alloy steel tubular products; and carbon steel wire.

Normalizing. This process consists of heating to an appropriate temperature above the critical range, followed by cooling to below that range in still air. This process promotes uniformity of structure. Products which can be normalized include: (1) carbon, alloy, and high-strength low alloy steel hot-rolled bars; (2) carbon, alloy, and high-strength low alloy steel hot-rolled plates; (3) carbon and alloy semifinished steel; (4) carbon alloy, and high-strength low alloy steel hot-rolled sheets; (5) carbon, alloy, and high-strength low alloy steel hot-rolled and cold-rolled strip; (6) carbon and alloy steel tubular products; and (7) carbon and alloy steel wire.

Annealing. For carbon steels, alloy steels, and martensitic and ferritic stainless steels, regular annealing consists in maintaining the steels at a temperature in or near the critical range, followed by cooling at a predetermined rate or cycle. In the case of austenitic stainless steels, these are generally annealed by holding at appropriate temperatures and rapidly cooling to minimize the precipitation of carbides. Annealing provides softness, improves machining, forming, or shearing, reduces stress, improves or restores ductility, and may modify other properties. Usually annealing is used on stainless and heat-resisting steels and may be performed on the same kinds of products as listed under normalizing. See also **Annealing**.

Box Annealing. A process of annealing steel in an appropriate metal container to shield the steel from objectionable oxidation. Sometimes, a reducing atmosphere is used.

Spheroidize Annealing. A process of prolonged heating at a suitable temperature, followed by slow or cyclic cooling to produce a globular condition of the carbide. The structure produced may be attractive for machining or cold-forming, cold-drawing operations, or it may be desirable for subsequent heat treatments.

Stress Relieving. In this process, internal stresses are reduced by heating to a temperature below the critical range and holding it for a sufficient time for equalization of the temperature throughout the piece.

Patenting. This is a continuous heating of individual strands to above the critical range, followed by relatively rapid cooling. The process applies to wire and wire rods and increases toughness for withstanding severe distortion or drawing without breakage.

Isothermal Annealing. This is a process of heating to the correct temperature above the critical for proper austenizing, followed by rapid cooling to a suitable temperature and holding sufficiently long for completion of the transformation.

ISOCYANTES, ORGANIC. Isocyanates are derivates of isocyanic acid, HN=C=O, in which alkyl or aryl groups, as well as a host of other substrates, are directly linked to the NCO moiety via the nitrogen atom. Structurally, isocyanates (imides of carbonic acid) are isomeric to cyanates, ROC≡N (nitriles of carbonic acid), and nitrile oxides, RC≡N → O (derivates of carboxylic acid).

Isocyanates are liquids or solids which are highly reactive. The basis for the high reactivity of the isocyanates is the low electron density of the central carbon.

Industrially, isocyantes have become large-volume raw materials for addition polymers, such as polyurethanes, polyureas, and polyisocyanurates. By varying the reactants (isocyanates, polyols, polyamines, and others) for polymer formation, a myriad of products have been developed, ranging from flexible and rigid insulation foams to the high modulus automotive exterior parts to high quality coatings and abrasion-resistant elastomers unmatched by any other polymeric material. The most significant mono-, di-, and oligomeric isocyanates, which constitute over 90% of global isocyanate production, are aromatic isocyanates [toluene 2,4-diisocyanate (TDI), toluene 2,6-diisocyanate (TDI), 4,4′-methylene diphenyl diisocyanate (MDI), 2,4′-methylene diphenyl diisocyanate, polymeric methylene diphenyl diisocyanate (PMDI), *p*-phenylene diisocyanate (PDI), naphthalene-1,5-diisocyanate (NDI)], aliphatic isocyanates [1,6-hexamethylene diisocyanate (HDI), isophorone diisocyanate (IPDI), 4,4′-dicyclohexylmethane diisocyanate (H_{12}MDI), 1,4-cyclohexane diisocyanate (CHDI), bis(isocyanatomethyl)cyclohexane (H_6XDI,DDI), tetramethylxylylene diisocyanate (TMXDI)] and monoisocyanates methyl

isocyanate (MIC), *n*-butyl isocyanate (BIC), phenyl isocyanate (PIC), 3-chlorophenyl isocyanate, 3,4-dichlorophenyl isocyanate, *p*-toluenesulfonyl isocyanate.

Synthetic Methods

Preparation from Amines. The most common method of preparing isocyanates, even on a commercial scale, involves the reaction of phosgene and aromatic or aliphatic amine precursors.

Preparation from Nitrene Intermediates. A convenient, small-scale method for the conversion of carboxylic acid derivatives into isocyanates involves electron sextet rearrangements, such as the ones described by Hofmann and Curtius.

Nonphosgene Preparation. The term nonphosgene route is primarily used in conjunction with the conversion of amines (or the corresponding nitro precursor) to isocyanates via the use of carboxylation agents.

Chemical Properties

Addition Reactions. Isocyanates undergo addition reactions with a wide variety of substrates. Preferred addition occurs across the C=N bond of the NCO moiety.

Insertion Reactions. Isocyanates also may undergo insertion reactions with C–H bonds.

Cycloaddition Reactions. Isocyanates undergo cycloadditions across the carbon–nitrogen double bond with a variety of unsaturated substrates. Addition across the C=O bond is less common.

Oligomerization and Polymerization Reactions. One special feature of isocyanates is their propensity to dimerize and trimerize. Aromatic isocyanates, especially, are known to undergo these reactions in the absence of a catalyst. The dimerization product bears a strong dependency on both the reactivity and structure of the starting isocyanate.

Commercial Manufacturing Processes

Aromatic Isocyanates. A variety of methods are described in the literature for the synthesis of aromatic isocyanates. Only the phosgenation of amines or amine salts is used on a commercial scale. Much process refinement has occurred to minimize the formation of disubstituted ureas arising by the reaction of the generated isocyanate with the amine starting material.

Aliphatic Isocyanates. Conventional aliphatic isocyanates have historically been manufactured using the hydrogen chloride salt slurry approach. Exceptions to this are the longer chain aliphatics which, due to the increased solubility, have reaction rates conductive to the free amine process. An alternative approach, generally referred to as a two-phase phosgenation, has gained wide scale acceptance for the production of aliphatic isocyanates.

Low boiling isocyanates, such as methyl isocyanate, are difficult to prepare via conventional phosgenation due to the fact that the *N*-alkyl carbamoyl chlorides are volatile below their decomposition point. A convenient method for the synthesis of these low boiling materials consists of the reaction of *N*, *N'*-dimethylurea with toluene diisocyanate to yield an aliphatic–aromatic urea which is pyrolyzed to yield the desired isocyanate. Alternatively, an appropriate aliphatic–aromatic urea can be prepared by the reaction of diphenylcarbamoyl chloride with methylamine.

Specialty Isocyanates. Acyl isocyanates, extensively used in synthetic applications, cannot be directly synthesized from amides and phosgene. Reactions of acid halides with cyanates have been suggested. However, the dominant commercial process utilizes the reaction of carboxamides with oxalyl chloride. Cyclic intermediates have been observed in these reactions which generally give a high yield of the desired products.

Of the many other methods leading to isocyanates, only a few are practical enough in regard to availability of starting materials to be of general applicability. One of the more promising approaches utilizes olefinic substrates which add isocyanic acid in Markovnikov fashion to form alkyl isocyanates. One approach uses the slow addition of the olefin to an excess of solvent and isocyanic acid in the presence of a catalytic amount of inorganic acid. Another approach involves the formation of the dichloro intermediate. The dichloro compound reacts at low temperatures with an excess of isocyanic acid in the presence of a Lewis acid. Pyrolysis approaches can also be used to prepare substituted isocyanates which cannot be prepared using other methods.

Carbodiimide Formation. Carbodiimide formation has commercial significance in the manufacture of liquid MDI. Heating of MDI in the presence of catalytic amounts of phosphine oxides or alkyl phosphates leads to partial conversion of isocyanate into carbodiimide.

Health and Safety Factors

Isocyanates are classified as dangerous substances (EEC Guidelines). They are generally labeled toxic and should be handled with care. Exposure hazards increase substantially when handling vapors or mists. Isocyanate vapors or mists may be irritating to the nose, throat, and lungs. Sensitization may result from excessive exposure.

Repeated or prolonged skin contact may cause irritation, blistering, dermatitis, or skin sensitization. Contact with the eye has been reported to cause irritations in testing with rabbits. For these reasons, isocyanates must be handled in well-ventilated areas. Respirators should be worn whenever the possibility of vapor exposure exists. Chemical goggles should be worn when handling isocyanates. In the event of direct skin contact, use a safety shower immediately, removing all clothing while washing. In all cases, call a physician immediately.

The most overlooked hazard and contaminant is water. Water reacts with isocyanates at room temperature to yield both ureas and large quantities of carbon dioxide. The presence of water or moisture can produce a sufficient amount of CO_2 to overpressurize and rupture containers. For these reasons, the use of dry nitrogen atmospheres is recommended during handling.

Also, the presence of strong bases, even in trace amounts, can promote the formation of isocyanurates or carbodiimides.

Temperature control is important in the handling and storage of isocyanates. Storage at inappropriate temperatures can cause product discoloration, viscosity increases, and dimerization.

Most commercial isocyanates have a high flash point and are classified as Class IIIB combustible liquids. These materials, however, burn in the presence of an existing fire or heat source in the presence of oxygen. In the event of an isocyanate fire, use a carbon dioxide or dry chemical extinguisher. For fires covering large areas, use of a protein foam or water spray is recommended. Personnel engaged in fighting isocyanate fires must be protected against nitrogen dioxide vapors and isocyanate fumes. Firefighters should wear approved positive pressure, self-contained breathing apparatus, and fire-resistant clothing.

Economic Aspects and Applications

Since 1971, the overall demand for isocyanates has increased at a compounded rate of 12%. Although this level will not likely be sustained in the future due to the maturation of key application markets, it is probable that additional growth will occur through the year 2000. This trend will likely include a shift in emphasis from TDI to MDI and polymeric MDI-based materials. New growth opportunities in the construction industry, structural applications, and growth in the automotive industry exist. Third-world markets are also anticipated to provide growth opportunities.

Globally, BASF, Bayer (Miles in North America), Dow, and ICI historically have been the leading producers of aromatic isocyanates. In North America, Olin is a principal supplier of TDI and aliphatic isocyanates. Rhône-Poulenc and Hoechst are principal suppliers in Europe.

Aromatic Isocyanates. In North America, aromatic isocyanates are heavily used as monomers for addition and condensation polymers. The principal applications include both flexible and rigid polyurethane foam and noncellular applications, such as coatings, adhesives, elastomers, and fibers.

Aliphatic Isocyanates. Aliphatic diisocyantes have traditionally commanded a premium price because the aliphatic amine precursors are more expensive than aromatic diamines. They are most commonly used in applications which support the added cost or where the long-term performance of aromatic isocyanates is unacceptable. Monofunctional aliphatic isocyanates, such as methyl and *n*-butyl isocyanate, are used as intermediates in the production of carbamate-based and urea-based insecticides and fungicides.

A number of markets have been established for light-stable, aliphatic diisocyanates in the United States. The largest market is in high performance coatings. The largest coating market is in automotive refinishes. Other coating include uv-cured coating for vinyl tile and sheet flooring, electronic circuit boards, powder coatings, and paints. Hydrogenated MDI ($H_{12}MDI$), *m*-xylylene diisocyanate (XDI), and isophorone diisocyanate are currently used in many of these coating applications.

Aliphatic isocyanates have a small but growing market application in thermoplastic polyurethanes (TPU). Medical applications include wound dressings, catheters, implant devices, and blood bags. A security glass system using light stable TPU as an inner layer is under evaluation for shatteroroof automotive windshield applications.

Developments in aliphatic isocyanates include the synthesis of polymeric aliphatic isocyanates and masked or blocked diisocyanates for applications in which volatility or reactivity are of concern.

Specialty Isocyanates. Specialty isocyanates are organic isocyanates having the isocyanate function attached to a carbonyl group or to elements other than carbon. *p*-Toluenesulfonyl isocyanate is used as a drying agent for organic solvents. Arenesulfonyl diisocyanates, such as *m*-phenylenedisulfonyl diisocyanate, are used as monomers for base-soluble polymers. Arenesulfonyl monoisocyanates are used as intermediates for pharmaceuticals and herbicides.

ISODESMIC STRUCTURE. An ionic crystal structure in which there are no distinct groups formed within the structure, i.e., where no bond is stronger than all the others.

ISODIAPHERE. One of two or more nuclides having the same difference between the number of neutrons and protons in their nuclei. In alpha-particle decay, for example, the parent and daughter nuclides are isodiapheres.

ISODIMORPHISM. The condition, double isomorphism, in which both crystalline forms of a dimorphous substance which is isomorphous with a second dimorphous compound are isomorphous with both forms of the second compound. Example: arsenious oxide and antimonious oxide, which crystallize in rhombs and also in regular octahedra.

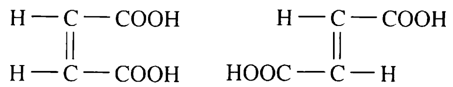
ISOELECTRIC POINT. See **Amino Acids.**

ISOLEUCINE. See **Amino Acids.**

ISOMER (Nuclear). One of two or more nuclides that are both isotopes (same atomic number) and isobars (same mass number) of each other, but which have some measurably different physical property, such as half life. Of any two isomeric states, one must be an excited metastable state of the other. Ultimately the nuclide in the excited state decays with a measurable lifetime to a lower energy state, usually its ground state. At present about 200 nuclear isomeric states with half-lives longer than 10^{-6} seconds are known. Metastable isomeric states are denoted by adding the letter *m* to the mass number where it appears in the nuclidic symbolism, as for example ^{80m}Br. In this particular case, ^{80m}Br and ^{80}Br are nuclear isomers. Ordinary excited states with lifetimes too short to be measured are generally *not* considered to be isomeric states, but this is only a matter of convention. On rare occasions, such as for ^{124}Sb, more than two isomeric states may exist for a single atomic number and a single mass number (isotopic isobar).

ISOMERISM. If two chemical compounds incorporate the same elements in exactly the same numbers, the compounds are referred to as *isomers* or *isomerides*. An excellent example of relatively simple isomers is the case of normal butane, $CH_3CH_2CH_2CH_3$, which is an open, straight chain of four carbon atoms, and of isobutane, $(CH_3)_2CHCH_3$, wherein one of the carbons lies in a short branch from the main chain of three carbon atoms. Obviously, as the number of carbon atoms in a compound increases, the possibility of branches and subbranches increases. Normally, then, compounds with high carbon counts, at least theoretically, are capable of numerous isomers.

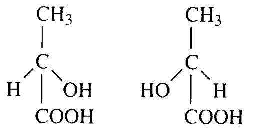
In *geometric isomerism*, the isomeric relationship can be explained in terms of two dimensions—as shown by the relationship of the two isomers, maleic acid and fumaric acid:



(Maleic acid) (fumaric acid)

Where the identical atoms or groups are in juxtaposition, as in maleic acid, the compound is designated as the *cis* form. (*Cis* = "on this side" in Latin.) Where the identical atoms or groups are on the opposite sides, as in fumaric acid, the compound is designated as the *trans* form.

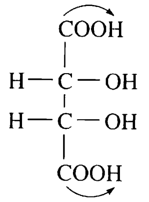
In *stereoisomerism*, three dimensions must be considered. In stereoisomerism (also termed optical isomerism), there is no plane of symmetry in the molecule, so that the two forms are mirror-images, and thus cannot be turned into a position of coincidence. Thus, compounds containing a carbon atom (or other tetravalent atom) to which four different atoms or radicals are bonded are optical isomers. They receive this name from the fact that one isomer rotates the plane of polarized light to the right (*dextro form*); the other rotates it to the left (*levo form*). Lactic acid is an example. See also **Lactic Acid**, and formulas below:



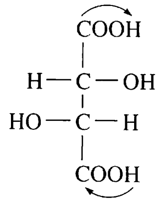
(*d*-lactic acid) (*l*-lactic acid)

The carbon atom, to which are attached the four different groups to produce stereoisomerism, is known as *asymmetric*, and when written (not shown structurally), that carbon may be printed more prominently than the nonasymmetric carbon atoms.

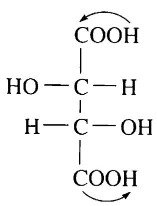
The projection formulas of the four forms of tartaric acids are shown below. Note that the arrows indicate the direction of rotation of light by the asymmetric carbon atoms.



inactive or *meso*-tartaric acid (internally compensated; possesses a plane of symmetry; optically inactive).



dextro-tartaric acid (arrangement of groups around each asymmetric carbon atom is cumulative; optically active; dextrorotatory).



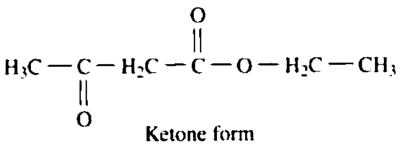
levo-tartaric acid (arrangement of groups around each asymmetric carbon atom is cumulative; optically active; levorotatory).

{*d*-tartaric acid, *l*-tartaric acid} *Dextrolevo*-tartaric acid, racemic tartaric acid (externally compensated; optically inactive; can beresolved into *d* and *l* components).

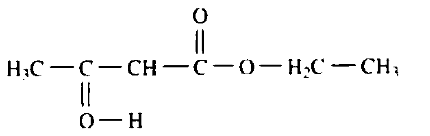
The two optically active tartaric acids when crystallized differ in the arrangement of the faces—one is the mirror image of the other. Pasteur

(1848), observing this difference, was able to separate the two optically active forms of ammonium sodium tartrate crystals made from racemic tartaric acid.

Tautomerism is a form of isomerism in which a substance exists in two forms which are in equilibrium and exhibit characteristic reactions: either one may predominate, depending upon the conditions. Thus acetoacetic ester may react as a ketone or an enol (a compound containing a carbon atom having both an alcoholic hydroxyl group and a double bond) depending upon the conditions:



Ketone form



Enol form
Acetoacetic ester

Chirality

In chemistry, *chiral* is a term used to describe asymmetric molecules that are mirror-images of each other, i.e., they are related to each other optically as right and left hands. Such molecules are also called enantiomers and are characterized by optical activity. An excellent summary of chirality in chemistry is given by Prelog, *Science*, **193**, 17–24 (1976).

ISOMERIZATION. The rearrangement of the structural configuration of a molecule without changing its molecular weight. Although structural changes of this type occur in other processes, e.g., catalytic reforming and cracking, isomerization can be the principal reaction desired in some processes. In petroleum refining, isomerization processes are used to change the structural configuration of C_4 paraffins (alkanes), such as normal butane, into isobutane in order to supplement other sources to provide enough butane for alkylation with olefins (alkenes) in the production of motor fuel. C_5 and C_6 paraffins are isomerized to the more highly branched structures to improve their antiknock ratings. Isomerization is also applied to a lesser extent in C_8 aromatic hydrocarbons.

One isomerization process (UOP) is shown in the accompanying diagram. This unit is arranged to process a C_5/C_6 mixture with fractionating facilities to provide for the recycling of both *n*-pentane and *n*-hexane. A desulfurized C_5/C_6 blend first is fractionated to remove the native isopentane as a net product. The de-isopentanizer bottoms are desiccant-dried before being joined by *n*-hexane recycle abd brought to reaction temperature by heat exchange and suitable preheating. Before entering the reactor, the combined feed stream is joined by hydrogen recycle gas, which functions to suppress catalyst-deposit formation.

The fixed-bed reactor effluent is cooled and passed to a high-pressure separator. Gas from the separator, along with a small quantity of dried make-up hydrogen, is recycled to the reactor. The separator liquid is stabilized as a next step to remove any C_4 and lighter hydrocarbons that may be introduced with the make-up hydrogen, plus a very minor amount of light hydrocarbons formed by hydrocracking in the reactor. Hydrogen dissolved in the separator liquid is also removed by the stabilizer.

The next fractionator in series receives the stabilized liquid, from which it separates an equilibrium isopentane-*n*-pentane mixture that is routed back to the deisopentanizer for separating the isopentane as a net product. Thus, the *n*-pentane content of the feed is converted entirely to isopentane in the arrangement shown in Fig. 1.

As a final step in the fractionation sequence, the hexane fraction is separated into a dimethylbutanes concentrate as a net overhead product and an *n*-hexane-rich bottoms stream to be recycled for the further isomerization of the *n*-hexane and methylpentanes. With economically practical fractionation, the methylpentanes split between the overhead and bottoms of the deisohexanizer column. For the C_5 fraction, the boiling points of the two isomers are far enough apart to make a relatively clean split economically feasible. For the C_6 fraction, the greater number of

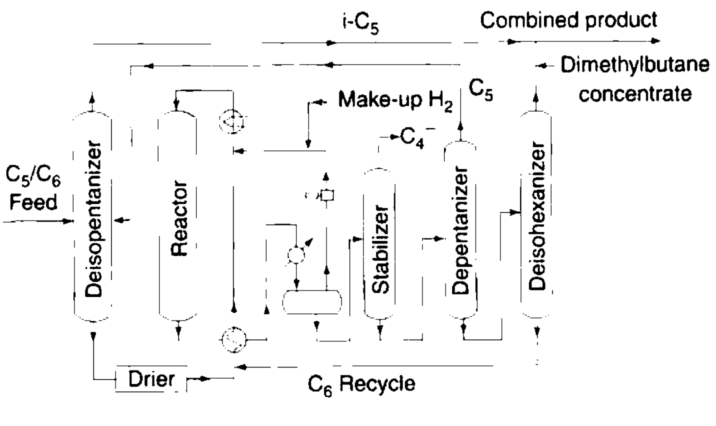


Fig. 1. C_5H_6 Isomerization unit. (*UOP Process Div.*)

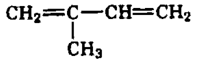
isomers and the bunching of some of their boiling points preclude precision separation in columns having a reasonable number of plates.

Once-through processing of a typical C_5/C_6 (68–70 octane number) straight-run fraction results in a product having a Research Method octane number (clear) of about 83. By recycling the unconverted *n*-pentane, *n*-hexane, and most of the methylpentanes, a product having an octane number of about 93 would result. Obviously, any octane number between 83 and 93 could be produced, depending on the amount and quality of the equipment installed to separate the reactor effluent into net product and recycle streams.

ISOPRENE. In the 1990s isoprene is used almost exclusively as a monomer for polymerization.

The isoprene unit exists extensively in nature. It is found in terpenes, camphors, diterpenes (e.g., abietic acid), vitamins A and K, chlorophyll, and other compounds isolated from animal and plant materials. The correct structural formula for isoprene was first proposed in 1884.



Properties

Isoprene (2-methyl-1,3-butadiene) is a colorless, volatile liquid that is soluble in most hydrocarbons but is practically insoluble in water. Typical properties of isoprene are listed in Table 1.

Conformation. The exact conformation of the isoprene molecule is still in doubt. It is generally accepted that rotation is restricted around the central C–C single bond. Isoprene may be considered as an equilibrium of two conformations, namely a cisoid (*s-cis*) conformation in which both vinyl groups are located on the same side of the C–C bond, and a transoid (*s-trans*) one with the vinyl groups located on the opposite sides of the bond.

Reactions

Isoprene is highly reactive both as a diene and through its allylic hydrogens, and its reactions are similar to those of butadiene. Apart from polymerization, the most widely investigated isoprene reactions are the formation of six-membered rings by the Diels-Alder reaction.

Free-Radical Reactions. Free radicals attack isoprene, and two competing mechanisms, at the double bond or involving C–H bonds,

$$R\cdot + R'H \xrightarrow{solvent} RH + R'$$

Halogens and Halogenated Compounds. The chlorination of isoprene in CCl_4 at −5 to −10°C, using an equimolar ratio of chlorine to isoprene, gives us a mixture of 44% of 1,4-dichloro-2-methyl-2-butene and 14% of 3,4-dichloro-2-methyl-1-butene as addition products, along with 42% of the substitution product, 2-chloromethyl-1,3-butadiene.

Bromination of isoprene using Br_2 at −5°C in chloroform yields only *trans*-1,4-dibromo-2-methyl-2-butene.

The reaction of dihalocarbenes with isoprene yields exclusively the 1,2- (or 3,4-) addition product, e.g., dichlorocarbene Cl_2C: and isoprene react to give 1,1-dichloro-2-methyl-2-vinylcyclopropane.

Isoprene reacts with α-chloroalkyl ethers in the presence of $ZnCl_2$ in diethyl ether from 0–10°C.

Hydrocarbons. The reaction of isoprene with toluene, ethylbenzene, or isopropylbenzene is catalyzed by sodium or potassium. The products are chiefly monopentenylated in the side chain, and no information can be obtained on whether the addition is 1,4- or 1,2-, because under these conditions the double bond migrates.

Other Compounds. Primary and secondary amines add 1,4- to isoprene.

Polymerization. Isoprene polymerization can proceed by either 1,4- or 1,2- (vinyl) addition.

Of the many catalysts that polymerize isoprene, four have attained commercial importance. One is a coordination catalyst based on an aluminum alkyl and a vanadium salt which produces *trans*-1,4-polyisoprene. A second is a lithium alkyl which produces 90% *cis*-1,4-polyisoprene. Very high (99%) *cis*-1,4-polyisoprene is produced with coordination catalysts consisting of a combination of titanium tetrachloride, $TiCl_4$, plus a trialkylaluminum, R_3Al, or a combination of $TiCl_4$ with an alane (aluminum hydride derivative).

The polymerization of isoprene by alkali metal and organometallic compounds (other than organolithium) is a heterogeneous reaction both in bulk and hydrocarbon solvents.

Production

The largest capacity has been and remains in the CIS (former USSR) region. Several plants around the world have been shut down, and the trend appears to continue downward. On the other hand the use of isoprene in block copolymers has grown rapidly. This growth has tended to offset some of the decline of *cis*-1,4-polyisoprene.

The principal route for production of isoprene monomer outside of the CIS is recovery from ethylene by-product C_5 streams.

Synthesis. Because of the limited availability of by-product isoprene much effort has been devoted to synthesis of isoprene. Most routes tend to have marginal selectivity and require large amounts of energy. The choice of which route is preferable depends on availability and cost of raw materials and cost of energy. Several synthetic routes have been practiced commercially including propylene dimer, dehydrogenation of tertiary amylenes, isobutylene–formaldehyde, isopentane dehydrogenation and acetone–acetylene.

Health and Safety

Isoprene is not known to present serious toxicological hazards in handling; however, as is the case with many other chemicals, studies concerning the safety of isoprene are ongoing. In humans, a one minute inhalation of 0.16 mg isoprene per liter air is mildly irritating to the mucous membranes of the eyes, nose, and upper respiratory passages. It was proposed that the limit of isoprene concentration on industrial sites be set at 0.04 mg/L air; it was also recommended that the maximum concentration of isoprene in water be set at 0.005 mg/L.

Isoprene is classified by the ICC as a flammable liquid requiring a red label. Because of the potential hazards on its exposure to oxygen, isoprene should be stored in an inert atmosphere (nitrogen) in the presence of at least 50 ppm of *t*-butylcatechol.

Economic Aspects and Applications

Isoprene pricing tends to vary considerably due to a fairly thin commercial market. Because isoprene raw materials are primarily petroleum-based and synthesis or recovery is energy intensive, most pricing is indexed to petroleum and energy. For large-scale applications, monomer production is in tandem with application production. Generally isoprene availability is less than butadiene, and the price is higher. Isoprene is used where the unique properties of the products can command a premium over butadiene. Almost all isoprene produced is used for the preparation of polymers or copolymers. *cis*-Polyisoprene is the largest application, with SIS block polymers being a rapidly growing secondary application. Butyl rubber is a significant third application.

ISOPROPYL ALCOHOL. [CAS: 67-63-0]. Also called dimethylcarbinol or secondary propyl alcohol, formula $(CH_3)_2$ CHOH, *isopropyl alcohol* is a colorless liquid at room temperature. Pleasant odor, bp 82.4°C, specific gravity 0.7863 (20/20°C), autoignition temperature, 400°C. The compound is soluble in water, ethyl alcohol, and ether.

Two basic methods of production are in commercial use: (1) absorption of propylene in sulfuric acid to form alkyl hydrogen sulfate, followed by the hydrolysis of the ester; and (2) by direct hydration with water, using a catalyst. An inherent disadvantage in the first process is the need to handle sulfuric acid. Further, the first process yields little more than 70% isopropanol as compared with the second process, in which liquid propylene is used as the charge stock. All direct-hydration processes can be represented by: $C_3H_6 + H_2O \rightarrow C_3H_7OH$ + heat.

Isopropyl alcohol is a widely used chemical, finding use as a starting material for making acetone and its derivatives; in the manufacture of glycerol and isopropyl acetate; as a solvent for essential and other oils, alkaloids, gums, and resins; as a latent solvent for cellulose derivatives; as a deicing agent for liquid fuels; in pharmaceuticals, perfumes, and lacquers; in extraction processes; as a dehydrating agent; and as a preservative.

See also **Alcohol**; and **Organic Chemistry**.

ISOTHERMAL. A term used to denote the following: 1. Of constant temperature, with respect to either space or time. Isothermal processes are those conducted without temperature change.

2. A line or curve expressing a relationship between variables such as pressure and volume, for all values of which the temperature remains constant.

3. A line joining points at the same temperature.

ISOTONE. One of two or more nuclides having the same number of neutrons in their nuclei.

ISOTOPE. An isotope is one of two or more nuclides that have the same number of protons in their nuclei. Any two isotopes have the same atomic number, Z. However, their mass numbers, A, differ. Isotope is a term that stems from the Greek words, *isos* (same) and *topos* (place), to designate substances having different atomic weights and yet having chemical properties so much alike that in the early days of research it was not possible to perform a chemical separation of the isotopes of a given element.

Sometimes, the term *nuclide* is confused with isotope. A nuclide may be defined as a species of atoms, with a specified atomic number and mass number. Different nuclides having the same atomic number should be described as isotopes. This is evident from the accompanying table. Different nuclides having the same mass number are termed *isobars*.

The existence of isotopes first became evident in the early years of this century, from the investigation of natural radioactivity. Then it was found that the natural radio elements underwent successive nuclear

TABLE 1. RELATIONSHIP OF ATOMIC AND MASS NUMBERS IN DESIGNATING ISOTOPES

Element	Mass number A	Atomic number Z	Atomic number Z	Atomic number Z	Atomic number Z	
Hydrogen	1	1				All nuclides
Hydrogen	2	1				
Hydrogen	3	1				
Helium	3		2			
Helium	4		2			
Helium	5		2			
Lithium	5			3		
Helium	6		2			
Lithium	6			3		
Lithium	7			3		
Beryllium	7				4	
Lithium	8			3		
Beryllium	8				4	
Beryllium	9				4	
Beryllium	10				4	
	Isobars	Isotopes				

Table indicates that hydrogen has three isotopes, each with same atomic number, but with differing mass numbers, and designated as ^1H, ^2H, and ^3H (thus using the mass number to designate a particular isotope. Similarly, the four lithium isotopes (all with atomic number 4) are designated by their mass number 4) are designated by their mass numbers, ^5Li, ^6Li, ^7Li, and ^8Li. Although redundant, because the element symbol implies the atomic number, symbols sometimes are sometimes are written to indicate both mass and atomic numbers, as ^7_3Li.

disintegrations, that they could be arranged in radioactive series according to these changes, and that in these series there were several instances in which atoms of the same atomic number (or as then stated, atoms occupying the same place in the periodic table) differed widely in their radioactive behavior. For example, it was found that radium C, radium E, thorium C and actinium C were all identical in their chemical properties with bismuth (atomic number 83) but differed in their radioactive properties and origins.

In the long course of research that led to the conclusion that more than one stable isotope of an element may exist, an important milestone was the method of positive-ray analysis. As applied by J.J. Thomson, an electric discharge was passed through a vessel containing a gas at low pressure. The effect of the discharge was to produce ions in the gas, and these ions, because of their electric charge, could be formed into beams, deflected and otherwise directed by applied electric and magnetic fields. An experimental apparatus was designed so that the amount of this deflection would depend upon the masses of the particles of the gas. By using neon gas (atomic weight 20.183) in the tube, Thomson obtained photographs showing two beams of particles, one of them in a position calculated for particles having a mass of about 20, and the other for a mass of about 22. Although the conclusion was not immediately reached, it was later concluded (from the work of Aston) that neon (and other elements) consisted of atoms of more than one mass. Aston expressed this conclusion in the whole number rule, according to which, all atomic weights of individual atomic species are close to whole numbers, and the whole number plus decimal values calculated chemically for the atomic weights of elements are due to the presence of two or more isotopes, each of which has an atomic weight that is approximately a whole number. The fact that the chemically determined values for the elements of naturally occurring materials from different sources are the same is because the isotopic composition of naturally occurring materials (except those of radioactive origin) is essentially the same.

Aston's work was founded upon accurate measurements of the deflections of charged particles. These measurements were made in an instrument he devised, the mass spectrograph. Many later instruments were developed following Aston's work, or following the Dempster instrument, which was built before Aston's. The direction-focusing mass-spectrographs and the later velocity-focusing instruments and composite instruments facilitated the determination, not only of the masses (and hence mass numbers) of the isotopes of an element, but their quantities as well. As a result of the immense amount of research in this field, the isotopic composition of the stable elements has been closely determined. And this data can now be said to be subject to only slight revision, as more refined methods, and the possible discovery of stable isotopes present in very small quantities, are found.

It will be seen from Table 1 that naturally occurring elements differ widely in the number of isotopes they contain. Some (usually of odd atomic number) are composed entirely of atoms of one mass number. Others have many stable isotopes. For example, the element of atomic number 50, which is tin, has at least ten stable isotopes and many radioactive ones.

The great importance of isotopes is due to two facts. (1) Since the atomic number of an atom determines its chemical properties, all the isotopes of a given element exhibit essentially the same chemical behavior; that is, all atoms of the same atomic number undergo essentially the same reactions with atoms of other atomic numbers. Thus, all three of the isotopes of hydrogen (protium, deuterium and tritium) undergo essentially the same reactions with oxygen, carbon, and all the other elements. Therefore, if we add to the ordinary form of an element (which has a known isotope composition) a measured amount of an isotope of that element, we can follow the course of our sample through chemical reactions, especially those in which the same element enters at other points. This instance cited is representative of the many applications of isotopes which will be discussed in this article. (2) The other fact that accounts for the great present-day importance of the knowledge of isotopes is that, while the isotopes of an element exhibit similar chemical behavior, the nuclear characteristics of these isotopes often differ greatly. A most important example of this difference is that between ^{235}U and ^{238}U See also **Uranium**, where the separation of these and other isotopes is described.

The isotopes of all elements are tabulated under **Chemical Elements**. Also, there are descriptions of isotopes under the alphabetical entries for each element. The nature and importance of radioisotopes are described under **Radioactivity**.

J

JACOBSEN REARRANGEMENT. Reaction of polymethylbenzenes with concentrated sulfuric acid to give rearranged polymethylbenzenesulfonic acids. Under identical conditions, halogenated polymethylbenzens undergo disproportionation.

JACQUEMART'S REAGENT. Analytical reagent used to test for ethyl alcohol. Consists of an aqueous solution of mercuric nitrate and nitric acid. See also **Ethyl Alcohol**.

JADE. Jade is a general term for a compact green mineral substance much prized for ornamental purposes. Jade is either a compact actinolite called nephrite, a variety of amphibole, or jadeite, a monoclinic pyroxene. It is easily worked, and many prehistoric implements have been found of this material in Mexico, Switzerland, France, Greece, and Egypt. The word jade is derived from the Spanish *pietra di hijada*, kidney stone, because it was supposed to be beneficial to diseases of the kidneys. Nephrite is derived from the Greek word for kidney, the allusion being the same as in the case of jade.

See also **Amphibole**; **Jadeite**; and **Pyroxene**.

JADEITE. The mineral jadeite, essentially sodium-aluminum silicate, $Na(Al, Fe^{2+})Si_2O_6$, is a monoclinic pyroxene usually appearing in crystalline masses, or may be granular, fibrous, or compact. It has a prismatic cleavage; splintery fracture; hardness, 6 in crystals, 6.5–7 massive variety; specific gravity, 3.24–3.43; luster, vitreous to pearly; color, various shades of green, bluish-green, greenish-white or almost white; translucent to opaque. The processes that have acted to form this mineral are little understood both because of the confusion that exists between jadeite and nephrite, and the fact that the localities are not well known. Jadeite is found in Myanmar and China and has been reported from Mexico. It has probably resulted from the metamorphism, at great depths, of rocks rich in soda and aluminum, such as nephelite syenites. Its association in Myanmar with serpentine suggests its origin in more basic igneous rocks. See also **Pyroxene**.

Jadeite is a tough and yet rather easily worked substance, and has long been used for ornamental purposes. Evidence has been found in Europe, Mexico, Egypt, and elsewhere that it was used in prehistoric times for both ornaments and implements. The word jadeite is the general term used for all green-colored tough compact stones that have been used as indicated above.

JAMESONITE. This mineral is commonly called brittle *feather-ore* from its brittle character and usual habit in acicular mats of crystals. It crystallizes in the monoclinic system and is of metallic luster, opaque with gray-black color and streak. It has a hardness of 2.5 and a specific gravity of 5.63–5.67. It is a sulfide of lead and iron antimony, $Pb_4FeSb_6S_{14}$.

Jamesonite occurs in low- to moderate-temperature hydrothermal veins with other lead sulfosalt minerals. Exceptional specimens are found in Bolivia, at Potosi and Oruro, and as choice felted masses on pyrite at Zacatecas in Mexico. Jamesonite is also found in Arkansas, Idaho, and Utah in the United States and in Ontario and British Columbia, Canada. It is named after the English mineralogist, Robert Jameson, from specimens obtained from Cornwall, England. It is a minor ore of lead.

JANOVSKY REACTION. Reaction of aldehydes and ketones containing α-methylene groups with m-dinitrobenzenes in the presence of a strong base, resulting in the formation of an intense purple coloration, used for the detection of carbonyl compounds. The color is due to the formation of Meisenheimer complex.

JAPP-KLINGEMANN REACTION. Formation of hydrazones by coupling of aryldiazonium salts with active methylene compounds in which at least one of the activating groups is acyl or carboxyl. This group usually cleaves during the process.

JAROSITE. The mineral jarosite is a basic hydrous sulfate of potassium and iron corresponding to the formula $KFe_3(SO_4)_2(OH)_6$. It is formed in the outcrops of ore deposits during oxidation of iron sulfides. It is a hexagonal mineral with basal cleavage; is brittle; hardness 2.5–3.5; specific gravity 2.9–3.26; luster vitreous to dull; color, dark yellow to yellowish-brown; pale yellow streak; translucent to opaque. Jarosite was originally reported from and named for Barranco Jaroso in the Sierra Almagrera, Spain. It has been found in Bohemia, France, the Island of Elba, Siberia, and Bolivia. In the United States it is found in Arizona, Colorado, Texas, New Mexico, Utah, Nevada, and South Dakota.

JASPER. A variety of chert, always quartz, that is associated with iron ores and thus contains iron-oxide impurities which give the rock a variety of colorations, often red, but ranging through yellow, green, grayish-blue, brown, and even black. The term also has been used with reference to any red chert or chalcedony. The material is dense, cryptocrystalline, and usually opaque, although it may be slightly translucent.

JATROPHONE. A diterpenoid growth inhibitor isolated from an alcohol extract of the plant *Jatropha gossypiifolia*. Its unique structure includes a 12-membered ring and is readily attacked by nucleophiles. *Jatrophone* is useful in the study of tumor growth inhibition and other biochemical research.

JELLY. A modified form of the word *gel* widely used in popular language but also used in chemical literature to refer to the mechanical strength of the gel structures occurring with pectins, gelatin, and various natural gums. "Jelly strength" is frequently specified in the food industry. Other uses of the word are found in "petroleum jelly" obtained as a distillation product of petroleum residues (petrolatum) and in the so-called *royal jelly*, a natural nutrient mixture of proteins and carbohydrates produced by bees as food for the queen bee. See also **Colloid Systems**; and **Petroleum**.

JENNER, EDWARD (1749–1823). An English physician, Jenner studied medicine in London and established his practice in the rural area of Gloucestershire. Here he discovered the technique of vaccination as a preventive of smallpox (1776). The idea of utilizing cowpox, a disease of cattle, as a protective medium was suggested by his observation that personnel working in dairies developed immunity to smallpox after contracting the much milder cowpox. Jenner's work not only led to almost complete elimination of smallpox in Europe, but also anticipated the development of immune reactions by Pasteur a century later. His success was no accident, but rather the result of detailed observations from which he drew correct conclusions. He was a scientist of the highest caliber and a noteworthy benefactor of mankind.

JET FUEL. A fuel for jet (turbine) engines, usually a petroleum distillate similar to kerosine. A number of types with somewhat different compositions and properties have been used. See also **Petroleum**.

JETSET. A fast-setting cement developed by the Portland Cement Association. Reported to harden in 20 minutes after pouring. Accelerating agent has not been disclosed.

Web Reference

Portland Cement Association: http://www.portcement.org/index.asp

JH. (methyl-*cis*-10,11-epoxy-7-ethyl-3,11-dimethyl-*trans,trans*-2,6-tridecadienoate). A synthetic hormone containing a 13-carbon chain; said to have possibilities as an insecticide. It acts by preventing insects from maturing. Its future depends on the possibility of large-scale production.

See also **Junvenile Hormones**.

JOLIOT-CURIE, FREDERICK (1900–1958). A French physicist who, along with his wife Irene Joliot-Curie, won the Nobel prize in chemistry in 1935. His important discoveries included artificial radioactivity. He did much work on atom structure, dematerialization of electrons, and inverse transformation. Work on hormone synthesis and thyroid substances containing radioactively labeled elements was significant. Sc.D. from the University of Paris was followed by a distinguished career filled with honors and appointments.

JOLIOT-CURIE, IRENE (1897–1956). A French nuclear scientist who won the Nobel prize for chemistry with her husband Frederick Joliet-Curie. Their joint work involved production of artificial radioactive elements by using α-rays to bombard boron. They discovered that hydrogen-containing material when exposed to what they considered γ-rays would emit protons. They were involved in many firsts: they gave the first chemical proof of artificial transmutation and of capture of alpha particles, and were the first to prepare positron emitter. Her career started with a Sc.D. at the University of Paris, and included scores of honors and awards.

JONES OXIDATION. The oxidation of primary and secondary alcohols to acids and ketones by the addition of the calculate amount of chromic anhydride in dilute sulfuric acid to a solution of the alcohol in acetone. This procedure does not attack triple bonds or shift double bonds into conjugation with the ketone formed in the oxidation.

JOSEPHSON, BRIAN DAVID (1940–). Josephson was born in Wales and was recognized even in his undergraduate studies at Cambridge University as having great natural insight on scientific ideas. In 1973, he won the Nobel Prize in Physics jointly with Leo Esaki and Ivar Giaever for his work in experimental superconductivity. He is remembered for the "Josephson effect" also explained as the tunneling phenomena, which is an important idea for modern physics. His discoveries helped advance technology, especially in the development of high-speed switching circuits used in instrumentation and computers.

Josephson was greatly influenced by transcendental meditation techniques of the 1960s and 1970s and believed that mystical experience should be incorporated into science. His latter research also included work in the theory of intelligence.

See also **Josephson Tunnel-Junction**; and **Thin Films**.

J.M.I.

JOSEPHSON TUNNEL-JUNCTION. As early as 1962, B. Josephson recognized the implications of the complex order parameter for the dynamics of the superconductor, in particular when one considers a system consisting of two bulk superconductors connected by a "weak link." The basic requirement for the weak link is that the amplitude of the order parameter at the link should be substantially smaller than in the bulk regions. In early experimentation, such a situation was realized in a variety of ways—two evaporated films separated by a thin (less than 20 angstroms) oxide layer; a light point contact between two bulk superconductors; a single hourglass-shaped evaporated film, with the constriction of dimensions small compared to the coherence length; or even a bare niobium wire with a pendant frozen blob of soft solder, where the weak links, indeterminate in number, are formed by solder bridges through pinholes in the surface oxide. Collectively, all such weak link junctions are referred to as *Josephson junctions*.

Both the dc and ac Josephson effects have found interesting and novel applications. The high sensitivity to magnetic field of the dc Josephson current in certain circuit configurations has been used to develop a family of devices called squids (super conducting *q*uantum *i*nterferometric *d*evices) which can be used to measure extremely small currents, voltages, and magnetic fields. The ac effect has been useful in making precise measurements in connection with research toward improving the maintenance of the U.S. legal volt.

Much interest is presently exhibited in the use of Josephson superconducting devices of the tunnel-junction type (operated at near absolute zero) in connection with building superfast computers. In such devices, the electrical signals have only a millimeter or two to travel. Switching time is about 10^{-11} second. The power dissipation of Josephson devices permits high circuit density. It is estimated that the power dissipation of transistors is about 100 times that of Josephson devices. Different materials are being studied to improve the original lead alloy thin-film materials. These include lead-indium-gold alloys and niobium-tin alloys.

JOULE, JAMES PRESCOTT (1818–1889). Joule was an English physicist. He was born into a family of brewers and as he grew up he became knowledgeable about steam engines used in the brewery. Also, the town he grew up in, Manchester, England had factories with machinery that depended on the steam engine and so it was almost natural that with his curiosity of science, Joule became interested in mechanical energies. By 1837, Joule published his first scientific paper on electric motors.

He is remembered for Joule's Law that describes the rate at which heat is produced by an electric current. Joule's work showed there were different kinds of energy, which can be changed into each other. He established the mechanical equivalence of heat. His work led to the law of conservation of energy. Also, he collaborated with William Thomson (Lord Kelvin) and verified experimentally the Joule-Thomson refrigeration effect.

See also **Joule Law**; **Joule-Thomson Effect**; and **Oxygen**.

JOULE LAW. The quantity of heat generated by a steady electric current is proportional to the resistance of the conductor in which the heat is generated, to the square of the current, and to the time of its duration: $H = KRI^2t$. If the resistance is in ohms, the current in amperes, the time in seconds, and the heat in calories, the constant K has the value 0.2390 calories/joule.

JOULE-THOMSON EFFECT. In passing a gas at high pressure through a porous plug or small aperture, a difference of temperature between the compressed and released gas usually occurs. This phenomenon is called the Joule-Thomson effect. The equation for this effect contains two partial derivatives and is

$$\left(\frac{\partial T}{\partial P}\right)_H = \frac{T\left(\dfrac{\partial V}{\partial T}\right)p - V}{C_P}$$

where the expression on the left is the rate of change of temperature with pressure at constant enthalpy (heat content) (since no heat is supplied to, or removed from the system). The expression on the right has in its numerator the difference between the product of the temperature and the rate of change of volume with temperature at constant pressure, from which the volume is subtracted; the denominator contains the molar specific heat at constant pressure. The term on the left of the equality sign is called the *Joule-Thomson Coefficient*. It varies with the temperature and pressure of the gas, passing from positive values through zero to negative values. The temperature at which it is zero is called the *Joule-Thomson Inversion Temperature* and varies with the particular gas. It is to be noted, however, that for hydrogen, and also for helium, the temperature is low, far below 0°C. For other gases, however, much higher values are found, the maximum value for oxygen being 1,058 K (785°C). At temperatures above their inversion temperature, gases are warmed, while at temperatures below it, they are cooled by the effect. For that reason, this type of expansion is often used in industrial processes for cooling gases. An interesting application is the application is the process for producing solid carbon dioxide by expanding carbon dioxide through an aperture.

For an ideal gas, $PV = RT$; thus, $(\partial V/\partial T)$ is equal to R/P, that is, to V/T, so that the numerator of the right-hand term in the equation above becomes 0; thus an ideal gas shows no Joule-Thomson effect.

JOURDAN-UIIMANN-GOLDBERG SYNTHESIS. Synthesis of substituted diphenylamines. The reaction products can be used as intermediates in the synthesis of acridones.

JUNVENILE HORMONES. One of several hormones, that retard the development of insects in the larval stage. So called because they prevent the insect from maturing by maintaining its juvenile characteristics. Obtained naturally from silk moths; various syntheses indicate possible use as insecticides, especially for fire ants. Composition of one type is $C_{18}H_{30}O_3$.

See also **JH**; and **Insecticide**.

K

KAOLINITE. The most common mineral of a group of hydrous aluminum silicates, which result from the breaking down of aluminum-rich silicate rocks, such as the feldspars and nepheline syenites, either through weathering or hydrothermal activity. Kaolinite, when pure, corresponds to the formula $Al_2Si_2O_5(OH)_4$, and occurs in white, clay-like masses. It has a perfect basal cleavage; is flexible but not elastic; hardness, 2–2.5; specific gravity, 2.6–2.63; luster, pearly to dull; color, white when pure, as described above, but may be yellow, red, blue, or brown; translucent to opaque.

Kaolinite is a mineral of widespread occurrence, well distributed throughout the world. The finest kaolinite locality in Europe is said to be in France, from whence the clay is obtained for porcelain ware. Cornwall and Devonshire in England supply large quantities of this mineral. In the United States, Pennsylvania, Virginia, Colorado, Georgia, and South Carolina contain deposits of kaolinite. The word kaolin or kaolinite is said to be a corruption of a Chinese word *kauling*, the name of a locality where this mineral is found. Kaolinite is very important commercially in the manufacture of china and pottery.

KARLE, JEROME (1918–). An American physical chemist who won the Nobel prize for chemistry along with Herbert A. Hauptman in 1985. He developed a series of mathematical equations that allow determination of phase information from X-ray crystallography intensity patterns. The advent of computers allowed the use of the equations to determine the conformation of thousands of chemicals. The work was done at the Naval Research Laboratory in Washington, DC., where Karle headed the Laboratory for the Structure of Matter.

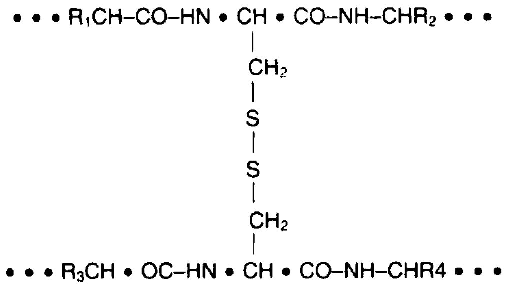
KARRER, PAUL (1889–1971). A recipient of the Nobel prize for chemistry in 1937 with Walter N. Haworth. Although born in Moscow, he attended European universities and received his doctorate in Zurich. He Initiated work on flavins, carotenoids, and vitamins A and B, and accomplished work on structure and synthesis of vitamin B_2 as well as vitamins A and E.

KAURI-BUTANOL VALUE. A measure of the aromatic content and hence the solvent power of a hydrocarbon liquid. Kauri gum is readily soluble in butanol but insoluble in hydrocarbons. The kb value is the measure of the volume of solvent required to produce turbidity in a standard solution containing kauri gum dissolved in butanol. Naphtha fractions have a kb value of about 30, and toluene about 105.

KEKULE, AUGUST (1829–1896). Born in Darmstadt, Germany, Kekule laid the basis for the ensuing development of aromatic chemistry. His idea of a hexagonal structure for benzene in 1865 was a monumental contribution to theoretical organic chemistry. This had been preceded in 1858 by the remarkable notion that carbon was tetravalent and the carbon atoms could be joined to each other in molecules. The theory of the benzene ring has been called the "most brilliant piece of scientific prediction to be found in the whole field of organic chemistry, for besides promulgating the idea, he had predicted the number and types of isomers which might be expected in various substitutions on the ring" (L. B. Clapp).

KENDREW, JOHN C. (1917–1997). An English molecular biologist who won the Nobel prize for chemistry in 1962 with Max F. Perutz, for their studies of the structures of globular proteins. His work verified Pauling's earlier thesis concerning the α-helix structure of the polypeptide chain. After receiving his Ph.D. from Cambridge, he was science advisor to the allied air commander-in-chief during World War II. He was also editor of the journal *Molecular Biology*.

KERATIN. A class of natural fibrous proteins occurring in vertebrate animals and humans, they are characterized by their high content of several amino acids, especially cystine, arginine, and serine. They are generally harder than the fibrous collagen group of proteins. The softer keratins are components of the external layers of skin, wool, hair, and feathers, while the harder types predominate in such structures as nails, claws, and hoofs. The hardness is largely due to the extent of cross-linking by the disulfide bonds of cystine by the mechanism shown below:



Kertains are insoluble in organic solvents but do absorb and hold water. The molecules contain both acidic and basic groups and are thus amphoteric.

Uses for kertains include: tablet coatings which dissolve only in the intestines, foam extinguishers and protein hydrolyzates.

KERATINASE. A water-soluble, proteolytic enzyme having the ability to digest the keratin in wool and other forms of hair, converting a portion of it to a water-soluble form. It thus acts as a depilatory and is used in removing hair from pelts and hides, as well as from human skin. It is inactivated by heating to 100°C.

KERMA. Of ionizing particles, the kerma is $\Delta E_K/\Delta m$, where ΔE_K is the sum of the initial kinetic energies of all the charged particles liberated by indirectly ionizing particles in a volume element of the specified material, and Δm is the mass of the matter in that volume element. In these definitions, the symbol Δ precedes the letters E_K and m to denote that these letters represent quantities that can be deduced only from multiple measurements that involve extrapolation or averaging procedures. Since ΔE_K is the sum of the initial kinetic energies of the charged particles liberated by the indirectly ionizing particles, it includes not only the kinetic energy these charged particles expend in collisions, but also the energy they radiate in bremsstrahlung. The energy of any charged particles is also included when these are produced in secondary processes occurring within the volume element. Thus the energy of Auger electrons is part of ΔE_K. In actual measurements, Δm should be so small that its introduction does not appreciably disturb the radiation field. This is particularly necessary if the medium for which kerma is determined is different from the ambient medium; if the disturbance is appreciable, an appropriate correction must be applied.

KERNITE. This hydrated sodium borate mineral, $Na_2B_4O_7 \cdot 4H_2O$, occurs in a single known world locality at Kramer, Kern County, California. It is found here as veins and interbedded masses in clay, hundreds of feet thick, thought to be a product of heating and dehydration of a large buried body of borax by intrusive igneous rocks. Crystals are monoclinic and attain individual size to 3 by 8 feet. Cleavage is very perfect to both the macro and basal pinacoids, with hardness, 2.5–3, and specific gravity of 1.908; possesses vitreous luster grading to satiny on cleavage surfaces; colorless to white; transparent. Surface alters readily to tincalconite, a white powder. It is a major source of borax and boron compounds. See also **Borax**.

KEROGEN. The organic component of oil shale, it is a bitumen-like solid whose approximate composition is 75–80% carbon, 19% hydrogen, 2.5% nitrogen, 1% sulfur, and the balance oxygen. It is a mixture of aliphatic and aromatic compounds of humic and algal origin and comprises a substantial proportion of the shale; after fractionating and refining, the oil is reported to yield 18% gasoline, 30% kerosene, 27% gas oil, 15% light lube oil, and 10% heavy lube oil.

See also **Oil Shale**.

KEROSINE. See **Petroleum**.

KETENES. Members of a class of compounds which contain the functional group =C=C=O. Examples are ketene itself (CH_2CO), methylketene $CH_3CH{=}C{=}O$, dimethylketene $(CH_3)_2C{=}C{=}O$, diphenylketene $(C_6H_5)_2C{=}C{=}O$, and carbon suboxide $O{=}C{=}C{=}C{=}O$. Of these, ketene is by far the most important. It is a reactive, colorless gas of considerable industrial importance. Physiologically, it is extremely poisonous and care must be taken to avoid breathing it.

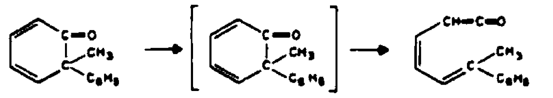
The availability of ketone by pyrolysis of acetone (or acetic acid) is the reason for the attention it has received, contrasted to other ketenes which are relatively unavailable. Ketene may be prepared also by pyrolysis of acetic anhydride or phenyl acetate or diketene. Other sources are quite unsatisfactory from a standpoint of yield. Small quantities may be made conveniently by heating acetone in a "ketene lamp." This is a glass apparatus containing a Nichrome filament, heated electrically to red heat. Larger amounts are made by passing acetone or acetic acid through a tube at 700°C. A very brief contact time is required, so that much of the acetone is undecomposed and has to be condensed and recycled. Also, it is imperative that the reaction tube be of inert material such as porcelain, glass, quartz, copper or stainless steel. A copper tube, if used, should be protected from oxidation by an iron sheath. Inert packing may be used (glass, vanadium pentoxide, porcelain), but just as good yields are obtained with empty tubes. No catalyst is known which accelerates this decomposition at significantly lower temperatures.

Methyl ethyl ketone is totally unsatisfactory as a source of methylketene by pyrolysis, but pyrolysis of propionic anhydride in a quartz tube at 400–600°C and low pressures does produce it in a stated yield of about 90%. Another synthetic approach is to prepare methylketene dimer by allowing a mixture of propionyl chloride and triethylamine to stand at 25° for 24 hours and then to pyrolyze the dimer.

The known disubstituted ketenes include dialkyl-ketenes, diarylketenes, and the ester analogs. Dimethylketene may be made from α-bromoisobutyryl bromide by reaction with zinc in boiling ether. Diphenylketene may be made similarly, but the usual way to prepare it is to oxidize benzil hydrazone with yellow mercuric oxide to benzoylphenyldiazomethane which, on heating in benzene solution, decomposes into the ketene.

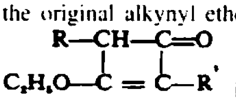
The best way to make carbon suboxide is a pyrolytic method, starting with tartaric acid. The latter is converted into diacetyltartaric anhydride and then pyrolyzed at 625–650°C (either in an empty tube or in a ketene lamp) into acetic acid and carbon suboxide, the latter in 35–50% yields.

Some recent synthesis of ketenes involve interesting chemistry. A butadienylketene is obtainable at −100 to −150°C by photolysis (mercury lamp) of the appropriate cyclohexadienone:



The reaction is reversed on warming, but the ketene may be captured by an amine to form an amide.

1-Ethoxy-1-alkyne, $R{-}C{\equiv}C{-}OC_2H_5$, pyrolyzes at 120° into ethylene and alkylketene, but the latter is consumed by the original alkynyl ether to form 2,4-dialkyl-3-ethoxy-2-cyclobutenone,



in high yield.

Ketene and diimide are formed during the alkaline decomposition of chloroacetic hydrazide. The diimide, however, spontaneously changes into hydrazine plus nitrogen, and the hydrazine consumes the ketene to form acetohydrazide, $CH_3CONHNH_2$. If an olefin is present in the reaction mixture it is reduced to a paraffin by the diimide, thus preventing hydrazine formation.

The formulas of acetic acid, acetic anhydride and ketene show that the anhydride differs from the acid by 0.5 mole of water, and that ketene differs by 1.0 mole. Ketenes, therefore, may be regarded as super acid anhydrides, and this viewpoint leads to a good appreciation of their reactions. Because of an original lack of understanding of this relationship, the monosubstituted ketenes were once classed as "aldoketenes," and the disubstituted ketenes as "ketoketenes." Such terms are quite misleading, however, and should be abandoned.

Ketene is absorbed in sodium hydroxide solution, yielding sodium acetate. Aniline adds to ketene to form acetanilide. Both of these reactions are quantitative and are used to assay the ketene in a gas stream.

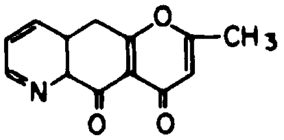
Primary alcohols react readily with ketene to form acetic esters but tertiary alcohols require the catalytic help of sulfuric acid. Even with primary alcohols, as 1-butanol, it has been established that addition of ketene ceases at about the 75% conversion point unless a little sulfuric acid is present as catalyst. Phenol, which is inert toward ketene at ordinary temperature, may be converted into phenyl acetate by reaction at the boiling point of phenol or by reaction at room temperature if a trace of sulfuric acid is present.

An important industrial synthesis of acetic anhydride is via acetic acid and ketone. Mixed acetic anhydrides are made similarly by passing ketene into the acid in question: $RCOOH + CH_2CO \longrightarrow RCO{-}O{-}COCH_3$. This is the basis of a good method of synthesizing symmetrical anhydrides in view of their formation from the mixed anhydrides on heating:

$$2\ RCOOCOCH_3 \longrightarrow (RCO)_2O + (CH_3CO)_2O.$$

Comparable reactions of ketene are those with mercaptans to form thio esters (CH_3COSR), with amino acids (in water) to obtain N-acetyl derivatives ($CH_3CONHCHRCOOH$), with hydroxylamine to yield acetohydroxamic acid ($CH_3CONHOH$), dimethylchloroamine to form chloroacetic dimethylamide ($ClCH_2CON(CH_3)_2$), and Grignard reagents to form ketones ($RCOCH_3$).

Ketene adds to pyridine in a 4:1 ratio to form a yellow, crystalline compound.



Quinoline, isoquinoline, and phenanthridine resemble pyridine in reacting comparably, and diketene may be substituted for ketene.

Aromatic aldehydes take up ketene in the presence of potassium acetate in the manner of a Perkin reaction. The product is a cinnamic acid:

$$ArCHO + CH_2CO \xrightarrow{AcOK} ArCH{=}CHCOOH.$$

Friedel-Crafts catalysts are effective in converting formaldehyde and ketene into β-propiolactone. This is a process of industrial importance. Similarly, furfural and ketene give rise to 3- (2-furyl)-propionolactone.

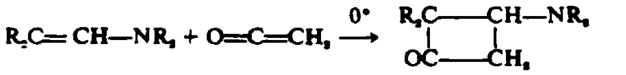
When aluminum chloride is used as catalyst, ketene reacts with benzene to form acetophenone: $C_6H_6 + CH_2CO \longrightarrow C_6H_5COCH_3$. Also, methyl chloromethyl ether under such conditions reacts to yield 3-methoxypropionyl chloride:

$$CH_3OCH_2Cl + CH_2CO \xrightarrow{AlCl_3} CH_3OCH_2CH_2COCl.$$

Ketones such as acetone, ethyl acetoacetate, ethyl levulinate or acetylacetone react smoothly with ketene if a trace of sulfuric acid is present. The products are enol acetates of the ketones, acetone giving rise to isopropenyl acetate,

$$CH_2{=}C(CH_3){-}OCOCH_3,$$

and ethyl acetoacetate changing into ethyl 3-acetoxycrotonate. Cyclobutanone derivatives are made quite easily by addition of ketenes to styrene or to vinyl ethers or to enamines:



One of the most characteristic reactions of ketene or dialkyl-ketenes is that of polymerization into dimers. Diarylketenes do not display this

tendency. The dimer from ketene, or "diketene," is a liquid that boils without decomposition at 43° (28 mm), but the compound tends to decompose (into dehydroacetic acid and resinous substances) on distillation (b.p. 127°C) at atmospheric pressure. The structure of diketene was in doubt for many years, but recent critical chemical and physical evidence indicates the structure as 3-buteno-β-lactone. Diketene is an acetoacetylating agent. Thus, with aniline it yields acetoacetanilide, and with methanol (catalyzed by sulfuric acid) it produces methyl acetoacetate. These reactions are useful industrially.

KETIMINE. A type or class of curing agent for epoxy resins that makes it possible to use very-high-solids content coatings in spray equipment. Reacts with epoxies very slowly and thus delays curing time, which prevents setting up of the resin during spraying operation. In presence of water or water vapor, ketimine breaks down to a polyamine and a ketone. Epoxy coatings cured with ketimine should not exceed a thickness of 10 mils.

KETONES. The homologous series of ketones (like aldehydes) has the formula $C_nH_{2n}O$. Structurally, the ketones consist of a carbonyl group (C:O) linkage between two radicals (R–CO–R′). R and R′ may be the same as in acetone (dimethyl ketone) CH_3–CO–CH_3; or they may differ as in methylethyl ketone CH_3–CO–C_2H_5. The latter may be referred to as a *mixed ketone*. A ketone is isomeric with the aldehyde that contains the same number of carbon atoms. Thus, acetone C_3H_6O is isomeric with propaldehyde C_3H_6O. Where R and R′ are alkyls, the ketone may be called an *alphyl ketone* and may be considered to be derived from the secondary alcohols. Ketones also may be formed from aromatic alcohols as in the case of benzophenone C_6H_5–CO–C_6H_5. The latter compound is a fully aromatic or *diaryl ketone*. Further, there are mixed *aryl-alphyl ketones* as in the case of acetophenone (phenylmethyl ketone) C_6H_5–CO–CH_3. The foregoing examples illustrate the use of trivial names for the ketones. In another system, the ketone may take its name from the alcohol from which it may be derived—thus, propione (from propyl alcohol); or the ketone may be named for the acid to which it may be oxidized—thus, acetone (acetic acid the oxidation product).

Essentially ketones exhibit the following properties: (1) all ketones up to C_{11} are neutral, mobile, volatile liquids. Ketones above C_{11} are solids under usual ambient conditions; (2) all ketones have a reasonably agreeable odor; (3) all ketones except those with a very high carbon count are soluble in H_2O, the solubility decreasing with a rise in formula weight; (4) most ketones are soluble in alcohol or ether, and (5) the specific gravity of ketones rises uniformly to about 0.83 with a rise in formula weight. The physical properties of some common ketones are listed in Table 1.

The presence of the double bond (carbonyl group C:O) markedly determines the chemical behavior of ketones. The hydrogen atom connected directly to the carbonyl group is not easily displaced. The chemical properties of the ketones may be summarized as follows: (1) they are readily reduced to form *secondary alcohols*, particularly in the presence of a catalyst. This property is used to advantage in the production of numerous organic compounds where ketones serve as a starting material or as an intermediate; (2) unlike the aldehydes, ketones are considerably more stable and do not combine readily with the alcohols, nor generally with NH_3 at ordinary temperatures and pressures; (3) they do not reduce alkaline solutions of metals and also, unlike aldehydes, ketones do not undergo polymerization; (4) they combine with hydroxylamine to yield *ketoximes*; (5) they react with hydrazine to form *hydrazones*; (6) they combine with semicarbazine to form *semicarbazones*; (7) with H_2SO_4 or HCl present, ketones can be induced to undergo a cyclic trimerization with the loss of H_2O; (8) when oxidized, ketones decompose to form two acids. Each acid will contain fewer carbon atoms than the originating ketone; and (9) ketones react with HCN to form *cyanohydrins*.

When ketones are reduced to secondary alcohols, varying amounts of ditertiary alcohols (pinacols) are produced. In a reaction known as the pinacol-pinacoline rearrangement, effective in synthesis of difficult compounds, ketones when treated with magnesium amalgam, after hydrolysis, yield a 1, 2-glycol. Important to the purification of methyl and some cyclic ketones is their ability to form crystalline additive compounds with sodium bisulfite solutions. Ketones also react with phosphorus pentachloride and pentabromide to form dihalogen derivatives of the alkyls in which instances the oxygen atom of the carbonyl group is replaced by two hydrogen atoms.

Ketones are widely used as starting and intermediate ingredients in the production of numerous synthetics, such as resins, and they find wide application as solvents. Other important ketones produced on a tonnage basis include methylethyl ketone (MEK) and methylisobutyl ketone (MIBK). Commercially, MEK may be manufactured by the direct oxidation of butylene in which air is used, along with a catalyst solution comprising copper chloride and palladium chloride. The overall reaction is $C_4H_8 + \frac{1}{2}O_2 \longrightarrow CH_3COC_2H_5$. During the reaction, the palladium chloride is reduced to elemental palladium and HCl. Cupric chloride causes reoxidation. The resulting cuprous chloride is reoxidized to cupric chloride during the catalyst regeneration cycle. The process proceeds under moderate pressures at a temperature of about 100°C. The MEK product must be treated with sodium bisulfite and caustic soda, followed by distillation, to yield pure MEK.

In the production of MIBK, acetone may be the chargestock. In a first step, acetone is converted to diacetone alcohol (DAA) by condensation under pressure with an alkaline catalyst. The latter may be calcium or barium hydroxide, both of which are slightly soluble in H_2O. After cooling, in a second step, mesityl oxide (MSO) is produced by dehydrating the DAA. For this step, an acid catalyst is used and the step proceeds in the temperature range of 100 to 120°C. When the MSO is formed from the DAA, the latter partially decomposes into acetone. Thus, a distilling phase is required to separate and recover the acetone. In a third step, the MSO is hydrogenated and a mixture of MIBK and methylisobutyl carbinol (MIBC) is produced. These must be separated by a further fractionating phase. The hydrogenation reactions are: $(CH_3)_2C{=}CHCOCH_3 + H_2 \longrightarrow (CH_3)_2CHCH_2COCH_3$ (MIBK); and $(CH_3)_2CHCH_2COCH_3 + H_2 \longrightarrow (CH_3)_2CHCH_2CHOHCH_3$ (MIBC). The temperature of the process and the hydrogen mole ratio used determines the ratio of MIBK/MIBC produced and thus the manufacturer has effective control over the amounts of end-products (MIBK and MIBC) which can be manipulated in accordance with market requirements.

Related Compounds

A polyhydric ketone is refereed to as a *ketose*. Monosaccharoses are examples of open-chain polyhydroxyaldehydes or ketones. The aldehyde sugars are termed *aldoses*; the ketone sugars are called ketoses. Fructose is a ketose. Dihydroxyacetone HO · CH_2· CO · CH_2· OH is a very simple ketose. Compounds that contain both a carbonyl and a carboxylic group are termed *ketonic acids*. They display the reactive properties of both an acid and a ketone. Pyroracemic acid CH_3· CO · CO_2H, acetoacetic acid CH_3· CO · CH_2· CO_2H, and laevulic acid CH_3· CO · CH_2· CH_2· CO_2H are examples of monobasic ketonic acids. *Ketonic hydrolysis* is a term used to describe such actions as the hydrolysis of the ethyl ester of acetoacetic acid into acetone, CO_2, and ethyl alcohol. Compounds such as ketene CH_2:CO, methyl ketene CH_3CH:CO, dimethyl ketene $(CH_3)_2C$:CO, and diphenyl ketene $(C_6H_5)_2C$:CO are of the family known as *ketenes*.

Health and Safety Factors

Ketones are flammable substances that do not exhibit a known high degree of chronic toxicity. Low molecular weight (C_3–C_{12}) saturated aliphatic ketones, which represent the bulk of industrially important ketones, may be classified among the solvents of comparatively low toxicity hazard. The eight-hour threshold limit value is generally above 100 ppm, although the odor threshold is in the range 5–25 ppm. High vapor concentrations of these volatile ketones induce anesthesia, however, the vapors are so irritating to the eyes and mucous membranes of the respiratory system that the atmosphere generally becomes intolerable before toxic concentrations are achieved. Many ketones are also powerful drying and degreasing agents, and prolonged skin contact can cause dermatitis.

[b] To convert J to cal, divide by 4.184.

The C_3–C_{12} ketones are all highly flammable liquids with flash points varying from −18°C for acetone to 85°C for isobutyl heptyl ketone. Ketones float on water, and become only partially soluble in water with increasing molecular weight. Thus, ketones typically require copious quantities of water to extinguish pool fires. Saturated ketones are in general stable at ambient conditions, and do not undergo hazardous polymerization in normal environment. Most ketones are incompatible with strong oxidizing and reducing agents; some ketones are also incompatible with bases and/or acids.

KETOSES. See **Carbohydrates**.

KEYES EQUATION. An equation of state for a gas, deduced from the concept of the nuclear atom. This equation is designed to correct the van der Waals equation for the effect upon the term b of the surrounding molecules. The equation is written as

$$P = \frac{RT}{V - Be^{-\alpha/V}} - \frac{A}{(V + l)^2}$$

in which P is pressure, T is absolute temperature, V is volume, R is the gas constant, e is the base of natural logarithms, 2.718 . . ., and A, α, and B, and l are constants for each gas.

KEYES PROCESS. A distillation process involving the addition of benzene to a constant-boiling 95% alcohol-water solution to obtain absolute (100%) alcohol. On distillation, a ternary azeotropic mixture containing all three components leaves the top of the column while anhydrous alcohol leaves the bottom. The azeotrope (which separates into two layers) is redistilled separately for recovery and reuse of the benzene and alcohol.

KIMBERLITE. The name applied to a mica peridotite which occurs at Kimberley and other places in the Republic of South Africa, the source of rich deposits of diamonds. These valuable gem stones were originally found in the decomposed kimberlite which, being colored yellow by limonite, was termed "yellow ground." Deeper workings disclosed the less altered rock, kimberlite, which the miners call "blue ground."

KINETIC MEASUREMENTS. Kinetic measurements are studies of the rates at which chemical reactions occur. Generally, these studies involve preparing a chemical system using reagent concentrations different from the equilibrium values and then monitoring the concentration changes as the system approaches equilibrium, although other, less direct strategies are sometimes exploited. Chemical kinetic data are used in materials science, biochemistry and molecular biology, earth and atmospheric science, and many branches of engineering. Related concepts appear in nuclear physics, but presuppositions and methods are different there.

Kinetic information is acquired for two different purposes. First, data are needed for specific modeling applications that extend beyond chemical theory. These are essential in the design of practical industrial processes and are also used to interpret natural phenomena such as the observed depletion of stratospheric ozone. Compilations of measured rate constants are published in the United States by the National Institute of Standards and Technology (NIST). Second, kinetic measurements are undertaken to elucidate basic mechanisms of chemical change, simply to understand the physical world. The ultimate goal is control of reactions, but the immediate significance lies in the patterns of kinetic behavior and the interpretation in terms of microscopic models.

Explaining chemical change by postulating mechanisms in terms of macroscopic concentrations is expected to continue for the foreseeable future. For a fundamental understanding of very simple reactions, however, traditional kinetics is being challenged by theoretical and experimental methods that focus directly on the behavior of individual atoms.

Macroscopic Behavior and the Rate Law

Chemical Equations. Chemical changes are discussed with the aid of the equations used to treat equilibrium, i.e., the reaction of reactants A, B, C, and so on, to produce products P, Q, and so forth.

The essential information implied by the chemical equation is the stoichiometry at the macroscopic level, i.e., if a moles of A react, then b moles of B do also; p moles of P formed, etc.

A kinetic study typically prepares some set of initial concentrations not at equilibrium and describes the subsequent evolution of each. A basic assumption is that each component evolves according to some differential equation where t represents time.

$$d[A]/dt = f([A], [B], \ldots, [P], \ldots \text{other conditions}) \qquad (1)$$

In general, the differential equation could be very complicated, e.g., the concentrations may be functions of spatial coordinates as well as time. Experimental measurements are arranged to ensure that simplified equations apply.

The Well-Stirred Mixture. A key assumption of most kinetic measurements is that of a well-mixed solution of reactants. Then any component can be characterized by a single time-dependent concentration, applicable to the entire system.

In particularly simple cases, which occur frequently, one may assume a dependence on powers of reactants and ignore products

$$d[A]/dt = -k[A]^x[B]^y[C]^z \qquad (2)$$

Experimental Verification of a Rate Law

It is possible to prepare a system having an initial concentration for each component, and then measure a finite, but small, change in the concentration of one component, $\Delta[A]$ for example, over a known interval of time, Δt. The experimental velocity $\Delta[A]/\Delta t$ and the concentrations can be substituted into a proposed rate law, like equation 2, along with postulated values for the exponents x, y, . . . to determine an observed constant k_{obs}. If this process is repeated for a reasonable range of concentrations, and the postulated rate law having the same exponents always yields the same k_{obs}, then it is asserted that the rate law has been verified for those concentration ranges and the rate constant determined. This approach is a reasonable strategy for an initial survey of a totally unknown system; but it is wasteful, in that it extracts very little data from each set of initial conditions. More often, the integrated form of the rate law is fit to multiple concentration measurements recorded at different times for each set of initial conditions.

Flooding and Pseudo-First-Order Conditions. Flooding is an experimental strategy that simplifies both measurement and analysis. For an example, consider a reaction that is independent of product concentrations and has three reagents. If a large excess of $[B_i]$ and $[C_i]$ are used, and the disappearance of a lesser amount of $[A]$ is measured, the rate law can be integrated with the assumption that all concentrations are constant excepts $[A]$. Consequently, simple expressions are derived for the time variation of $[A]$. Under flooding conditions and using equation 2, if x happens to be 1, the time-dependent concentration of A exhibits an exponential decrease from its initial value $[A_i]$ to its final equilibrium value, or endpoint, $[A\infty]$:

$$[A(t)] - [A_\infty] = ([A_i] - [A_\infty])\exp(-k_{obs}t) \qquad (3)$$

The conditions chosen make the reaction appear to be first-order overall, although the reaction is really not first-order overall, unless y and z happen to be zero. The pseudo-first-order rate constant k_{obs} is related to the k in the originally postulated rate law by

$$k_{obs} = k[B_i]^y[C_i]^z \qquad (4)$$

If x is not 1, equation 3 is replaced by a different, but still simple, integrated rate law.

The Initial Conditions. One of two very different strategies are used in kinetic measurements to produce the initial, nonequilibrium concentrations of reactants. Either the separate reagents are mixed or a system previously at equilibrium is perturbed.

Mixing known quantities of reagents to produce desired initial concentrations can be carried out with either a continuous flow or a stopped

flow apparatus. Engineering details become important for fast reactions, especially those occurring in less than one millisecond.

Perturbation methods can be divided further into two categories. One uses a flash of light (flash photolysis) or other radiation (radiolysis) to create a homogeneous distribution of a desired reagent from some precursor molecule. This method is capable of very fast time resolution; recent advances in lasers allow the study of processes occurring in 10^{-14} s. The other perturbation method does not affect reagents but instead changes some intensive thermodynamic property, such as temperature, pressure, or an electric field. Concentrations are monitored as the system adjusts to the requirements of the new equilibrium.

Indirect and Novel Methods. A direct measurement is a record of changing concentrations as a function of time. In principle, the same information is available as a Fourier transform in the frequency domain. Since the latter part of the nineteenth century, it has been possible to measure the absorption of electromagnetic radiation as a function of frequency (or wavelength) and interpret lineshapes to yield kinetic information on the picosecond time scale. In gases, line widths increase at high pressure owing to collision broadening. Dissociation or ionization may also determine a linewidth. More subtle effects occur in liquids. More recently, chemical reactivity on slower time scales has been measured by lineshape analysis in Mossbauer spectroscopy and magnetic resonance.

Dramatic progress is being made in extending kinetic analyses to microscopic samples, such as single biological cells. One strategy infuses precursor molecules into the correct part of a cell and then uses flash photolysis to start a reaction that is monitored continuously by fluorescence microscopy. Within such small volumes, there may be only thousands of molecules of a given type and their number may change due to statistical fluctuations, even in a system at equilibrium. Such fluctuations obey the same laws of chemical kinetics as any other perturbation; and a study of fluctuations can determine kinetic parameters, although this is far from being a routine technique. Pioneering experiments are even being carried out for kinetic studies on single atoms, not in cells, but isolated in a magnetic or optical trap.

Rapid instrumental measurements have largely, but by no means completely, supplanted an earlier tradition that relied on a more chemical strategy of measuring concentrations of reactants or intermediates by intercepting these with a scavenger that reacted quickly to form a stable product that could be quantified later. Such trapping methods can be construed as being indirect in the sense that they rely on one chemical reaction being faster or slower than another.

Experimental Variation of Chemical Rates with Temperature and Pressure

The experimentally measured dependence of the rates of chemical reactions on thermodynamic conditions is accounted for by assigning temperature and pressure dependence to rate constants.

Microscopic Models in Kinetics

Mechanism is a technical term, referring to a relatively detailed, microscopic description of a chemical transformation, which, nevertheless, still falls far short of a complete dynamical description at the atomic level. A mechanism for a reaction is sufficient to predict the macroscopic rate law of the reaction. This deductive process is valid only in one direction, i.e., an unlimited number of mechanisms are consistent with any measured rate law. A successful kinetic study postulates a mechanism, derives the rate law, and demonstrates that the rate law is sufficient to explain experimental data over some range of conditions. New data may be discovered later that prove inconsistent with the assumed rate law and require that a new mechanism be postulated. Mechanisms state, in particular, what molecules actually react in an elementary step and what products these produce. An overall chemical equation may involve a variety of intermediates, and the mechanism specifies those intermediates.

KINETIC THEORY. A theory (proved by experiment) that explains the phenomena of heat and pressure as due to the kinetic motion and elastic collisions of atoms and molecules. The phenomena include gas and vapor pressure, evaporation, and diffusion of fluids.

Gases expand indefinitely when released, not because of repulsion between the molecules as formerly supposed (though the Joule-Thomson effect under certain conditions may involve this), but because the molecules are in rapid motion and do not stop unless they collide with something. Air is not "forced" out through a tire puncture; only those air molecules pass out which, in their aimless wanderings, happen to encounter the opening. Molecules also pass in from the outside; but since there are several times as many per unit volume inside as outside, many more pass out than in. This continues until, a statistical equilibrium being reached, the air inside is no more dense than that outside, and the tire is "flat." The rapidity with which this takes place emphasizes the speed of the molecular motion and the relative insignificance of the "internal friction" opposing it.

What appears to be a steady pressure is due to the incessant impacts of the gas molecules on any surface exposed to them. If n molecules of equal mass m are released in an enclosure of volume v, and if their speeds are $u_1, u_2, \ldots u_n$, it is easy to show that the average pressure set up by these impacts, neglecting the effects of collisions and gravity, is

$$p = \frac{m}{3v}(u_1^2 + u_2^2 + \cdots + \cdots u_n^2) \tag{1}$$

This may be written

$$P = \frac{1}{3}\frac{nm}{v}\frac{\sum(u^2)}{n}$$

or, since nm/v is the gas density ρ, and $\rho(u^2)/n$ is the mean square molecular speed $\overline{u^2}$,

$$p = \tfrac{1}{3}\rho\overline{u^2} \tag{2}$$

This relation gives the mean square speed as $\overline{u^2} = 3p/\rho$; which is the square of the effective speed, corresponding to average kinetic energy. From this it may be shown that the average speed is

$$\overline{u} = \sqrt{\frac{8p}{\pi\rho}} \tag{3}$$

easily determined since p and ρ are measurable.

Again, Equation (1) may be written

$$pv = \tfrac{2}{3}\left(\tfrac{1}{2}mu_1^2 + \tfrac{1}{2}mu_2^2 + \cdots + \tfrac{1}{2}mu_n^2\right) = \tfrac{2}{3}E \tag{4}$$

in which E is the total kinetic energy of linear motion of the molecules. From this it follows that the absolute temperature T of the gas bears a constant ratio to this total kinetic energy, and hence to the average translational kinetic energy of the molecules. See also **Ideal Gas Law**.

Further analysis shows that when gravity is considered, the pressure in an undisturbed pure gas of uniform temperature, at an elevation h, is given by

$$p = p_0 e^{-3gh/\overline{u^2}} \tag{5}$$

in which p_0 is the pressure at the zero of elevation. This is a form of Laplace's "law of atmospheres," useful in barometric altitude determinations.

A quantity much used in kinetic theory is the "mean free path," which is the average distance traversed by a molecule between collisions. There are ways of calculating this and also the effective diameters of molecules, and these data lead to many conclusions as to frequency of collisions and rate of diffusion.

Irreversibility. The kinetic theory assumes that the velocity of a molecule may depend on the conditions in the region where it has just suffered a collision, but is otherwise random—in other words, independent of its previous history. This assumption permits one to use the methods of probability theory even though, in classical mechanics, the actual motions of the molecules are regarded as completely determined by their initial configurations. As long as one uses the theory only to calculate properties of a gas that can actually be measured during a relatively short time, the assumption of randomness leads to no serious errors. However, it introduces an element of irreversibility that is inconsistent with the reversibility of

the laws of classical mechanics. A reversible process is one that can go equally well forwards or backwards, in contrast to an irreversible process. Lord Kelvin pointed out the importance of irreversible processes in 1852. The irreversible aspect of the kinetic theory is shown most clearly by Boltzmann's "H-theorem," which has led to a considerable controversy over the foundations of kinetic theory. Boltzmann showed in 1872 that a certain quantity, later called H, which depends on the velocity distribution, must always decrease with time, unless the velocity distribution is Maxwell's distribution, in which case H remains constant. In the latter case, which corresponds to the equilibrium state, H is proportional to the negative of the entropy. Thus, the H-theorem provides a molecular interpretation of the second law of thermodynamics or, in particular, the principle that the entropy of an isolated system must always increase or remain constant.

Irreversible processes are those in which entropy increases. The entropy itself can be regarded as a measure of the degree of randomness or disorder of the gas, although it must be recognized that disorder really means a lack of knowledge about the details of molecular configurations. The equilibrium state represents the maximum possible disorder; the H-theorem implies that a gas which is initially in a nonequilibrium (partly ordered) state will eventually reach equilibrium and then stay there forever if it is not disturbed.

If the long-term consequences of the H-theorem were applicable to all matter in the universe, one might expect that the universe would eventually "run down"—although the total energy might always remain the same, no useful work could be done with this energy, because all matter would be at the same temperature. This final state has been called the "heat death" of the universe.

The contradiction between the H-theorem and the laws of classical mechanics is shown by two well-known criticisms of the kinetic theory: (1) the reversibility paradox and (2) the recurrence paradox. The first paradox is based on the fact that Newton's laws of motion are unchanged if one reverses the time direction, so that it would seem to be impossible to deduce from these equations a theorem that predicts irreversible behavior. Kelvin discussed this paradox in 1874, and concluded that while any single sequence of molecular motions could be reversed, leading to an ordered state, the number of disordered states is so much greater than the number of ordered states that it is virtually impossible to stay in an ordered state for any period of time. Thus, irreversibility is a statistical, but not an absolute consequence of kinetic theory. Boltzmann gave a similar answer when the problem was pointed out to him by Loschmidt a few years later.

The second paradox is based on a theorem of Henri Poincaré—if a mechanical system is enclosed in a finite volume, then after a sufficiently long time it will return as closely as one likes to its initial state. Hence H must return to its original value; if it has decreased during some period of time, it must increase during some other period. The time between successive recurrences of the same state for the molecules in one cubic centimeter of air is much longer than the present age of the universe, so one does not have to be concerned about recurrences in any actual experiment. In his attempt to resolve the recurrence paradox, Boltzmann was finally led to a remarkable psycho-cosmological speculation; he suggested that the direction of time as perceived by an animate being is determined by the direction of irreversible processes in his environment and in his body. Thus, when the time comes for a recurrence, entropy will decrease, but subjective time will flow in the opposite direction. The concept of alternating time-directions in cosmic history was further explored by Reichenbach in 1956 and has been proposed again in recent theories of the expanding (and contracting) universe.

Updating of Kinetic Theory. Since the late 1940s, there has been a revival of interest in the classical kinetic theory of gases, based on the assumptions of Clausius, Maxwell, and Boltzmann, and ignoring quantum effects except insofar as these may determine the intermolecular force law. In part this interest grew out of applications involving high speed aerodynamics and plasma physics and, in part, from renewed attempts to construct reliable theories of liquids as well as dense gases. Methods for obtaining accurate solutions of the Boltzmann equation were developed by Grad, Pekeris, Ikenberry, and Truesdell, among others. These solutions were used to describe the behavior of gases in many circumstances more complex than those treated in the 1800s (including the interactions of charged particles and magnetic fields). Problems such as the propagation and dispersion of sound waves were treated by Uhlenbeck and his collaborators.

In 1946, three general formulations of kinetic theory were published (Born and Green; Kirkwood; and Bogoliubov). In each case, the goal was to derive a generalized Boltzmann equation in a form that would be valid when simultaneous interactions among more than two molecules have to be taken into account, and thence to obtain solutions of the equation from which transport properties of dense gases and liquids could be calculated. In each formulation, certain approximations had to be made in order to obtain practical results. Because of the difficulty in estimating the error involved in these approximations, and the great complexity of the equations involved, there was no clear evidence that the results for properties such as the viscosity coefficient would be significantly more accurate than those obtained by Enskog from his modified kinetic theory for dense gases, published in 1922. Eventually, in the early 1960s, attention was centered on the systematic derivation of series expansions for the transport coefficients in ascending powers of the density, together with attempts to calculate the first few terms in such series for special molecular models, such as elastic spheres.

In the meantime, an alternative and apparently more rigorous method for deriving theoretical expressions for transport coefficients, based on the fluctuation-dissipation theory introduced in 1928 by H. Nyquist in electrical engineering problems, was developed by Green, Mori, and Kubo. This method had the heuristic advantage of bringing out clearly the connection between transport theory and the description of fluctuations in equilibrium statistical mechanics. Later, it was proved that the Green-Mori-Kubo method gives results precisely equivalent to those that could be obtained from the Born-Green, Kirkwood, and Bogoliubov methods. Thus, just as in the case of quantum mechanics, several alternative approaches are equally valid in modern kinetic theory.

After intensive efforts to calculate terms in the density expansion of transport coefficients, it was finally discovered in 1965 that such a density expansion does not actually exist, for mathematical reasons associated with the persistence of weak correlations between colliding particles over very long times. The divergence of the expansion (and thus the inadequacy of the approximations on which most earlier theories had been based) was established by a number of investigators, including Dorfman and Cohen, Weinstock, and Goldman and Friedman. The result was an increased overall interest in kinetic theory.

KININS. Chemical substances that stimulate differentiation of plant cells that otherwise may have lost permanently the power of differentiation. The kinins contain adenine, which seems to give these substances their biological activity. Small bits of a carrot taken from a region containing no cambium can be stimulated to growth and differentiation to produce entire new carrot plants through the addition of kinins and a small amount of indoleacetic acid.

See also **Adenine**.

KISHNER CYCLOPROPANE SYNTHESIS. Formation of cyclopropane derivatives by decomposition of pyrazolines formed by reacting $\alpha\beta$-unsaturated ketones or aldehydes with hydrazine.

KISTIAKOWSKY, GEORGE B. (1900–1982). Born in Kiev, Russia, where he fought in the White Russian Army, he studied in Germany under Maxwell Bodenheim, where he obtained his doctorate in chemistry. In 1926, he came to the U.S. and became an American citizen in 1933. For 41 years, he was Professor of Chemistry at Harvard; in addition to many chemical awards, he was the recipient of the Priestley Medal as well as distinguished Medals of Honor from three Presidents of the U.S. President Eisenhower appointed him as his assistant for science and technology, and he was chairman of the Science Advisory Committee from 1957 to 1963. Among his many achievements in both chemistry and physics, he was a world-famous authority on explosives. A key member of the Manhattan

Project, he devised the detonating mechanism for the first experimental atomic bomb in New Mexico, at which time he was head of the Los Alamos Laboratory. Though he ranks high among those who developed the bomb, he perceived the awesome destructive potential of nuclear weapons and became an ardent opponent of their future use. Resigning from the Pentagon in 1967, he returned to teaching at Harvard. Among other distinguished organizations, he was a member of the Royal Society of London, the AAAS, and the ACS.

KJELDAHL TEST. An analytical method for determination of nitrogen in certain organic compounds. It involves addition of a small amount of anhydrous potassium sulfate to the test compound, followed by heating the mixture with concentrated sulfuric acid, often with a catalyst such as copper sulfate. As a result ammonia is formed. After alkalyzing the mixture with sodium hydroxide, the ammonia is separated by distillation, collected in standard acid, and the nitrogen determined by back-titration.

KLUG, AARON S. (1926–). A South African-born chemist who won the Nobel prize for chemistry in 1982 for his work with the electron microscope and research into the structure of nucleic and protein complexes. His use of crystallographic electron microscopy to analyze the structures of biologically important complex chemicals was noteworthy. He was cited in particular for his establishment of Fourier microscopy.

KOMAROWSKY REACTION. The reaction between certain alcohols and *p*-hydroxybenzaldehyde in dilute sulfuric acid solutions to give soluble colored complexes. 1,2-Propylene glycol gives a colored product while ethylene glycol does not. The reaction has also been employed to determine cyclohexanol in cyclohexanone.

KONOWALOFF RULE. The vapor over a liquid is relatively rich in the component whose addition to the liquid mixture results in an increase of the total vapor pressure.

KOPP'S LAW. The molecular heat of a solid compound is an additive function of the atomic heat capacities of its individual atoms. The molecular volume of a liquid is equal to the sum of the atomic volumes of its constituent atoms.

KRAFT PULP PROCESS. See **Pulp (Wood) Production and Processing.**

KREBS CITRIC ACID CYCLE. See **Carbohydrates.**

KROLL PROCESS. A widely used process for obtaining titanium metal. Titanium tetrachloride is reduced with magnesium metal at red heat and atmospheric pressure, in the presence of an inert gas blanket of helium or argon. Magnesium chloride and titanium metal are produced. The reaction is $TiCl_4 + 2Mg \longrightarrow Ti + 2MgCl_2$. Essentially the same process is also used for obtaining zirconium.

KROTO, SIR HAROLD W. (1939–). A British chemist who won the Nobel prize for chemistry along with Robert F. Curl, Jr. and Richard E. Smalley in 1996, the 100th anniversary of Alfred Nobel's death. The trio won for the discovery of the c_{60} compound called buckminsterfullerene. He received a Ph.D. from the University of Sheffield.

See also **Buckminsterfullerene (Buckyballs); Curl, Robert F., Jr. (1933–); and Smalley, Richard E. (1943–).**

KRYPTON. [CAS: 7439-90-9]. Chemical element, symbol Kr, at. no. 36, at. wt. 83.80, periodic table group 18 (inert or noble gases), mp −156.6°C, bp −152.3°C, density 3.4 g/cm^3 (solid at −273°C). Solid krypton has a face-centered cubic crystal structure. At standard conditions, krypton is a colorless, odorless gas and does not form stable compounds with any other element. Due to its low valence forces, krypton does not form diatomic molecules, except in discharge tubes. It does form compounds under highly favorable conditions, as excitation in discharge tubes, or pressure in the presence of a powerful dipole. Krypton forms a hydrate at 14.5 atmospheres pressure and 0°C. The element also forms addition compounds with a number of organic substances, such as $Kr \cdot 2C_6H_5OH$ with phenol, which has a dissociation pressure of 6 to 10 atmospheres at 0°C. Krypton also forms compounds, possibly clathrates, with certain substances in nonstoichiometric proportions. Examples are its crystalline compounds with benzene and the compounds formed in aqueous solutions of hydroquinone, under 40 atmospheres pressure of krypton, which contains 15.8% krypton by weight. First ionization potential, 13.996 eV; second, 26.4 eV; third, 36.8 eV.

Krypton occurs in the atmosphere to the extent of approximately 0.000114% and thus is the second least abundant of the rare gases in ordinary air. In terms of abundance, krypton does not appear on lists of elements in the earth's crust because it does not exist in stable compounds. However, because of its limited solubility in H_2O, krypton is found in seawater to the extent of approximately 1.4 tons per cubic mile. Commercial krypton is derived from air by liquefaction and fractional distillation. With exception of very special applications, krypton usually is not prepared in pure form, but supplied along with other rare gases, such as argon and neon, for filling fluorescent and incandescent light. As a filter in lamps, the gas assists in reducing filament evaporation and enables higher operating temperatures for lamps. Very high-candlepower aircraft-approach lamps contain krypton. When contained in an electric-discharge tube, krypton, when pure, emits a characteristic pale-violet light; when impure, it emits a brilliant red color characteristic of so-called neon tubes. Krypton also has been used in lasers. There are five natural isotopes ^{78}Kr, ^{80}Kr, and ^{82}Kr through ^{84}Kr, and five radioactive isotopes ^{76}Kr, ^{77}Kr, ^{79}Kr, ^{81}Kr, and ^{85}Kr. The latter isotope is generated in atomic reactors, and is a beta emitter with a half-life of approximately 10.6 years. This isotope, in solid form combined with a hydroquinone, has been used for activating phosphors and in luminous paints. ^{81}Kr, has a particularly long half-life of 2.1×10^5 years. While investigating the properties of liquid air in 1898, Ramsay and Travers found krypton in the residue remaining after nearly all of the liquid air had boiled away. The element then was identified spectroscopically. The element emits a characteristic brilliant green and yellow line in its spectrum.

In 1989, physicists at the Los Alamos National Laboratory's High-Energy Physics facility developed a krypton-fluoride laser at a cost of about $1 million. The laser's energy beam is capable of striking a very small target. Key to the success of the small laser is the ability to compress modest energy into pulses of less than 1 picosecond duration. The laser is being used in research on new materials. With the laser, tiny targets can be heated to temperatures approaching those of the sun's core.

By international agreement in 1960, the *fundamental unit of length*, the *meter*, is defined in terms of the orange-red spectral line of ^{86}Kr. This corresponds to the transition $5p[O_{1/2}]_1 - 6d[O_{1/2}]_1$. One meter = 1, 650, 763.73 wavelengths (in vacuo) of the orange-red line of ^{86}Kr.

Meteorological Effects of Krypton-85 in the Atmosphere. As pointed out by Boeck (1976), projections indicate that ^{85}Kr, a radioactive, chemically inert gas, may be produced and released in such quantities that it will create atmospheric ions at rates comparable to the present ion production rate near the tropical ocean surface. Krypton-85 is a byproduct in nuclear fission reactors and explosions. The ^{85}Kr is sealed in fuel elements of reactors, but during reprocessing of the fuel or plutonium separation, ^{85}Kr is released in a controlled manner to the atmosphere. The radioactive half-life of ^{85}Kr is 10.76 years. With no apparent natural mechanism to remove it, the gas will accumulate in the atmosphere until a balance between the rate of release and decay is reached. Ultimately this could produce a unique form of atmospheric radiation as contrasted with such natural radioactivity as emanates from uranium, thorium, etc., which are limited to producing ions near ground level. In the atmosphere, of course, are several radioactive isotopes (half-lives are given in parentheses): ^{22}Na (2.6 years); ^{32}P (14.22 days); ^{7}Be (53.6 days); ^{33}P (24.4 days); ^{35}S (87.1 days), among others. Not much concern has been given to these isotopes because of their comparatively short half-lives. Boeck (1976) makes a case for the need for more fundamental research into the possible effects of ^{85}Kr in the atmosphere, including possible climatic alterations.

Krypton in Meteorites. Along with other rare gases, krypton has been found in meteorites, notably the Murchison carbonaceous chondrite. Some scientists have been predicting for years that meteorites may entrap materials that date back to the beginning of the universe. For many years, the field was dominated by the dogma of an isotopically and chemically uniform early solar system (Srinivassan and Anders, 1978). However, careful analyses of the Murchison meteorite have produced anomalies in the form of unexpected differences in the ratios of the various rare element isotopes present.

KUCHEROV REACTION. The hydration of acetylenic hydrocarbons with dilute sulfuric acid in the presence of mercuric sulfate or boron trifluoride as catalyst.

KUHN, RICHARD (1900–1967). A German chemist who won the Nobel prize for chemistry in 1938. He worked on cartinoids and synthetic vitamins and discovered the chemical formula for vitamin B_6. He also discovered a method for dissolving simplexes from plants, using invert soaps. He received his Ph.D. in Munich, and went on to teach in Switzerland.

KUHN-WINTERSTEIN REACTION. Conversion of 1,2 glycols into *trans* olefins by reaction with diphosphotetraiodide (P_2I_4) or other halogenated reagents. This reaction is useful in the preparation of polyenes.

KYANITE. The mineral kyanite is an aluminum silicate, corresponding to the formula Al_2SiO_5. It is triclinic, and has a good cleavage parallel to the macropinacoid. Its hardness varies considerably, depending on the crystallographic direction from 5 to 7.5; specific gravity, 3.56–3.67; luster, vitreous to pearly; color, commonly blue to white, but sometimes gray to green or nearly black; transparent to translucent; usually found in long-bladed crystals or columnar to fibrous structures. Kyanite is found in some metamorphic rocks as gneisses or mica schists. Of the many European localities for fine specimens might be mentioned the Ural Mountains of the former U.S.S.R.; the Czech Republic and Slovakia; Austria; Trentino, Italy; the St. Gotthard region of Switzerland; and France. In the United States, Chesterfield, Massachusetts; Litchfield, Connecticut; and Gaston County, North Carolina, have furnished fine specimens. Kyanite derives its name from the Greek word meaning *blue*, in reference to the delicate blue of the inner portions of the bladed crystals.

L

LACQUER. A protective or decorative coating that dries primarily by evaporation or solvent, rather than by oxidation or polymerization. Lacquers were originally comprised of high-viscosity nitrocellulose, a plasticizer (dibutyl phthalate or blown castor oil), and a solvent. Later, low-viscosity nitrocellulose became available; this was frequently modified with resins, such as ester gum or rosin. The solvents used are ethanol, toluene, xylene, and butyl acetate. Together with nitrocellulose, alkyd resins are used to improve durability. The nitrocellulose used for lacquers has a nitrogen content of 11–13.5% and is available in a wide range of viscosities, compatibilities, and solvencies. Chief uses of nitrocellulose-alkyd lacquers are for coatings for metal, paper products, textiles, plastics, furniture, and nail polish. Various types of modified cellulose are also used as lacquer bases, combined with resins, and plasticizers. Many noncellulosic materials such as vinyl and acrylic resins are also used, as are bitumens, with or without drying oils, resins, etc.

See also **Paints and Coatings**; and **Nitrocellulose**.

LACTIC ACID. [CAS: 50-21-5]. Alpha-hydroxy-propionic acid, $H{-}C_3H_5O_3$, formula weight 90.05, colorless or yellowish syrupy liquid, mp 18°C, bp 122°C, sp gr 1.248, miscible with water, alcohol, or ether in all proportions. It was first discovered in 1780 by the Swedish chemist Scheele. The substance exists in two forms: (1) *dextro* lactic acid, which rotates the plane of polarized light to the right; and (2) *levo* lactic acid which rotates the plane of polarized light to the left. A mixture of these two forms is ordinary lactic acid, which does not rotate the plane of polarized light. Ordinary lactic acid is termed dextrolevo lactic acid. Lactic acid is a product of corn refining.

Lactic acid was one of the first biological substances to be investigated from the standpoint of the existence of the two optically active forms.

Lactic Acidosis

Lactic acid is the cause of one of many possible disorders in human acid-base metabolism. Lactic acidosis represents an accumulation of lactic acid in the blood and tissues. This condition gradually depletes the natural buffers in the body and there is a consequent lowering of pH. As described in the entry on **Glycolysis**, lactic acid is the end product of that process. Lactic acid blood levels are determined by at least four factors. The rate of generation of lactic acid; the rate of transport from tissues to plasma and from plasma to the liver (point of utilization of lactic acid); the rate of utilization; and excretion of lactic acid by the kidneys. Normally, all of these functions are maintained in balance to give a normal blood lactate concentration of about 1 mEq/l.

On the generation side, three factors are involved. (1) The availability of oxygen is a major controlling determinant of lactic acid generation because, as adenosine triphosphate (ATP) generation from oxidative phosphorylation diminishes, the cells naturally respond with a greater rate of glycolysis. This increases tissue lactate levels and ultimately lactate blood levels. See also **Phosphorylation (Oxidative)**. (2) If, as may be caused by various factors, there is an increase in pH, the activity of phosphofructokinase will increase (this is the rate-limiting enzyme of glycolysis). With increases in pH, the enzyme is more active and more lactate is formed. (3) Factors that affect the biological oxidation-reduction potentials also influence the rate at which glucose is metabolized to lactate.

Fundamental predisposing conditions causing an increased generation of lactate include: decreased tissue perfusion associated with shock, which may occur in cardiac arrest; increased skeletal muscle activity (the rate of glycolysis increases with exercise; this also may be associated with convulsive states that may follow severe exercise—brought about by increased blood lactate concentrations); large tumors, since tumors (leukemias, lymphomas, etc.) may have an increased rate of glycolysis even in the presence of a sufficient supply of oxygen; and both cyanide and carbon monoxide poisoning, which can increase lactate levels because of insufficient oxygen supply.

On the utilization side, there are a number of influencing factors. The liver is the principal lactic acid utilization center. In liver failure, a surplus of lactate builds up, a condition which may be associated with reduced hepatic perfusion, hepatocyte failure, and hepatocytes replaced by tumor. Blood lactate concentrations are elevated in persons with diabetic ketoacidosis. The observed elevation of lactic acid levels in cases of alcoholism is not fully understood; the condition may increase generation or by decreasing utilization. The latter effect is now favored by many authorities, the theory being that ethanol completes for electrons in the liver, thus decreasing utilization of lactic acid in that organ.

Specifications, Quality Control, and Analytical Methods

Lactic acid is generally sold under four general product categories: synthetic: a highly purified product from a chemical synthesis process. It is water-white, has excellent heat stability, and can be used in both food and industrial applications; fermentation: a food-grade product from carbohydrate fermentation refined by ion exchange and activated carbon. The product contains residual carbohydrate or protein impurities and is not heat stable; heat-stable fermentation: a highly refined, heat-stable product from esterification of fermentation-derived lactic acid, followed by hydrolysis of the recovered ester to produce the acid; and technical: a crude product from either a synthetic or fermentation process, used in industrial applications where high purity is not required.

The fermentation-derived food-grade product is sold in 50, 80, and 88% concentrations; the other grades are available in 50 and 88% concentrations. The food-grade product meets the Food Chemicals Codex III and the pharmaceutical grade meets the FCC and the United States Pharmacopoeia XX specifications. Other lactic acid derivatives such as salts and esters are also available in well-established product specifications. Standard analytical methods such as titration and liquid chromatography can be used to determine lactic acid, and other gravimetric and specific tests are used to detect impurities for the product specifications. A standard titration method neutralizes the acid with sodium hydroxide and then back-titrates the acid. An older standard quantitative method for determination of lactic acid was based on oxidation by potassium permanganate to acetaldehyde, which is absorbed in sodium bisulfite and titrated iodometrically.

Lactic acid is generally recognized as safe (GRAS) for multipurpose food use. Lactate salts such as calcium and sodium lactates and esters such as ethyl lactate used in pharmaceutical preparations are also considered safe and nontoxic. The U.S. Food and Drug Administration lists lactic acid (all isomers) as GRAS and sets no limitations on its use in food other than current good manufacturing practice.

Uses

Currently, the principal use of lactic acid is in food and food-related applications, which in the United States accounts for approximately 85% of the demand. The rest (~15%) of the uses are for nonfood industrial applications. The expected advent of the production of low cost lactic acid in high volume can open new applications for lactic acid and its derivatives, because it is a versatile molecule that can be converted to a wide range of industrial chemicals or polymer feedstock's.

As a food acidulant, lactic acid has a mild acidic taste, in contrast to other food acids. It is nonvolatile, odorless, and is classified GRAS for general-purpose food additives by the FDA in the United States and by other regulatory agencies elsewhere. It is a good preservative and pickling agent for sauerkraut, olives, and pickled vegetables. It is used as acidulant, flavoring, pH buffering agent, or inhibitor of bacterial spoilage in a wide variety of processed foods such as candy, breads and bakery products, soft

drinks, soups, sherbets, dairy products, beer, jams and jellies, mayonnaise, processed eggs, and many other processed foods, often in conjunction with other acidulants. An emerging new use for lactic acid or its salts is in the disinfection and packaging of carcasses, particularly those of poultry and fish, where the addition of aqueous solutions of lactic acid and its salts during processing increase shelf life and reduce the growth of anaerobic spoilage organisms such as *Clostridium botulinum*.

Polymers of lactic acids are biodegradable thermoplastics that can be made from a variety of renewable carbohydrate resources. A fairly wide range of properties is obtainable by copolymerization with other functional monomers such as glycolide, caprolactone, polyether polyols, etc. The polymers are transparent, which is important for packaging applications. They offer good shelf life because they degrade slowly by hydrolysis which can be controlled by adjusting the composition and molecular weight. The properties of lactic copolymers which approach that of large-volume petroleum-derived polymers such as poly-styrene, flexible poly(vinyl chloride) (PVC), vinylidene chloride, etc. have been summarized by Lipinsky and Sinclair. There are numerous patents and articles on lactic acid polymers and copolymers, their properties, potential uses, and processes, dating back to the early work by Carothers at Du Pont.

LACTONE. An inner ester of a carboxylic acid formed by intramolecular reaction of hydroxylated or halogenerated carboxylic acids with elimination of water. They occur in nature as odor-bearing components of various plant products, also made synthetically.

LACTOSE. [CAS: 63-42-3]. Also called milk sugar or saccharum lactis, formula $C_{12}H_{22}O_{11} \cdot H_2O$. White, hard, crystalline mass or white powder; sweet taste; odorless; stable in air. D 1.525, mp decomposes at 203.5C., soluble in water; insoluble in ether and chloroform; very slightly soluble in alcohol, formed from whey, by concentration and crystallization. Cows' milk contains about 5% lactose.

Uses for lactose include: Infant foods; bacteriology; backing and confectionery; margarine and butter manufacture; manufacture of penicillin, yeast, edible protein, and riboflavin; culture media; adsorbent in chromatography and pharmacy.

LACTULOSE. See **Sweeteners**.

LADDER POLYMER. An ordered molecular network of double-stranded chains connected by hydrogen or chemical bonds located at regular intervals along the chains. Many complex proteins, including DNA, are of this nature.

LAKES (Colors). See **Colorants (Foods)**; **Dyes**.

LAMBDA PARTICLE. A hyperon with a rest-mass energy of 1115.6 MeV, an isospin quantum number zero, an angular momentum spin quantum number $\frac{1}{2}$, and a strangeness quantum number 1. Symbol, λ.

LAMBERT. See **Units and Standards**.

LAMBERT'S LAW. See **Bouguer and Lambert Law**.

LAMINAR FLOW. A condition of fluid flow in a closed conduit in which the fluid particles or "streams" tend to move parallel to the flow axis and not mix. This behavior is characteristic of low flow rates and high viscosity fluid flows. As the flow rate increases (or viscosity significantly decreases), the streams continue to flow parallel until a velocity is reached where the streams waver and suddenly break into a diffused pattern. This point is called the *critical velocity*. See also **Turbulent Flow**.

Laminar flow is characterized by a parabolic flow profile where the maximum velocity at or near the center of the conduit is approximately twice the average velocity in the profile. Laminar flow often is referred to as *viscous flow*, streamline flows, and *low-Reynolds number flow*. Special attention must be paid to the constancy of coefficient of most flowmeters in the region of laminar flow. See also **Reynolds Number**.

Laminar Sublayer

When a fluid is in turbulent flow past a rigid surface, fluctuations of velocity in the direction normal to the surface are inhibited, and very close to the surface they may be negligible. Then the Reynolds shear stress is small compared with the viscous stresses, and it has been common to describe the region as a laminar sublayer. In fact, turbulent fluctuations of velocity in planes parallel to the wall are considerable in comparison with the mean velocity.

See also **Fluid and Fluid Flow**.

LAMINATE. A composite made of any one of several types of thermosetting plastic (phenolic, polyester, epoxy or silicone) bonded to paper, cloth, asbestos, wood, or glass fiber. High tensile and dielectric strength and low moisture absorption are characteristic of these products. Available as sheet, rod, or tubing in mechanical, electrical, and general-purpose grades (National Electrical Manufactures Association). Plywood is composed of a verneer with grain oriented at a 90-degree angle on successive layers and bonded with a thermosetting adhesive of the urea or phenol-formaldehyde type to give a high strength, dimensionally stable, weather-resistant construction material. It can be made nonflammable by treatment with salt solution. Polyvinyl butyral sheet is used in safety glass.

See also **Reinforced Plastics**.

LAMPBLACK. A black or gray pigment made by burning low-grade heavy oils or similar carbonaceous materials with insufficient air and in a closed system such that the soot can be collected in settling chambers. Lampblack is markedly different from carbon black, strongly hydrophobic and nonflammable.

Uses for lampblack include: Black pigment for cements, ceramic ware, mortar, inks, linoleum, surface coating, crayons, polishes, carbon paper, soap, etc.; ingredient of insulating compositions, liquid-air explosives, matches, fertilizer, furnace lutes, lubricating compositions, carbon brushes; reagent in cementation of steel.

See also **Carbon Black**.

LANGMUIR, IRVING (1881–1957). Langmuir was an American scientist whose fields of contribution include chemistry, physics, and technology. He graduated as a metallurgical engineer from the School of Mines at Columbia University in 1903. Postgraduate work in Physical Chemistry under Nernst in Göttingen earned him the degrees of M.A. and Ph.D. in 1906.

Returning to America, Dr. Langmuir became Instructor in Chemistry at Stevens Institute of Technology, Hoboken, New Jersey, where he taught until July 1909. In 1909, Langmuir began working for the General Electric Company in Schenectady, New York where he eventually became Associate Director.

His work on filaments in gases led directly to the invention of the gas filled incandescent lamp and to the discovery of atomic hydrogen. He later used the latter in the development of the atomic hydrogen welding process.

He was the first to observe the very stable adsorbed monatomic films on tungsten and platinum filaments, and was able, after experiments with oil films on water, to formulate a general theory of adsorbed films. He also studied the catalytic properties of such films.

Dr. Langmuir received twenty-three scientific medals and prizes, including the Nobel Prize in Chemistry in 1932 for his work on surface chemistry.

J.M.I.

LANTHANIDE CONTRACTION. The decreasing sequence of crystal radii of the tripositive rare-earth ions with increasing atomic number in the group of elements (57) lanthanum through (71) lutetium of the Lanthanide Series in the periodic table.

LANTHANIDE SERIES. The chemical elements with atomic numbers 58 to 71 inclusive, commencing with cerium (58) and through lutetium (71) frequently are termed collectively, the Lanthanide Series. Lanthanum, the anchor element of the series, appears in group 3b of the periodic table. Some authorities consider lanthanum a part of the series. Members of the series, along with lanthanum and yttrium, are described under **Rare-Earth Elements and Metals**. See also **Actinide Series**.

LANTHANUM. [CAS: 7439-91-0]. Chemical element, symbol La, at. no. 57, at. wt. 138.91, periodic table group 3, homolog of the Lanthanide Series of elements, mp 918°C, bp 3464°C, density 6.146 g/cm^3 (20°C). Elemental lanthanum has a double close-packed hexagonal crystal structure at 25°C. The pure metallic lanthanum is silver-gray in color, but with a luster that remains only briefly upon exposure to air, rapidly oxidizing to a white powder. The oxide is hygroscopic and tends to spall, thus exposing fresh surfaces of the metal for oxidation. Thus, the metal must be handled in an inert atmosphere. Chips and powdered lanthanum are quite pyrophoric. Under required inert atmospheric conditions, the metal is easy to work with normal tools, paralleling tin in its workability. There are two natural isotopes ^{139}La and ^{138}La. The latter is mildly radioactive with a half-life of 10^{10}–10^{15} years. The element becomes a superconductor below 6 K. There are 19 known artificial isotopes, all radioactive. Of the light (or cerium-group) rare-earth metals, lanthanum is the second most plentiful and ranks 57th in abundance of elements in the earth's crust, exceeding gold, tantalum, platinum, mercury, bismuth, and several other commonly-used elements. The element was first identified by C.G. Mosander in 1839. Electronic configuration

$$1s^2 2s^2 2p^6 3s^2 3p^6 3d^{10} 4s^2 4p^6 4d^{10} 5s^2 5p^6 5d^1 6s^2.$$

Ionic radius La^{3+} 1.045 Å. Metallic radius 1.879 Å. First ionization potential 5.577 eV; second, 11.06 eV. Oxidation potentials $La \longrightarrow La^{3+} + 3e^-$, 237 V; $La + 3OH^- \longrightarrow La(OH)_3 + 3e^-$, 2.76 V.

Other important physical properties of lanthanum are given under **Rare-Earth Elements and Metals**.

Much of the commercial lanthanum production uses bastnasite, a rare-earth fluorocarbonate found in Inner Mongolia and Southern California, as the source. See also **Bastnasite**. The element is separated from other rare-earth elements by a liquid solvent extraction or an ion-exchange process after acid leaching of bastnasite (or monazite) minerals. Pure lanthanum is obtained by (1) electrowinning from the oxide La_2O_3 in a molten fluoride electrolyte, (2) electrolysis of fused anhydrous $LaCl_3$, or (3) metallothermic reduction of LaF_3 by calcium in a reactor under an inert atmosphere.

Lanthanum metal dissolves readily in dilute mineral acids. The oxide is dissolved by concentrated mineral acids and acetic and formic acids. The metal is a component of mischmetal used for lighter "flints" and in the cores of carbon electrodes for high-intensity lighting. See also **Cerium**. Several of the best grades of optical glass require pure lanthanum oxide as an ingredient for lowering the dispersion of light and for improving the index of refraction. The oxide melts at 2,310°C. The oxide ranks eleventh among the most refractory metal oxides, but finds limited use because of its highly hygroscopic nature. The oxide also is used as a host matrix for fluorescent phosphors and in thermistors and capacitors and other elements of electronic circuitry. Lanthanum oxide combined with transition metal (e. g. Mn, Co, Cr) oxides are being used in solid oxide fuel cells (SOFC) as electrodes. By far, the largest use of lanthanum (mixed with other rare-earths) is for molecular-sieve catalysts for cracking crude petroleum.

As an alloying metal, lanthanum finds broad use. Although lacking mechanical strength, lanthanum has a high affinity for oxygen, sulfur, nitrogen, and hydrogen and thus makes an effective component for scavenging gases from molten metals. Cobalt-base alloys containing lanthanum have shown increased resistance to oxidation and hot corrosion. One of the intermetallic compounds of lanthanum $LaCo_5$ possesses excellent magnetic properties—well in excess of those of alnico and platinum cobalt permanent magnets. The intermetallic compound LaNI.C."eye"$_5$ shows exceptional properties for absorbing and desorbing large amounts of hydrogen at room temperature. It is the major component of rechargeable metal hydride batteries, which is a rapidly expanding major application.

LASER-ENRICHMENT PROCESS (Uranium). See **Uranium**.

LASER-INDUCED FUSION. See **Nuclear Reactor**.

LASER-INDUCED REACTION. See **Photochemistry and Photolysis**.

LASERS. An acronym for *light amplification by stimulated emission of radiation*. The device is identical in theory of operation to the maser except that it operates at frequencies in the optical region of the electromagnetic spectrum, rather than in the microwave. See also **Maser**. By common usage, these devices are all called lasers, although more precise terminology would aptly use such terms as ultraviolent maser, optical maser, infrared maser, etc. Although the original microwave maser offers an extremely stable frequency source, its main use has been as an amplifier with very low noise output. In contrast, one of the principal attributes of the laser is its ability to produce a single frequency at high intensity in the optical region. Not only may the output be a single monochromative wave, but the wave may be coherent, or in phase, over the whole face of the radiator. In this mode of operation, the laser is an oscillator whose output depends upon the selective amplification of one of the single-frequency modes of the resonant cavity containing the active laser medium.

The decade of the 1980s represented the period when laser technology received profound acceptance, to the point where lasers, like semiconductors and digital computers before them, are now considered important components (hardware) of larger systems. The development of laser technology continued apace during the early 1990s, with numerous new and practical applications occurring at an accelerated rate. lasers now range from microlasers that measure but a few millionths of a meter, for use in optical communications and information processing, to the building-sized x-ray research laser that can deliver 100,000 joules of energy in less than one-billionth of a second—that is, a 10^{14}-watt pulse. One other feat, accomplished in the mid 90's, is a veritable tour de force. A group at MIT managed to coax single excited barium atoms crossing a miniature resonator to serve as a laser. The crucial part is the extreme precision of the mirror arrangement that keeps the photons emitted by the atoms resonating. So far the main goal of this work has been pure physics: to test the theory of quantum electrodynamics (QED).

Historical Perspective

The fundamental theoretical concepts of the maser and laser date back many years, to the early workers in quantum mechanics who appreciated that an incident electromagnetic beam of an appropriate resonant frequency, passing through a medium, might stimulate molecules in an upper quantum energy state to return to a lower quantum energy state, and thus reinforce the primary beam by negative absorption. As early as 1940, Fabrikant (Russia) suggested that experiments be made to prove negative absorption. Fabrikant was the first scientist to introduce the term "collisions of the second kind" (later to prove of importance in laser patent litigation). By this he meant a collision in which some of the kinetic energy of motion of colliding particles is converted to internal energy (or a change in energy state of at least one of the colliding particles).

It is also interesting to note that, as early as 1950, researchers Lamb and Retherford (Columbia University), observed that, if an upper quantum energy state could be caused to be more highly populated (as compared with a lower quantum energy state), the result would be a net induced emission to an incident beam. They further indicated that such a population inversion would probably occur between the $2p$ and $2s$ levels in hydrogen. There shortly followed experiments by Purcell and Pound (Harvard University) who used magnetic techniques to invert the population of a pair of nuclear

spin states in lithium fluoride and thus were the first researchers known to directly observe negative absorption of an applied pulse, a phenomenon which they called negative temperature.

Townes (Columbia University) is generally credited with first recognizing that stimulated emission could be utilized in the making of practical hardware. In 1951, Townes described an approach wherein an ammonia beam would be divided into two portions along the lines of experimentation carried out in Germany, wherein a quadrupolar focusing technique was used for separating a beam of molecules into two portions, one of which contained molecules predominantly in the upper of two energy states. Townes proposed to pass the high-energy portion through a cavity resonant at the frequency corresponding to the energy separation of the two states and so reported this proposal. Instead of a millimeter wave generator, a microwave oscillator was used. The latter was given the name maser. This led to the award of U.S. Patent No. 2,879,439, which covered the use of stimulated emission for the amplification and/or generation of oscillatory electromagnetic energy. This patent subsequently was licensed to laser manufacturers.

Following the development of the microwave maser, Schawlow (AT&T Bell Laboratories) and Townes in 1958 proposed that optical maser action could be obtained by placing an active medium in an optical cavity. The medium would be a gas or a solid excited electrically or by light in such a manner that any optical wave present would be amplified as it moved through the material. This work led to the ultimate awarding of the basic laser patent in March 1960 (U.S. Patent No. 2,929,922). During the 1960s, laser research was carried on at a rapid pace at AT&T Bell Laboratories, among others. Considering the work at AT&T Bell Laboratories, in 1960 a laser capable of emitting a continuous beam of coherent light (using helium-neon gas) was developed; in 1961, the continuous-wave solid-state laser (neodymium-doped calcium tungstate) was developed. As a refinement of the helium-neon laser, in 1962 the basic visible light helium-neon laser was developed, of which several hundred thousand are in use as of the early 1980s. In 1964, the carbon dioxide laser (highest continuous-wave power output system known to date) was developed. Other developments during 1964 included the neodymium-doped yttrium aluminum garnet laser, the continuously operating argon ion laser, the tunable optical parametric Oscillator, and the synchronous mode-locking technique, a basic means for generating short and ultrashort pulses. In 1967, the continuous wave helium-cadmium laser (utilizing the Penning ionization effect for high efficiency) was developed. These lasers find use in high-speed graphics and biological and medical applications. In 1969, the magnetically tunable spin-flip Raman infrared laser, used in high-resolution spectroscopy, as well as in pollution detection in both the atmosphere and the stratosphere, was developed. Laser developments continued and, in 1970, semiconductor heterostructure lasers capable of continuous operation at room temperature were introduced. The distributed feedback laser, a mirror-free laser structure compatible with integrated optics, was introduced, in 1971. These were followed by the tunable, continuous-wave color-center laser (1973), techniques for creating optical pulses of less than one-trillionth second duration (1974), and, in the late 1970s, long-life semiconductor lasers for lightwave communications.

Laser Principles

The basic concept of the laser may be described in general terms as follows. Optical maser action can be obtained by placing an active medium in an optical cavity. The medium may be a gas, solid, or liquid which can be excited electrically, by light, chemically, or thermally in such a manner that any optical wave present will be amplified as it moves through the material. One of the first cavities proposed, for example, is a Fabry-Perot resonator—two plane, parallel reflecting plates with a small transmission through which the radiation can escape. Upon excitation of the material, light is emitted with a band of frequencies determined by the particular material. In addition, the direction of emission is nominally random. In the presence of the cavity, some of the waves escape after several back-and-forth reflections from the parallel plates, "walking off" the edge of the reflectors, so to speak. Those waves that travel normal to the walls remain in the cavity and are amplified, provided that they reinforce each other after each round-trip reflection at the two surfaces, this reinforcement or resonance is only satisfied if the spacing of the plates is an integral multiple of one-half the wavelength in the medium. Thus, after a short time, only that frequency which satisfies the resonant condition and those waves traveling normal to the reflector will build up an appreciable intensity. The resultant light which is partially transmitted through one of the reflectors will thus be a single frequency, or several discrete frequencies if there is more than one cavity resonance within the band of frequencies emitted by the laser material. In addition, the wave front will be in phase across the surface of the reflector since waves striking the surface at normal incidence are amplified most strongly. The resultant beam will then be diffraction limited, i.e., the beam will spread by an angle in radians given approximately by the ratio of the wavelength to the diameter of the beam. In actual practice, single-mode operation is obtained only under special conditions. Several frequency modes may be present because of the multiple resonances of the cavity and numerous "off-axis" modes may be found that correspond to resonant waves, which travel at small angles from the normal to reflectors. These waves "walk off" so slowly that they still are amplified appreciably. Refinements of the simple cavity may consist of concave reflectors that decrease the diffraction losses, or several parallel reflectors, which limit the oscillation to a frequency common to each pair in the set, among other approaches.

Basic Requirements of Lasing Media. The key to successful laser operation is the active medium that amplifies the wave. Qualitatively, a material that fluoresces or exhibits luminescence is an obvious candidate. In fluorescence, electrons are excited to an upper-energy state by short-wavelength light, such as ultra-violet, while luminescence is produced by passing an electron current through the medium, such as in a gaseous discharge. In either process, stimulated emission can occur only if more electrons are produced in the upper-energy state than in the lower or terminal state for the radiating transition. In this case, an incident photon will stimulate further transitions and amplification will result. If the final state were more heavily populated, then the photon would cause more upward or absorbing transitions and the net effect would be absorption.

Laser source requirements vary widely among specific applications. Practical systems require a large range of wavelengths, output powers, spatial and temporal beam characteristics, among other features. In many applications, the following factors apply: (1) an optimum wavelength exists; (2) a specific minimum power level is required; (3) capital and operating costs of the laser must be minimized; (4) size and weight constraints must be met; (5) the laser should be capable of operating for extended periods with little maintenance; (6) the laser output should have a specific temporal and spatial characteristics; and (7) operator safety must be considered in design and use of the overall laser system.

Wavelength characteristics of available laser types are given in Table 1.

Types of Lasers

From the above list of media requirements, it is obvious that a majority of materials are not candidates for making an effective laser. When the laser was first conceived, the possibility of finding numerous materials, as has turned out to be the case, initially was not envisioned by most researchers in the field.

Early Ruby Laser. It is recorded that the first optical laser was demonstrated by Maiman (Hughes Aircraft Research Laboratories) in 1960. Maiman used a ruby single crystal of aluminum oxide doped with chromium impurities. By applying semitransparent reflective coatings on the ends of a rod about 2 inches (5 centimeters) long, Maiman made the cavity and the crystal an integral unit. See Fig.1. Exposure to an intense exciting light from a xenon flashtube was found to invert the population between the red-emitting level and the ground or lowest-energy state of the electrons. The result was a burst of intense red light emanating in a beam through the end reflectors. This was a powerful laser.

TABLE 1. WAVELENGTH RANGE OF SOME LASERS

Type of laser	Wavelength (micrometers)
Solid state	1.06
Ion	0.514, 0.488
Carbon dioxide	10.6
Diode	0.65–1.8
Dye	Visible (tunable)
Helium-neon	0.63
Rare gas halide	0.35, 0.25, 0.19
Helium-cadmium	0.422

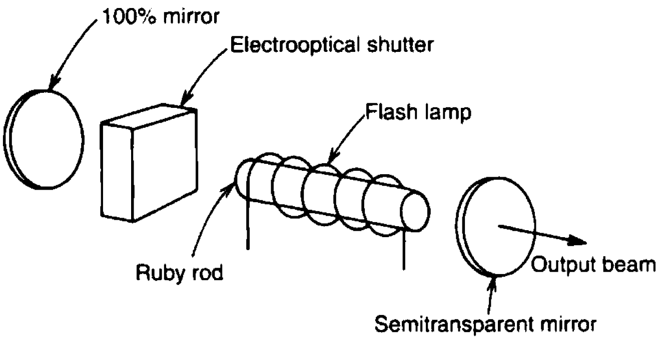

Fig. 1. Schematic diagram of early giant pulsed ruby laser

Because of off-axis modes and multiple resonances, the output is not a single frequency, single plane-wave mode, but generally consists of the order of 100 separate modes. The beam is still quite narrow, being of the order of 1 milliradian or 0.05 degree. As a comparison with conventional light sources, the energy radiated from 1 square centimeter of the brightest flash lamp is less than 10 kW and is distributed over the entire visible spectrum. In addition, the radiation is incoherent and is spread out uniformly in all angles from the source. Thus, the directivity and spectral purity of the laser source are many orders of magnitude superior to that of an incandescent source. The ruby laser suffers from low efficiency, about 1%, and except with elaborate cooling systems, only operates on a pulsed basis. The ruby laser was first reported in the literature (Maiman, 1960) and, in 1967, Maiman was awarded U.S. Patent No. 3,353,115 for the optically pumped ruby laser.

Other crystalline or glass systems with impurity ions have been developed, which yield wavelengths from the ultraviolet to approximately 3 micrometers wavelength in the infrared. Some, such as neodymium-doped yttrium aluminum garnet (YAG), operate in a continuous mode at the one-watt level, while peak powers have reached values as high as 10^{14} W, or greater, in pulses of the order of 10^{-12} second. These ultrahigh powers are obtained in neodymium-doped glass systems, using several stages of amplification and novel pulse-forming techniques.

Gas Lasers. In 1961, Javian, Bennet, and Harriott demonstrated laser action in a gaseous discharge of helium and neon. The parallel-plate reflector cavity was used, but with much greater spacing. Later, concave mirrors were used to decrease the loss of energy out the sides of the cavity. See Fig. 2. The gas laser operated continuously and delivered power up to about one watt. Pulsing the gas discharge yielded peak power as high as 100 watts. The first laser radiated at 1.15 micrometers in the infrared, while further development with different gases yielded output from the ultraviolet to 330 micrometers or 0.33 millimeters in the far infrared. In contrast to the ruby laser, the gaseous laser beam may be diffraction limited and the frequency is pure, i.e., oscillation may be limited to one mode. By careful design, the frequency may be stabilized to within a few thousand cycles per second, or approximately one part in 10^{13} or better. Although the original gas laser utilized electrical excitation of electronic transitions, later versions use vibrational transitions in molecules, such as carbon dioxide, and the excitation may be electrical, chemical, or thermal. The helium-neon laser is commonly used in supermarket bar-code scanners.

In the chemical laser, atomic species such as hydrogen and fluorine can be reacted to produce molecules in an excited vibrational state, which, in turn, yields amplification or oscillation. Electrically excited lasers, particularly those using carbon dioxide at 10 micrometers, can operate at atmospheric pressure, using spark discharges or pre-ionization voltages in the 100-kV range. The high pressure and the powerful electrical excitation result in peak powers in the 10 to 100 MW region. For continuous laser operation, the gas may be circulated rapidly to avoid excessive heating.

In a gas dynamic laser, an appropriate fuel is burned to produce carbon dioxide and nitrogen at high temperature and pressure. When released through a nozzle into the optical resonator region, the gas cools rapidly in terms of its kinetic or translational energy, but the population of the vibrational energy levels of the carbon dioxide molecules becomes inverted since the lower level of the laser transition relaxes much more rapidly. In addition, the vibrationally excited nitrogen molecules are in near resonance with the upper laser state of the carbon dioxide and transfer energy with high efficiency to maintain the inversion. Lasers of this type are capable of producing continuous power at a relatively high level.

Semiconductor Laser. In the semiconductor laser, a solid (semiconductor) material is used. The electron current flowing across a junction between *p*- and *n*-type material produces extra electrons in the conduction band. These radiate upon making a transition back to the valence-band or lower-energy states. If the junction current is large enough, there will be more electrons near the edge of the conduction band than there are at the edge of the valence band and a population inversion may occur. To utilize this effect, the semiconductor crystal is polished with two parallel faces perpendicular to the junction plane. The amplified waves may then propagate along the plane of the junction and are reflected back and forth at the surfaces. See Fig. 3.

A major advantage of the gallium arsenide (GaAs) laser is that it has the electron distribution of a semiconductor. The main difference between electrons in semiconductors and electrons in other laser media is that in semiconductors all of the electrons occupy and thus share the entire crystal volume. Although all semiconductors possess this property, not all of them can be used as lasers. See Fig. 4.

The gain in the material is high enough so that the reflection at the semiconductor-air interface is sufficient to produce oscillation without special reflective coatings. The first such device used gallium arsenide and radiated at 8400 angstroms, or just beyond the visible region in the infrared. The efficiency of this laser, first demonstrated in 1962, was high (about 40%) and the power source was low-voltage direct current.

The compactness and efficiency of the semiconductor laser make it particularly attractive for systems use. Other substances used have included indium arsenide, indium phosphide, indium antimonide, and alloys such as gallium-arsenide-phosphide. These lasers may be tuned over several percent of their normal frequency of operation by varying the current flow through the device. The tuning results from the variations in temperature with current, which, in turn, changes the index of refraction and the resultant resonant frequency of the cavity.

Free Electron Laser. Lasers of this type depart markedly from conventional lasers. Free electron lasers employ an electron beam and a magnetic field. A "free" electron may be defined as an electron that is not bound into atoms or molecules. Traditional lasers use bound electrons. Thus, the conventional laser is limited to producing light (radiation) that is consistent with those frequencies that are specific to the vibration of a

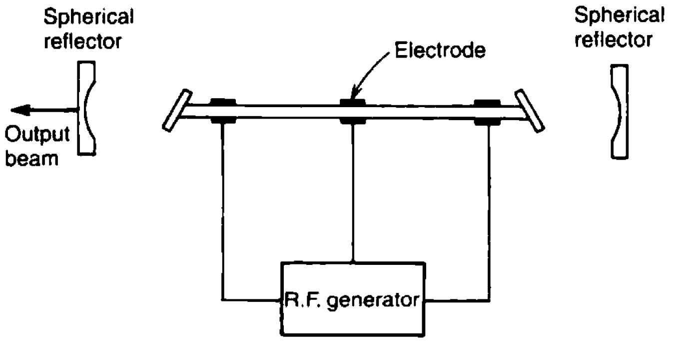

Fig. 2. Schematic diagram of early helium-neon laser with external spherical reflectors. Curvature of reflectors is exaggerated

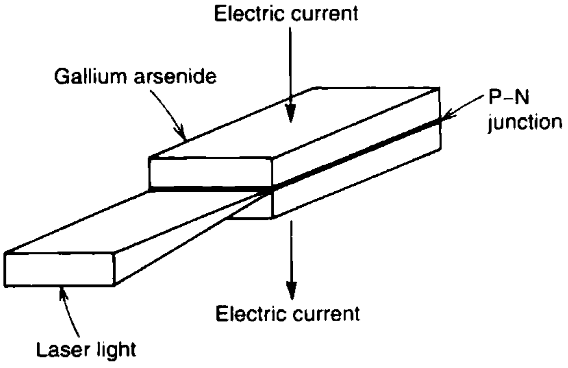

Fig. 3. Schematic diagram of early gallium arsenide laser

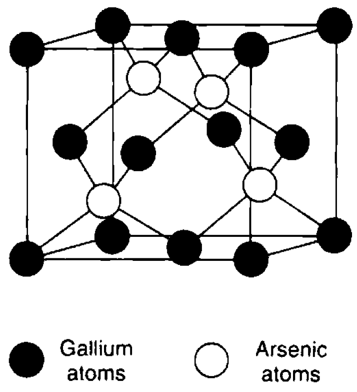

Fig. 4. Schematic diagram of a gallium arsenide (GaAs) crystal, which is commonly referred to as a zinc-blende structure. The structure consists of a face-centered cubic lattice of gallium atoms with arsenic atoms positioned on the body diagonals. The arsenic atoms also lie on a face-centered cubic lattice displaced relative to the gallium lattice by one-fourth the body diagonal of the cube

given atom or molecule. Carbon dioxide and helium lasers, for example, are so inhibited.

Free electrons are caused to vibrate by passing them through an alternating magnetic field. By changing (tuning) the apparatus, a broader range of frequencies is obtainable. Coherent radiation can range from the far-infrared to the far-ultraviolet regions of the spectrum. See Fig. 5.

Currently, free electron lasers are large and costly, but are ideal for certain kinds of research. Developers believe that ultimately the free electron laser will find numerous applications beyond research. Kim and Sessler suggest that applications may include surgery, fixing polymers, pharmaceutical manufacture, and lithography. It is predicted that the free electron laser will continue to expand in research usage, including condensed matter studies, nonlinear plasma studies, nonlinear quantum electrodynamics, nonlinear optics, and nonlinear microwaves, as well as microscopy, DNA studies, and cell response research in biology. One study is in progress to determine the feasibility of adapting the free electron laser to perform precision radar measurements in space. Researchers will study the potential of the laser as a compact space radar transmitter for discriminating objects in space, as would be required, for example, in connection with the Strategic Defense Initiative (SDI) program. The program will take advantage of the electron laser's inherent tunability, high power and efficiency, and ability to operate in frequency bands of 100 GHz and higher. The program's ultimate goal is a space-based, multiband, adaptive laser capable of operating efficiently at randomly chosen, stable frequencies.

Researchers have found that electrostatic accelerators are well suited for the far-infrared spectrum. An early device of this type was built at the University of California at Santa Barbara for the main objective of free-electron research and studies in solid-state physics and biophysics. The accelerator has an operating range of 2–6 MV, corresponding to wavelengths in the range from 100–800 micrometers. Pulse duration is from 3–30 microseconds.

Solid-State Laser Development. Over the years, the progress of solid-state lasers has depended heavily on the improvement of old and the establishment of new pump sources. The helical lamp used by the early ruby laser was replaced by the linear flash lamp and arc discharge lamps. The next step was that of using a diode laser to pump another solid-state laser. This latter approach is advantageous because the diode laser emits optical radiation into a narrow spectral band. If the emission of the wavelength of the diode laser lies within the absorption band of the ion-doped solid-state laser medium, diode laser optical pumping can be very efficient and accompanied by little excess heat generation. By contrast, flash lamp pumping is limited by the broad emission spectrum and by excess heat production.

As pointed out by R.L. Byer (Stanford University), "The diode laser is essentially a continuous wave device with low energy storage capability, whereas the solid-state laser can store energy in the long-lived metastable ion levels." Stored energy can be extracted by Q-switching (rapid switching) to provide peak power levels that are orders of magnitude greater than obtainable from the diode laser per se. Important, too, is the fact that a solid-state laser can collect output from several diode lasers and thus furnish greater average power than is obtainable from a single diode laser. Furthermore, the line width of the diode laser-pumped solid-state laser is many times less than that of the diode laser source. Finally, the solid-state laser source emits optical radiation in a diffraction-limited spiral beam that is easily focused into a fiber or small space.

As early as 1982, a diode laser-pumped miniature Nd:YAG laser with a linewidth of less than 10 kHz was demonstrated. The research in this area continued apace at Stanford University and by a number of commercial electronics firms, with emphasis placed on the development of three-level lasers, Q-switched and mode-locked operation, single-frequency operation (monolithic nonplanar ring oscillator), visible radiation by harmonic generation, and array-pumped solid-state lasers. See Fig. 6.

A new class of lasers, so called vibrionic solid state lasers, can emit—in contrast to other solid state lasers—a comparatively broad range of wavelengths. The lower level in these lasers is a band of energy levels that is caused by interaction between the electron motion and lattice vibrations. With the help of the usual tools (filters, etalons etc.) a narrow and tunable frequency bandwidth is selected for the laser output. The most popular materials are Ti-sapphire, i.e., titanium doped Al_2O_3 with output range from 600 to 1180 nm and Alexandrite, i.e., chromium doped $BeAl_2O_4$ lasing between about 700 and 825 nm.

Laser Microminiaturization—Target Optical Computer. For many years, scientists have accepted the fact that optical computers would not become a reality until optical components of micro size and exceptional performance equivalent to the already existing electronic switches and circuits could be developed. Thus, the optical computer became a major driving force toward the development of optical components. The problem was extraordinarily complex because size reductions of several orders of magnitude were mandatory.

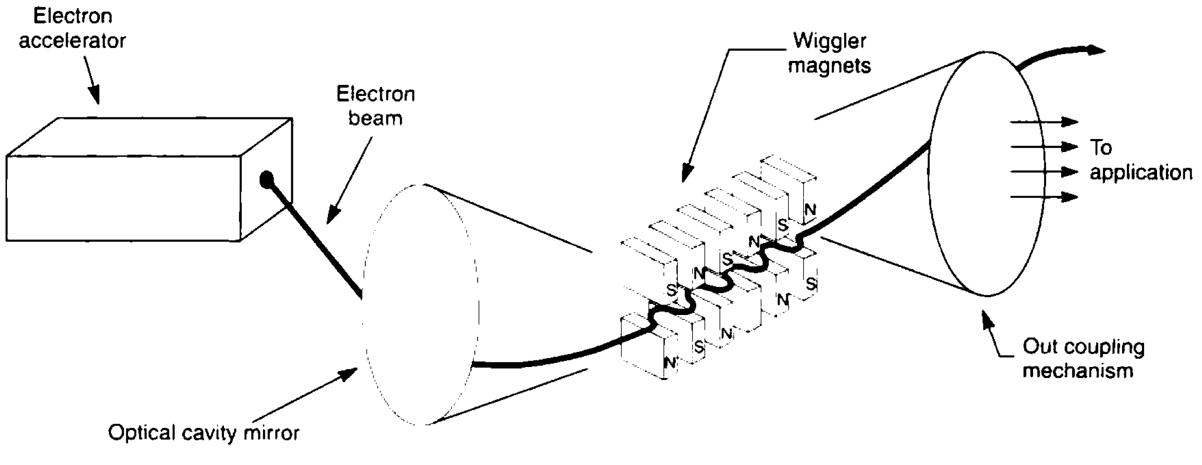

Fig. 5. Schematic diagram of a free-electron laser. Beam of accelerated electrons passes through a field of alternating magnetism (wiggler magnets). The coherent light is generated and contained in an optical cavity defined by mirrors. (*Kim and Sessler.*)

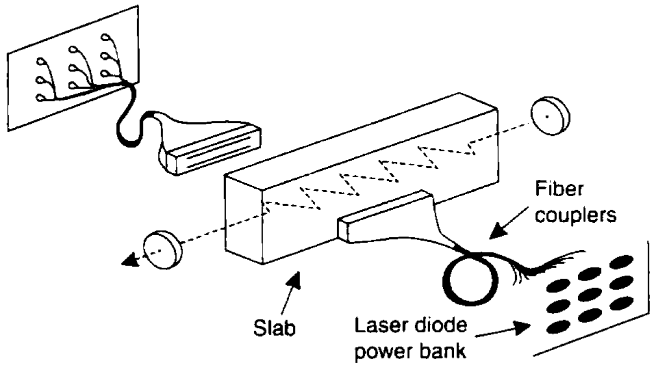

Fig. 6. Diagram of high-average power slab laser oscillator pumped by an array of diode lasers. Such an arrangement offers lower cost, ease of power scaling, and long-term reliability. (*After Byer.*)

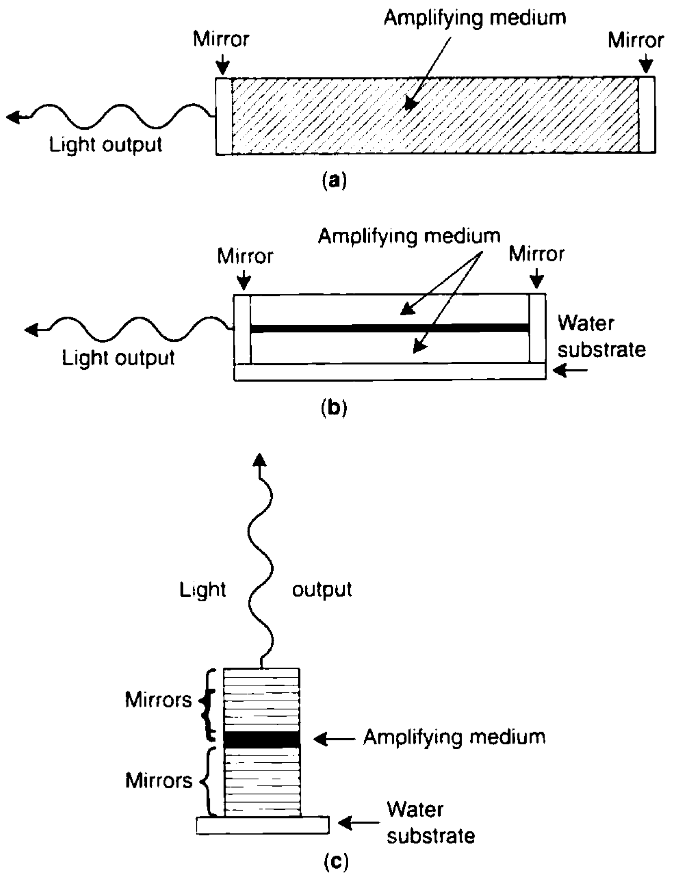

Fig. 7. Comparison of constructional configurations of (**a**) conventional helium-neon laser, (**b**) traditional diode laser, and (**c**) microlaser. Several orders of magnitude in size difference cannot be depicted here. The helium-neon laser ranges from 100 to 1,000 times longer than a traditional diode laser. The latter is some 100 times longer than a microlaser. (*After Jewell, Harbison, and Scherer.*)

As early as 1989, researchers at AT&T Bell Laboratories fabricated more than a million micron-size lasers (microlasers) on a single semiconductor chip, about 7 mm wide by 8 mm long. Individual devices ranged in size from 1 to 5 microns. Thus, these devices were two orders of magnitude smaller than conventional diode lasers. Researchers feel that it may be feasible to manufacture such devices that measure only between 1/2 and 1/4 micron. Traditional devices that measure a few microns wide by several hundred microns long have been well established for use in compact-disk players and fiber-optic communications. Thus, the *much, much smaller* devices coming out of research comprise a major step toward achieving the needs of optical computing. Much competitive research continues during the early 1990s because the market demand for microminiature lasers can be immense.

As pointed out by Jewell and associates (Bellcore), "The principles of operation underlying a diode laser are the same as those for any laser. Atoms in a part of the laser called the *amplifying medium*—typically a solid, liquid, or gas- are pumped, or energized, either electrically or with a source of electromagnetic radiation. When a light wave of a specific wavelength traveling through the amplifying medium encounters a pumped atom, it can induce the atom to release its energy in the form of a light wave at the same wavelength. The process is coherent, which is to say that the crests and troughs of the waves match up, and the intensity of the light increases. Mirrors on each end of the amplifying medium form a cavity, and they force the light to bounce back and forth many times through the medium, maximizing the increase in intensity.

The differences in construction of a microlaser from a conventional gas laser or conventional diode laser are shown in Fig. 7.

To date, manufacture of the very tiny microlasers depend upon critical production techniques. For example, molecular beam epitaxy allows the basic material of each laser to be built up from layers of semiconducting materials. A typical microlaser may comprise 500 or more individual layers.

It was reported in late 1991 that a semiconductor laser that emits a blue-green light had been developed (3 M Company). Manufacturers of optical disks and other consumer electronic devices have been seeking a laser that would produce light in this range of the spectrum. The detailed development procedures required are beyond the scope of this article. However, it has been reported that the layered device is comprised of a gold electrode, a *p*-type zinc selenide, a quantum well (cadmium zinc selenide), an *n*-type zinc selenide, a substrate (gallium arsenide), and an indium electrode. By the end of the decade, progress in semiconductor research has led to reliable diode lasers with output in the blue and green part of the spectrum. In particular, SiC and GaN based systems promise to yield successful applications (See further reading by Fasol and by Fasol, Nakamura and Davies).

Liquid Lasers. Lasers operating in liquid media utilize rare earth ions in such organic hosts as chelates. Laser action is obtained in liquids using a flash tube or another laser as the pump. Early versions used rare earths in an organic liquid, while organic dyes, introduced somewhat later, were found to be more efficient, but required a separate laser for the exciting radiation. The dye laser has the special attraction that one laser may be tuned over a significant fraction of the visible spectrum by using a reflection grating as one of the cavity mirrors. One of the major areas of applications for dye lasers is the field of spectroscopy—for both basic research and applications such as combustion diagnostics or trace element analysis (See section on **Laser Spectroscopy**).

Another type of liquid laser utilizes a different principle and depends upon stimulated Raman scattering. Raman laser action was discovered by Woodbury in 1962, using a ruby laser and nitrobenzene. Here the laser excites the nitrobenzene, which in turn shows amplification at a frequency displaced from the ruby line by the vibrational frequency of the molecule. There is not true inverted population in this case. The incident photon is scattered by the molecule, which absorbs an amount of energy determined by its vibrational energy. The molecule is left in an excited state and the scattered photon is frequency-shifted by the energy loss. The process may be stimulated inasmuch as the rate at which the scattered photons are produced is proportional to the number of photons already present in the cavity at the scattering wavelength. As in the normal stimulated emission case, the frequency and phase of the output wave are identical with the wave that stimulates the scattering.

The Raman laser normally operates using the Stokes line, or the wavelength corresponding to the loss of one vibrational quantum. Other modes of operation utilize the second or third Stokes lines corresponding to double or triple vibrational absorptions. Similarly, higher-order effects in the medium may produce a series of anti-Stokes lines, which correspond to vibrational energy being added to the initial energy of the photons from the driving laser. The wavelength range of Raman lasers using different liquids is from the visible to the near-infrared.

X-Ray and Other Very High-Power Lasers. Almost since the inception of laser technology, the laser has been of interest to the military in connection with a variety of applications—weapons, radars, illuminators, rangers, etc. Among the highly sophisticated laser applications long envisioned by the military is the use of a laser to propel a spacecraft. In early concepts, a laser beam produced at ground level would vaporize an appropriate fuel, which could be water, and the supersonic jet caused by vaporization would be sufficient to place the vehicle into orbit without

any chemical energy being expended by the craft itself. In the late nineties, experiments with tethered vehicles have shown initial albeit limited success in this quest. A small test craft without any on-board fuel was propelled 75 feet upward by 450 joule pulses from a powerful carbon dioxide (CO^2) laser. The small craft operates by expelling air that is rapidly heated by the absorbed laser energy. No longer motivated by SDI, the stated long-term goal is to loft small "picosatellites" into orbit (See further reading by Appell). Within the last few years, a major interest of the military has been directed toward the development of an x-ray laser for possible application in connection with the SDI (Strategic Defense Initiative) program. There are, of course, also strictly scientific interests in tunable coherent x-rays.

It is generally understood that for a laser to serve as a weapon it must have appropriate wavelength and brightness characteristics. The wavelengths produced by most lasers are absorbed by the atmosphere. Laser wavelengths between 0.3 and 1 micrometer are generally the most easily transmitted. Investigators have estimated that if a laser firing over a 3000 km engagement distance is to burn through a missile skin in 1 second, it must deliver 10,000 joules of energy per centimeter. (These requirements correspond to a brightness of 10^{21} watts per steradian, or unit of solid angle.) It is further estimated that a laser having the desired wavelength and brightness would require a beam power of approximately 100 MW. By comparison, a typical nuclear power plant has an output of about 1000 MW.

European Superlaser. In mid-1990, five European countries agreed to fund ($200 to $500 million) construction of a European High Performance Laser Facility. Sponsored by France, Germany, Italy, Spain, and the United Kingdom, the new laser would be three to four times more powerful than the Lawrence Livermore National Laboratory's NOVA, currently the world leader. The program was to progress in two principal stages, commencing with two intermediate power lasers—one neodymium glass and one KrF laser, built side by side. The major goal was to free European laser scientists from the dependence on high-powered machines in the United States and Japan. A superlaser of this type can be used to investigate some fundamental problems of physics. The intense pulse of the proposed laser would create conditions even hotter than the core of a burning star.

As of the late 1980s and early 1990s, four kinds of laser were under development. (1) *Chemical lasers* utilize chemical reactions between two gases to generate radiation. This technology is probably the most mature of the four kinds of lasers. It has been reported that the brightest of the chemical lasers is the MIRACL (mid-infrared advanced chemical laser), which in a demonstration at the White Sands Missile Test Range (New Mexico) destroyed a mock-up of a missile standing about a half-mile distant from the laser. The MIRACL was estimated to have a brightness of about 10^{17} watts per steradian, short of the SDI goal by a factor of about 10,000. (2) The *Excimer* (meaning excited dimer) consists of an unstable compound made up of two molecules. An electric discharge excites the molecules to form the dimer, and in breaking down, the dimer emits radiation. In some way, this radiation triggers a cascade of reactions that produce a laser beam. Radiation in the beam is estimated between 0.2 and 0.4 micrometer. A krypton-fluoride laser, tested at the Los Alamos National Laboratory, is estimated to operate at a wavelength of about 0.25 micrometer, delivering 10,000 joules of energy in a 380 nanosecond pulse. (One nanosecond = One billionth of a second.) It is reported that while the energy produced meets SDI goals, the pulse duration is off by a factor of about 3 million. (3) In the *free-electron laser*, a beam of electrons passes by a series of so-called wiggler magnets, which cause the electrons to vibrate and emit radiation. The wavelength can be tuned, theoretically, to any value between about 0.1 and 20 micrometers. The smaller the wavelength, the greater the energy. It is reported that a free-electron laser operated at wavelengths down to 10 micrometers in tests at Los Alamos. More recent research targets a 1-micrometer radiation of 100 microsecond pulses, containing 30 kW of power. As of the mid-1990s, both excimer and free-electron lasers were relatively poor converters of electric energy into beam energy, requiring massive power supplies—hence difficulties in locating the needed equipment in space. See prior description of free-electron laser in this article. (4) The *X-ray laser* also appears to be plagued with heavy and costly support equipment. Essentially, the x-ray laser consists of a nuclear explosive surrounded by an array (cylindrical configuration) of metal fibers. The emission of x-rays during the nuclear explosion stimulates the emission of a beam of x-rays from the fibers. This occurs within a microsecond prior to immolation of the device per se. For obvious reasons, further details remain sparse. It has been reported that to make an effective weapon, a particle beam would require energy of 250 MeV. If one assumes an acceleration gradient of 10 MeV per meter, it follows that the structure must be 25 meters long. When accounting is made of the mass of the power supply and its fuel, the weight of the weapon is found to be 50 to 100 tons. (Current typical payloads weigh a comparatively few tons.) Much additional work of a guarded nature continues.

Soft X-Ray Laser. A modern 1- to 2-billion-eV synchrotron radiation facility, based on high-brightness-electron beams and magnetic undulators, would generate coherent, laserlike soft x-rays of wavelengths as short as 10 angstroms. This radiation would be broadly tunable and subject to full polarization control. Radiation with these properties could be used for phase- and element-sensitive microprobing of biological assemblies and material interfaces as well as research on the production of electronic microstructures with features smaller than 1000 angstroms. These short-wavelength capabilities, which extend to the K-absorption edges of C, N, and O, are neither available nor projected for laboratory XUV (soft x-ray and ultraviolet radiation) lasers. Higher-energy storage rings (5 to 6 million eV) would generate significantly less coherent radiation and would be further compromised by additional x-ray thermal loading of optical components. Synchrotron radiation is discussed further in the article on **Particles (Subatomic)**.

To extend scientific and technological opportunities, authorities suggest that a bright source of tunable, partially coherent, XUV radiation is needed. Coherence, in the limited sense used here, refers to the ability to form interference patterns when wave fronts are separated and recombined. The availability of a tunable source of coherent soft x-rays, combined with other developments in x-ray optical techniques, would make it possible to construct an x-ray microprobe of sufficient intensity to permit fundamentally new, phase-sensitive experimentation in a number of scientific and technological fields. Various imaging and scattering techniques would be enhanced by the greatly increased photon flux available to study small samples, as well as providing the capability of tuning the radiation to the wavelength of interest. For example, with soft X-rays well matched to the absorption edges of elements, such as carbon (284), nitrogen (400), and oxygen (532), as well as other elements of relatively low atomic numbers (Na, P, S, K, and Ca), it should be possible to study elemental distributions and motion within biological specimens without the need for dehydration, fixing, or staining. Three-dimensional imaging, made possible by combining partially coherent undulator radiation and x-ray microholographic techniques, would complement the information available from electron microscopes.

Extensive development and experimental designs of soft x-ray lasers have been underway at the Lawrence Livermore National Laboratory and the Princeton Plasma Physics Laboratory, among other research institutions.

Researchers Suckewer and Skinner (Princeton University Plasma Physics Laboratory), in an early 1990 paper, observe, "Most of what is known about the internal structure of cells has been learned by the development and application of the techniques of electron microscopy. This knowledge rests on the premise that the intensive procedures necessary to prepare a specimen for electron microscopy do not significantly influence the structure, form, and high-resolution detail observed. Nonetheless, unanswered questions remain about the fidelity of the image of a cell that has been fixed, stained with heavy metals, and sectioned to the original living cell. X-ray microscopy offers a new way to look at unaltered cells in their natural state." X-ray laser microscopy can offer numerous advantages in this regard.

In summarizing the current status of soft x-ray laser research, the aforementioned researchers comment, "The general impact soft X-ray lasers will have in science and technology will depend on improvements in their performance and cost. It is necessary for their successful commercialization that these devices operate routinely at high gain-lengths ($GL > 4$), with the use of a low-cost driver laser, and this needs more system development and engineering. Most applications of visible-wavelength lasers are based on the fact that the brightness of these lasers is several orders of magnitude greater than that of conventional spontaneous emission sources, and this is achieved principally by the laser cavity mirrors. This technology is significantly more difficult in the x-ray region because of intrinsic limitations of x-ray absorption in materials and present limits in the soft x-ray laser pulse lengths. Nevertheless, a 'revolution' in x-ray optics is under way and the precedent of visible-wavelength lasers illustrates the potential benefits awaiting the creative inventor of applications of this technology to novel fields."

Laser Applications

During the early phases of laser development (late 1950s to early 1970s), there was a high tempo of research activity and confidence in the ultimate potential for practical applications. Some of the early suggestions for laser use included instrumental applications in metrology and spectroscopy, as well as working tools for industry, such as cutting, welding, and annealing. But during that period it was also observed by some researchers that the laser was an invention for nonexistent needs. The decade of the 1980s removed all such doubts, and as science entered the 1990s, the laser had become established as an essential component in numerous laboratory research programs and industrial and medical applications. Just a cursory inspection of the literature during the late 1980s and early 1990s is indicative of the wide scientific interest in the laser.

Atomic Cooling and Trapping. During the last few years, the ability to control the position and velocity of isolated atoms and microscopic particles has progressed markedly. By the end of 1998 molecules have also been laser cooled and several groups have obtained sufficiently low temperatures and high densities to achieve Bose-Einstein condensation of trapped atoms. In such a state of matter—predicted by Bose and Einstein—the quantum nature of the atoms causes them to lose their individual existence and to coalesce into one collective system. The tremendous success of these efforts has been recognized by the award of the 1997 Nobel Prize in physics to Steven Chu, Claude Cohen-Tanoudji and William Phillips for development of methods to cool and trap atoms with laser light. As pointed out by S. Chu (Stanford University) in a late 1991 paper, "Light can exert forces on an atom because photons carry momentum. The exchange of photon momentum with an atom can occur *incoherently*, as in the absorption and reemission of photons, or *coherently*, as in the redistribution (or lensing) of the incident field by the atom."

Coherent interaction is called the *dipole force*. The incoherent interaction that alters the momentum of an atom is called the *scattering force*.

Successful atom manipulation, however, often depends more upon cooling the atoms than upon exciting the aforementioned forces. Dramatic cooling of atoms to extremely low temperatures is accomplished by employing counterpropagating laser beams, arranged along x, y, and z axes—in essence, creating three-dimensional cooling. As pointed out by Chu, "Because the cooling force is viscous (linearly proportional to the velocities of the atom for low velocities), we named the laser beams that generate the drag force, 'optical molasses'."

In 1991, a research team (Ecole Normale Superieure, Paris) reported the cooling of a sample of cesium atoms to 2.5 μK. At about the same time, a research group (Joint Institute for Laboratory Astrophysics, Boulder, Colorado) reported the achievement of 5 μK. The aforementioned "optical molasses" technique was used in both cases.

Laser cooling, trapping, and related techniques are finding numerous research and practical applications. For example, practical laser-cooled atomic clocks are now possible, constituting a major improvement in accuracy over present atomic clocks. As mentioned by Chu, "A cesium time standard based on a sealed design for which the cooling, manipulation, and detection of the atoms are all done with diode lasers should exceed the stability of the best present-day time standards."

In an excellent paper, Chu (See reference) observes, "Perhaps the most exciting applications in the field of laser cooling and trapping will come out of the ability to study problems in polymer physics and biology on a single molecular basis. Normally one examines the behavior of a large number of molecules, and the fundamental chemistry of the molecules must be inferred from the average behavior of the entire ensemble. On the other hand, the processes that govern the behavior of a single molecule are important: for example, the nucleus of a cell has a single molecular copy of its genetic blueprint, and its chemistry depends in part on the chemistry of single molecules."

In a 1990 paper, Zewail (See reference) describes how atoms can collide, interact, and give birth to molecules in less than a trillionth of a second. As an example of how high-speed imagery has improved over the years, he compares photos of a galloping horse (10 meters per second) taken in 1887 with quantitative observations (made in 5 trillionths of a second) of hydrogen iodide colliding with carbon dioxide to form carbon monoxide, hydroxide, and iodine.

Lasers as Mini-Manipulators. As scientists continue to probe the very minute aspects of natural organs and substances (nanotechnology), small lasers have been found to possess "manipulative" abilities of a kind not envisioned in the early years of laser technology. Scientists (Massachusetts Institute of Technology) in 1990 reported of how lasers can be used effectively as manipulators at the microscopic level. In a study of "mechanoenzymes," which are responsible for the rotary motions of flagella, laser light was used to lift up, move, and position microscopic objects with the "pressure" of the laser light itself, a phenomenon that has been described by Amato as "akin to a blast of air levitating a plastic ball."

Laser mini-tweezers also have been used to clip off regions of chromosomes, moving organelles around inside cells, pushing molecules tiny distances within crystals, and, when used as tiny scalpels or scissors, to catch, trap, puncture, and splice subcellular structures. Recently, measurements have been made of the elastic properties of DNA. Also, it has been found that bacteria can be moved around in a water solution without apparent damage to the organism. Medical applications are described later.

Laser Spectroscopy. In the early years of laser technology, spectroscopy was one of its major uses, an application that has expanded markedly during the past few decades. The review by Gupta provides a good starting point for further reading since it includes an—at the time—up-to date resource letter featuring a large number of annotated references. The techniques of laser spectroscopy parallel those of microwave or radio-frequency spectroscopy, but because lasers are imbued with high spectral purity, they permit vastly improved resolution of fine detail. Early lasers were limited to molecular lines that were coincident with the laser wavelengths. Then lasers using fluorescent organic dyes appeared. These instruments had relatively wide emission bands, offering a tuning capability. Both continuous-wave and pulsing dye lasers have been widely used in most of the visible and near-visible ranges of the spectrum. During the interim, much progress has been made, particularly in providing tunability to lasers. For example, a methyl fluoride molecular gas laser is continuously tunable over broad portions of the far infrared, a region that previously had been difficult. A highly schematic diagram of the operating principle used in early laser-probe emission spectrography is given in Fig. 8.

A particularly interesting development is that of the so-called "atomic fountain." As noted by Chu in 1991, "The precision of a spectroscopic measurement depends on both the high Q (Q = quality factor of the resonance defined by $Q = V/\Delta V$) and the signal-to-noise ratio of the signal. Thus, it is important to create a high-flux source of cold atoms. Also, many applications would benefit from a continuous beam of atoms instead of the pulsed sources." An extreme limit of a slow beam is an "atomic fountain," which first was envisioned by Zacharias in the early 1950s. A group of Stanford University scientists has constructed an atomic fountain by first trapping atoms from a thermal beam in a magneto-optic trap and then pushing the atoms upward with a pulse of light from a continuous-wave laser. See Fig. 9.

One reason for the rapid advancement of chemical reaction dynamics research has been the availability of tunable laser sources that operate throughout the infrared, visible, ultraviolet, and vacuum ultraviolet regions of the spectrum. By using nonlinear optical techniques, the outputs from high-power, pulsed visible dye lasers can be summed and mixed to yield useful tunable ultraviolet and vacuum ultraviolet light, with wavelengths as short as 100 nm. Techniques have been developed to probe almost any kind of atomic or molecular state, quite often with sensitivities approaching number densities of 10^5 cm^{-3}, and, in special situations, with detection sensitivity for single atoms.

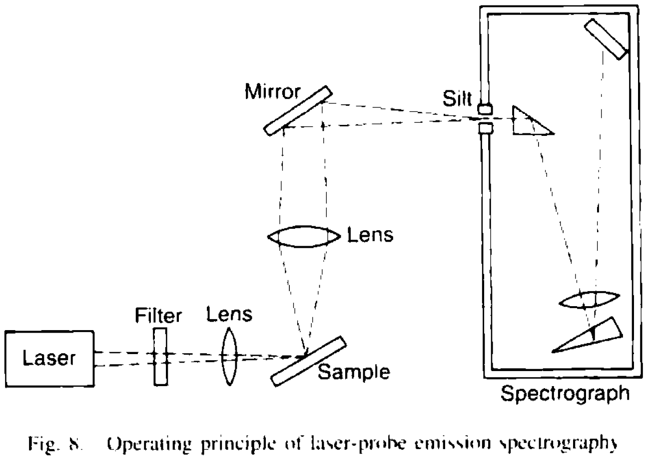

Fig. 8. Operating principle of laser-probe emission spectrography.

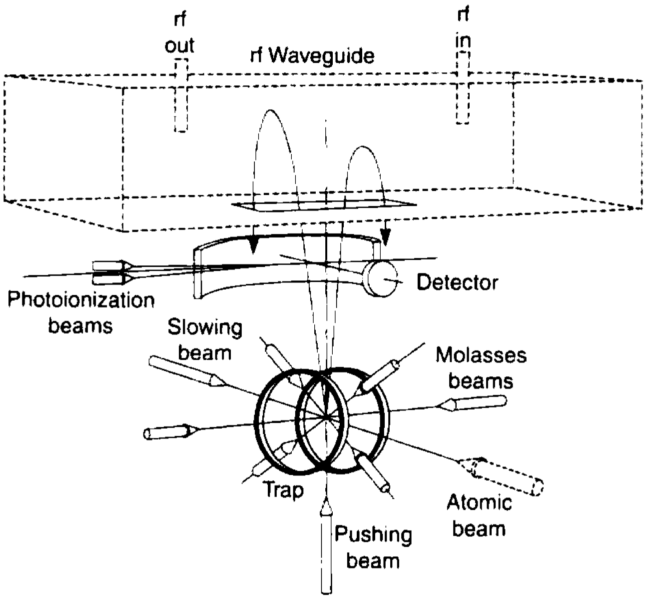

Fig. 9. The atomic fountain makes it possible to determine precisely the energy states of atoms. Upon injection, the atoms in question are slowed down by a laser beam. Then, the atoms are captured and cooled by means of a magnetic field and several light beams. The cooled atoms follow a ballistic trajectory through a radio frequency (rf) waveguide and a resonant photoionization detection region. (*After Kasevich, Riis, Chu, and DeVoe.*)

In a detailed reference, Grant and Cooks (Purdue University) explain in considerable detail the combining of the latest advances in mass spectrometry with laser spectrometers. This technique is contributing in a major way to studies of chemical dynamics, cluster structures, and reactivity, and to the elucidation of the properties of highly excited molecules and ions.

Laser Remote Sensing of Atmospheric Properties

LIDAR (an acronym for light detecting and ranging) is analogous to radar. In lidar, the projection of a short laser pulse is followed by reception of a portion of the radiation reflected from a distant target or from atmospheric constituents, such as molecules, aerosols, clouds, or dust. As explained by Killinger and Menyuk (See reference), the incident laser radiation interacts with the aforementioned constituents to cause alteration in the intensity and wavelength in accordance with the strength of the optical interaction and the concentration of the interacting species in the atmosphere. Information on both composition and physical state of the atmosphere can be deduced from lidar data. The range of the interacting species can be determined from the temporal delay of the backscattered radiation. See Fig. 10.

Among specific uses of lidar have been: (1) measurement of movement and concentration of urban air pollution; (2) determinations of chemical emissions from and in the vicinity of industrial plants; (3) determination of atmospheric trace chemicals in the atmosphere; (4) measurement of the velocity and direction of winds near storms and airports, including windshear and gust fronts; and (5) determination of the global circulation of volcanic ash emitted into the atmosphere, relatively recent examples including Mount Pinatubo and Kilauea; among several other applications.

Shortly after the discovery of lasers (early 1960s), Fiocco and Smullin bounced a laser beam off the moon (1962). These researchers also investigated the turbid layers in the upper atmosphere. As early as 1963, Ligda used a ruby laser to obtain the first lidar measurements of cloud heights and tropospheric aerosols. In 1964, Scotland used a temperature-tuned ruby laser to detect water vapor in the atmosphere. Lidar, in recent years, has been greatly improved because of the availability of several kinds of laser sources and improvements made in optical instrumentation and data processing.

As summarized by Killinger and Kenyuk, the future of laser remote sensing is promising and will depend upon several factors, including: (1) development of practical, eye-safe laser sources that cover certain spectral gaps where lidar is currently weak; (2) a further simplification of lidar systems, including lowering size and cost of equipment needed; and (3) more experience to be gained from promising new applications.

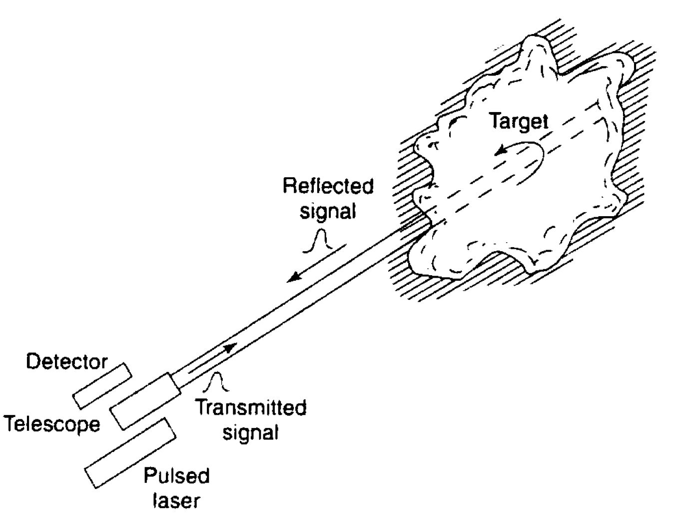

Fig. 10. Basic components of lidar system used for remote sensing of the atmosphere. Backscattered information sometimes will contain spectral information useful for determining composition and physical characteristics of the cloud or of the intervening atmosphere

Among these new applications are: (a) detection of methane gas leaks in coal mines, using a diode laser lidar system; (b) detection of methane and natural gas leaks in industrial plants, using a laser coupled to a low-loss optical fiber network; (c) measurement of global wind fields through the use of Doppler lidar systems mounted in a satellite as a means for improving weather forecasting; and (d) the planned use of lidar on the NASA space-borne Earth Observing System for measurements of global temperature, water vapor, and pressure.

Classification of Lidar System. Lidar systems can be classified on the basis of particular optical interactions which they utilize. Classes of lidar include:

1. *Atmospheric backscatter lidar*, wherein the lidar system transmits one laser wavelength and detects changes in the backscatter due to the aerosols or dust in the atmosphere. This is the most common type of lidar and consists of a nontunable, high-power, pulsed laser. Atmospheric constituents having comparatively large optical scattering cross sections are relatively easy to detect. These systems are used in tracking turbid effluent and gas plumes from factories as well as for mapping rain, snow, ice crystals, and dense clouds in the atmosphere. This type of system was used for checking volcanic ash in the atmosphere.

2. *Differential-absorption lidar* (DIAL), a system which measures the concentration of a molecular species in the atmosphere. This is accomplished by transmitting two wavelengths, only one of which is absorbed. The difference in the intensity of the returns at the two wavelengths is measured. Backscatter in DIAL may come from a hard target or aerosols and dust. One wavelength will be absorbed by the target molecules; the other wavelength will not be absorbed. Many DIAL studies have been carried out in the infrared (IR) range, where almost all molecules of interest have extensive absorption bands. Molecules so far studied include SO_2, NH_3, O_3, CO, CO_2, HCl, NO, N_2H_4, N_2O, and SF_6.

3. *Fluorescence lidar* uses two wavelengths (as in DIAL) plus spectrometric techniques for separating the wavelength-shifted fluorescence signal from the strong Rayleigh backscatter in the atmosphere. The laser is tuned to an absorption line of the species to be measured. Reradiated fluorescence is detected by selective spectral filtering of the returned radiation. The fluorescence radiation may be at the same wavelength as the excitation wavelength, or it may have a longer wavelength because of the red-shift. The backscatter coefficient for fluorescence is greater in the ultraviolet (UV) than in the IR— this due to combined effects of absorption cross section, which is greater in the UV than in the IR. For some applications, fluorescence lidar is limited for remote sensing because of detector sensitivity coupled with solar background radiation. The latter tends to confine fluorescence measurements to nighttime studies and to wavelengths shorter than 1 micrometer, where photomultiplier detection can be used. Nevertheless, some investigators have been quite successful in using the method, particularly in the study of alkali metal (Na, K,

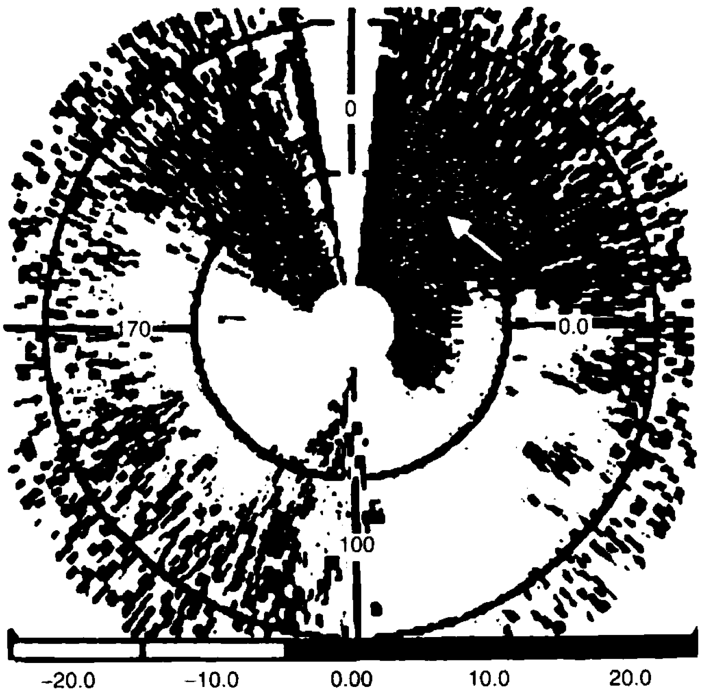

Fig. 11. Doppler lidar measurement of wind direction and velocity near an airport during a storm. White arrow points to presence of a strong, localized downburst-gustfront

Li, and Ca) profiles at altitudes of 80 to 100 km. The method also has been useful for studying the hydroxyl free radical (OH). This radical is of principal interest because of the catalytic role which it exerts in atmospheric chemistry. The OH radical, along with chlorine and nitrogen oxides, is involved in the ozone destruction cycle.

4. *Raman lidar*, a method that is limited by the small optical interaction strength for Raman scattering. High-energy pulsed lasers are employed in this method. The method is limited to the UV or visible regions to permit the use of sensitive photomultiplier tubes for detection. Raman lidar has been used effectively for species that either are at close range or in high concentration, such as N_2, O_2, and H_2O. As mentioned by Killinger and Menyuk, this method does have some attractive features, the most noteworthy of which is that the laser wavelength need not be tuned across an absorption line because the spectral information is given by the frequency shift of the emission (independent of laser wavelength).

5. *Doppler lidar*, a method that detects only a very narrow spectral range ($\sim 10^{-5}$ nm) that encompasses the Doppler-shifted backscatter lidar return. Doppler shifts in the return lidar signals have been used to measure wind velocities and to differentiate between molecular and aerosol returns in the atmosphere. Optical heterodyne techniques are used to detect the shifts which are very small—for example, a fractional change in frequency of about 10^{-8} for a velocity of 1 m/sec at a wavelength of 10 micrometers. Carbon dioxide lasers which provide high power and stable single-frequency operations, are commonly used in Doppler lidar systems. These are in the 10-micrometer range. The system has provided information on boundary layer flow near storm gust fronts and wind shears near airports. They also have been used to measure aircraft vortices and clear air turbulence. See Fig. 11.

Doppler broadening effects also have been used to separate backscattered lidar signals into molecular and aerosol components. Characteristics of some lidar systems are summarized in Table 2.

Laser Techniques in High-Pressure Geophysics

Laser techniques used in conjunction with the diamond cell make it possible to study the high-pressure properties of material that heretofore had to be inferred from samples found on the surface. Spontaneous Raman scattering of crystalline and amorphous solids at high pressure demonstrates that dramatic changes in structure and bonding occur on compression. High-pressure Brillouin scattering is sensitive to the pressure variations of single-crystal elastic moduli and acoustic velocities. Laser heating techniques with the diamond anvil cell can be used to study phase transitions, including melting, under deep-earth conditions. Laser-induced ruby fluorescence has been essential for the development of techniques for generating maximum pressures now possible with the diamond anvil cell, and currently provides a calibrated *in situ*measure of pressure well above 100 gigapascals. Hemley, Bell, and Mao (Carnegie Institution of Washington) point out that applications of new spectroscopic techniques, such as double resonance, ultrafast kinetics, Fourier-transform, Raman, and nonlinear optical methods, are likely prospects in future work on geophysical problems with the diamond anvil cell. Recent high-pressure studies involving the use of picosecond spectroscopy and hyper-Raman scattering of perovskites may be representative of this trend. Time-resolved studies may permit the detailed investigation of the kinetics of high-pressure phase transitions and the rheology of minerals under *in situ*deep-earth conditions. The combination of spectroscopic and x-ray diffraction probes with laser-heating techniques may yield detailed structural information on earth materials at high temperatures and pressures, thus advancing an understanding of the connection between atomic-scale properties and global deep-earth processes.

Laser Metrology

Lasers are widely used for making precision measurements of geometric variables. In the early 1960s, laser pioneers demonstrated precise measurements with the device. Lasers introduced the concept of frequency metrology as contrasted with wavelength metrology. In an early experiment with a super-stabilized laser, scientists at the Massachusetts Institute of Technology during the early 1960s worked out a laser version of the famous Michelson-Morley experiment at Case Institute of Technology in Cleveland. The MIT scientists concluded that an advance in measurement sensitivity by a factor of 1000 over the Michelson-Morley data was potentially available through the use of frequency rather than length metrology. In 1962, the first laser measurement of the speed of light (c) was made, yielding a value of 299, 792, 462 ± 18 meters per second.

Since that time, several more sophisticated determinations have been made by leading metrology laboratories, including the National Institute of Standards and Technology (Boulder, Colorado), the National Physical Laboratory (United Kingdom), the Laboratoire de Physique des Lasers (Villetaneuse, France), and the Laboratory for Spectroscopy (Russia),

TABLE 2. SUMMARY OF LIDAR SYSTEM CHARACTERISTICS

Type of lidar	Type of laser used	Nominal accuracy	Range (km)	Atmospheric targets
Atmospheric backscatter	Ruby, Nd:YAG	1–10%	10–50	Dust, clouds, volcanic ash, smoke plumes
DIAL, Raman	Dye, CO_2, optical parametric amplifier, $CO:MgF_2$	1 ppb–100 ppm	1–5	H_2O, O_3, SO_2, NO, NO_2, N_2O, C_2H_4, CH_4, HCl, CO_2, CO, Hg, SF_6, NH_3
Fluorescence	Dye	10^2 - 10^7 atoms/cm	1–90	OH, Na, K, Li, Ca, Ca^+
DIAL, Raman	Dye, Nd:YAG	1 K, 5 mbar	1–30	Temperature, pressure
Doppler	CO_2	0.5 m/sec	15	Wind speed

After Leone (1987).

among others. Based on these measurements, c is now given as precisely 299,792.458 meters per second. Furthermore, the length unit has been abandoned as a fundamental unit and is now derived from the time unit and the above quoted value for the speed of light.

At the practical manufacturing level of metrology, laser guidance systems can be used. Mergler (Case Western Reserve University) introduced a machine in 1978 along these lines. In a conventional machining operation, a part is cut, then measured, then remachined until the required dimensions are obtained. Manual measuring methods are tedious, time consuming, and somewhat limited in accuracy. In Mergler's system, a small modulated gas laser beam follows the surface of the part being machined and, within a precision of 1/5000 inch (0.005 millimeter) measures the piece as it is being cut. In later systems, the gas laser was replaced by a solid-state laser which occupies less space.

Laser Doppler Flowmeter

As shown in Fig. 12 fluid flow can be determined by measuring the doppler shift in laser radiation scattered from particles in the moving fluid stream. No sensor is required in the moving stream. The laser radiation focal point can be moved across the flow tube to measure velocity profiles. Fluid linear flows from 0.01 to 5000 inches (0.03 centimeter to 127 meters) per second have been measured. Contaminants, such as smoke, may have to be added to gases to provide scattering centers for the laser beam.

Laser Gyroscope

As early as the beginning of the 20th century, some investigators suggested that light will exhibit gyroscopic behavior, that is, the time required by light to traverse a circular pathway depends on whether the pathway is stationary or rotating. Thus the time difference can be used as a measure of the amount of rotation. The practical application of this observation, however, had to await vast improvements in optical systems, including the discovery of the laser, advances in fiber-optics, and better reflective mirrors. Within recent years, this principle has been applied in two configurations—fiber gyroscopes and ring-laser gyroscopes. The latter is described briefly here. As of the late 1980s, several aircraft depend upon ring-laser gyroscopes instead of their mechanical counterparts. The ring-laser gyroscope is more sensitive, has virtually no moving parts, and is as accurate as the best mechanical instruments. The rotation-induced difference in length of light path traversed is called the Sagnac effect, after the researcher who first demonstrated the phenomenon in 1913.

As previously mentioned in this article, a laser usually incorporates a resonant cavity. C.V. Heer (Ohio State University) in 1958 proposed that a resonant cavity could be used to measure rotation rates. In such an instrument, light circulates many times around a given path, not just back and forth between two mirrors. The first gyroscopes of this kind were constructed on a large scale, consisting of four glass tubes, each a meter long and arranged in a square. Light was made to travel around the device by placing a mirror in each corner. Over the last several years, the device has been markedly reduced in size (fits in the palm of the hand).

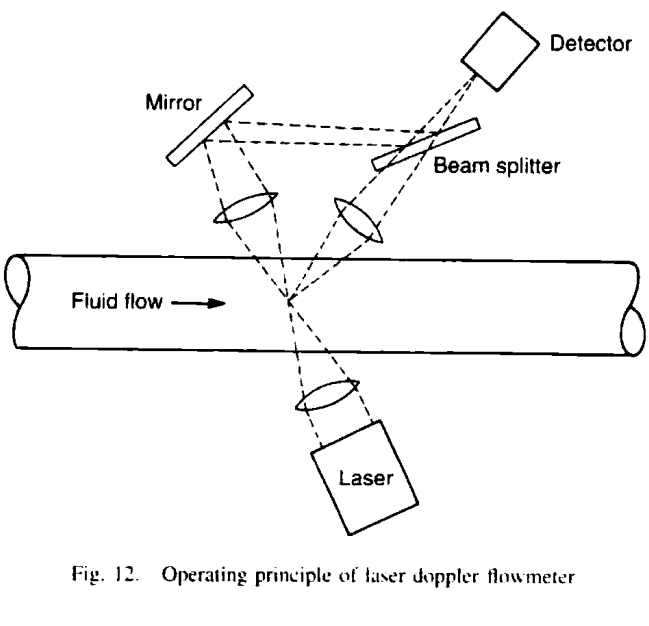

Fig. 12. Operating principle of laser doppler flowmeter

Contemporary gyroscopes of this type are made from a single block of glass, into which a square channel is drilled. The channel is filled with a mixture of helium and neon. The laser is completed by attaching a small number of electrodes and four mirrors. As explained by Anderson, some ring-laser gyroscopes have a triangular channel and three mirrors; others have a hexagonal channel and six mirrors.

Beyond the scope of this article, Anderson explains the operation of the gyroscope in intimate detail and describes two problems that have proved most vexing to manufacturers of the ring-laser gyroscope, namely, frequency locking at low rotation rates and the bias effect. Improvements in this instrument are expected in the relatively near future because of what scientists have recently learned pertaining to the phenomenon of optical phase conjugation.

Lasers in Manufacturing Operations. A principal advantage of the laser in manufacturing operations is its ability to apply an extremely high flux of energy to the surface of a workpiece, as compared with traditional heat sources, such as flames, torches, electric arcs, and plasma jets. For manufacturing operations, lasers are usually placed in two categories. (1) *Light-duty lasers* range from a few tens of watts to a few hundred watts. Typical applications include cutting and drilling ceramic substrates in the electronics industry, drilling gems (for example, rubies in watchmaking), and cutting light-gauge metals as well as cloth, plastics, wood, and a variety of materials. Light-duty lasers that have been used include ruby lasers, neodymium-doped glass lasers, and neodymium-doped yttrium aluminum garnet lasers, among others. Depending upon the particular laser selected, the laser may operate in a pulsed or continuous mode. Argon and CO_2 lasers usually are operated in the continuous-wave mode. (2) *Heavy-duty lasers* range from a few kilowatts to a few tens of kilowatts. Typical applications include pipeline welding, automobile part welding, surface heat-treating of engine and other parts, with the applications expanding as experience is gained.

The high flux of electromagnetic energy applied to the surface of a workpiece by a laser is absorbed in an outer layer only about 10 nanometers thick. Thus the heat source is confined essentially to a thin film. Through careful design of equipment, the heat energy required is maintained in a comparatively small region, thus preventing or reducing thermal damage to the rest of a given part, and achieving a very high energy efficiency, estimated to range from 10 to 1000 times greater than can be achieved with conventional energy sources.

The electronics industry utilizes laser welders for joining dissimilar materials, fixing electrodes to batteries and connectors to a host of devices. A whole new area of laser technology, sometimes called laser microchemistry, has been exploited in the microstructure engineering of semiconductors. Lasers are used to initiate chemical reactions that result in deposition of material at a surface, for removing materials, and for alloying or diffusively mixing two or more solids on microscopic spatial scales. Lasers thus have played a major role in establishing new dimensions in microfabrication technology. It is possible to use a single laser to produce both gas-phase photolysis and surface heating. As described by Christensen (See reference), solar cells have been fabricated by using a UV laser to photodissociate trimethylboron, $B(CH_3)_3$, over a silicon surface in the manufacture of solar cells. The laser also heats the surface so that the boron atoms absorbed on the surface after the photolytic step rapidly diffuse into the bulk of the material. After irradiation, the silicon is heavily doped with boron near the surface, and the p-n junction thus formed functions as a photovoltaic cell. In some other applications, it has proved advantageous to use two lasers of different wavelengths to separately achieve photolysis and heating.

Perspective. The industrial applications for lasers developed comparatively slowly. As previously mentioned, lasers depend upon raising active molecules of the lasing medium to what might be called an *upper laser level* of energy, after which they relax to a *lower laser level*. Energy is given up during this process. Part of this energy is represented by photons of which the laser beam is composed. The other part is waste heat, which raises the temperature of the lasing medium. Thus, an excess of waste heat be removed so that the upper-level population can be maintained, a significant problem in the case of a continuously emitting high-power laser. Higher packets of energy in pulses can be attained, but waste heat must be removed by conduction between pulses. The end result is a pulsed high-power laser, but one that has a comparatively low average energy level simply because of the pauses in between.

In early laser designs, the quantity of waste heat generated was a limiting factor and consequently the average power output was low. Such lasers were excited by diffuse longitudinal electric discharges in long tubes with relatively large diameters. Heat generated at the center of the tube diffused to the side walls essentially by conduction, and the rate of heat transfer varied inversely with the tube radius and essentially directly with the length of the tube. Thus, the length of laser tubes increases as greater output power was sought.

Various component cooling schemes were proposed and used, but a major improvement was made when the concept of cooling a flowing laser medium was proposed, thereby taking advantage of the far more effective cooling by convection than by conduction. Gas lasers were considered the most apt for application of this concept and this led to the gas dynamic laser.[1]

With this concept, gas dynamic lasers increased in power outputs from less than 10 kilowatts by a factor of 13 to 14 within less than a decade (by the late 1960s). Success with the early gas lasers in this respect catalyzed a number of other refinements and improvements. However, the problem of maintaining a high-pressure glow discharge remained. Population inversion can be produced when electrons in an ionized gas are at a temperature relatively high as compared with the kinetic temperature of ions or molecules. This is a condition referred to as *glow discharge*. But an arc may form when the discharge is destabilized as the result of greatly increased gas pressure. Overheating of the molecules and ions destroys the population inversion. This problem was overcome by the concept of the ionizer/sustainer.

With the availability of high-power continuous electric discharge lasers capable of operating at up to 20 kilowatts output, a number of the previously predicted applications for lasers became practical. One of the first uses of a laser beam strictly for its power in cutting (exploding) a material was the fabric cutting system developed by Hughes Aircraft Company (circa 1966–1967) for which U.S. Patent No. 3,761,675 was awarded to W.J. Mason, D.W. Wilson, D.M. Considine, F.J. Viosca, and J.P. Wade on September 25, 1973. See Fig. 13. In this system cloth is carried in a single layer into a cutting area where a laser beam focused on the cloth is directed by computer commands to travel within the cutting area so as to cut many patterns in the cloth rapidly and accurately. The cut produced by the focused laser beam is sharp and narrow, leaving the fabric unfrayed. With synthetic materials, such as nylons and Dacrons®, the laser beam also serves to seal the cut edges by melting them during the cutting process. Unlike a mechanical blade, the laser beam does not dull; its cut remains uniform and is effective in cutting a wide range of materials, even those having metallized threads.

In the early 1980s, a helium-neon laser was used in a scanner system for inspecting textiles. The system uses laser output split into three beams, each of which scans the fabric independently in a pattern covering the entire surface. The system, moving at a rate of four meters per second, detects flaws through changes in reflected light and flags these areas for elimination or repair. In terms of economics, one laser system working one shift performs the same function as human inspectors at two plants working two shifts.

High-power lasers can perform many metalworking operations, including welding, cutting, surface hardening, and surface alloying. For small devices, the laser can perform much as a conventional electron beam, but without requiring the need for operation under a vacuum. High power densities can be achieved—up to 10^6 watts per square centimeter. It has been shown that a 16-kilowatt laser can make a 0.75-inch (1.9-centimeter) penetration weld in stainless steel at a rate of about 30 inches (76 centimeters) per minute. The laser beam can be directed by mirrors, thus making it effective for welding pipe from the inside. It also has been shown that a continuous-wave carbon dioxide device (15 kilowatts) can be used for welding half-inch (1.2-centimeter) thick steel plates at the rate of about 50 inches (127 centimeters) per minute. If the laser is focused to a spot size of about 0.03 inches (0.08 centimeter) in diameter, power densities of some 2200 kilowatts per square centimeter are produced.

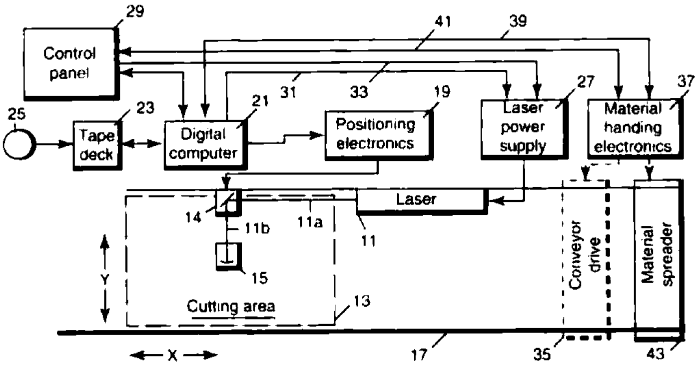

Fig. 13. A cloth cutting system wherein cloth is carried in a single layer into a cutting area, where a laser beam is focused on the cloth and is directed by computer commands to travel within the cutting area so as to cut a plurality of patterns through the cloth rapidly and accurately. Invented by W.J. Mason, D.W. Wilson, D.M. Considine, and J.P. Wade (*Hughes Aircraft Company*) in 1973, this was one of the very early and successful industrial applications of the laser. Diagram is part of U.S. Patent 3,761,675

Laser Recording. For many years, it has been known that lasers can be used to encode information on materials that respond in an irreversible manner to exposure to high-intensity light. However, it is only comparatively recently that the concept has been reduced to commercial practice—with the almost sudden appearance of optical disk recording (compact disk) in the entertainment field. It is because of the coherence and relatively short wavelength of laser radiation that such large volumes of information can be written onto a very small space of the recording medium. The potential for microlasers in this field is discussed earlier in this article.

[1] Invented by Kantrowitz in the late 1960s. In essence, the device had two compartments separated by a nozzle. In the first compartment, gas was held at a temperature of about 1400 K and pressure of 17 atmospheres. This high-pressure compartment held about 10% of the active CO_2 molecules in the total system. Expansion of this gas through an orifice caused cooling. Because of the cooling, the lower-level population essentially vanished a few centimeters downstream from the nozzle. This occurred before the upper-level population had an opportunity to decline significantly. The population "inversion" resulting was adequate for effecting a laser beam of considerable power.

LATENT HEAT. Heat gained by a substance or system without an accompanying rise in temperature during a change of state. As examples, the latent heat of fusion is the amount of heat necessary to convert a unit mass of a substance from the solid state to the liquid state at the same temperature, the pressure being that to allow coexistence of the two phases. A considerable part of the latent heat arises from the entropy increase consequent on the greater disorder of the liquid state. The latent heat of sublimation is the amount of heat necessary to convert a unit mass of a substance from the solid state to the gaseous state at the same temperature, the pressure being that to allow coexistence of the two phases.

LATERITE. The sub-aerial decay of rocks in tropical regions, having a distinctly moist or rainy climate, results in the development of a residual, reddish, and usually sticky soil frequently containing concretions. The principal products of laterization are the hydrated oxides of aluminum and iron either in the crystalline or amorphous form. If the concentration of iron oxide is sufficiently high the laterite may be valuable as an iron ore. If, on the other hand, the concentration of alumina is high the laterite may be valuable as an ore of that metal.

LATEX. Latex is a milky substance found in many plants. It is a complex emulsion in which such substances as proteins, alkaloids, starches, sugars, oils, tannins, resins, and gums are found. In most plants the latex is white; but in some it is yellow; in others, orange or scarlet.

The cells or vessels in which latex is found make up the laticiferous system. There are two very different ways in which this system may be formed. In many plants the laticiferous system is formed from cells laid down in the meristematic region of the stem or root. Rows of these cells are formed. The cell walls separating them are dissolved, so that continuous tubes, called latex vessels, are formed. This method of formation is found in the poppy family; in the rubber plant, *Hevea brasiliensis*; and in the *Cichorieae*, a section of the composite family distinguished by the presence of latex in its members. Dandelion, lettuce, hawkweed, and salsify are members of the *Cichorieae*. See also **Latex Technology**; and **Rubber (Natural)**.

LATEX TECHNOLOGY. Latex technology encompasses colloidal and polymer chemistry in the preparation, processing, and conversion of natural and synthetic latices into useful products.

Worldwide concern over the AIDS epidemic has sharply increased the demand for latex used in the preparation of rubber gloves and similar dipped goods. Estimates are for a 5–7% annual growth rate in this market.

Many synthetic latices exist. They contain butadiene and styrene copolymers (elastomeric), styrene–butadiene copolymers (resinous), butadiene and acrylonitrile, chloroprene copolymers, methacrylate and acrylate ester copolymers, vinyl acetate copolymers, vinyl and vinylidene chloride copolymers, ethylene copolymers, fluorinated copolymers, acrylamide copolymers, styrene–acrolein copolymers, and pyrrole and pyrrole copolymers. Many of these latices also have carboxylated versions.

Traditional applications for latices are adhesives, binders for fibers and particulate matter, protective and decorative coatings, dipped goods, foam, paper coatings, backings for carpet and upholstery, modifiers for bitumens and concrete, thread, and textile modifiers. More recent applications include biomedical applications as protein immobilizers, visual detectors in immunoassays, as release agents, in electronic applications as photoresists for circuit boards, in batteries, conductive paint, copy machines, and as key components in molecular electronic devices.

By 1935 emulsion polymerization became the method of choice in making synthetic rubber because of its many advantages: (*1*) the reaction mass viscosity remains low throughout polymerization, providing for improved heat transfer, agitation, and product handling; (*2*) the sensible heat of the water in the emulsion balances the heat of reaction generated by free-radical polymerization; and (*3*) the rate of reaction is rapid, while producing very high molecular weight.

Synthetic Latex Manufacture

Kinetics and Mechanisms. In 1945 the first recognized qualitative theory of emulsion polymerization was presented. This mechanism for classic emulsion preparation was quantified and the polymerization separated into three stages—stage I: particle nucleation; stage II: growth in polymer particles saturated with monomer; and stage III: growth in polymer particles with a decreasing monomer concentration.

Basic Components. The principal components in emulsion polymerization are deionized water, monomer, initiator, emulsifier, buffer, and chain-transfer agent. A typical formula consists of 20–60% monomer, 2–10 wt % emulsifier on monomer, 0.1–1.0 wt % initiator on monomer, 0.1–1.0 wt % chain-transfer agent on monomer, small amounts of various buffers and bacteria control agents, and the balance deionized water.

Process. Commercial processes manufacturing latex can be divided into batch, semibatch, and continuous methods.

Latex Properties

The observable properties of a latex, i.e., stability, rheology, film properties, interfacial reactivity, and substrate adhesion, are determined by the colloidal and polymeric properties of the latex particles. Important polymer properties include molecular weight distribution, monomer sequence distribution, glass-transition temperature, crystallinity, degrees of cross-linking, and free monomer. Methods for analyzing each of these properties exist, depending on the end use of the product. An overview of the various polymer colloid characterization methods is available.

Improving Properties Through Compounding. The potential value of most polymers can be realized only after proper compounding. Materials used to enhance polymer properties or reduce polymer cost include

antioxidants, cross-linking reagents, accelerators, fillers, plasticizers, adhesion promoters, pigments, etc.

LATTICE COMPOUNDS. Chemical compounds formed between definite stoichiometric amounts of two molecular species that owe their stability to packing in the crystal lattice, and not to ordinary valence forces.

LATTICE ENERGY OF CRYSTAL. The decrease in energy accompanying the process of bringing the ions, when separated from each other by an infinite distance, to the positions they occupy in the stable lattice. It is made up of contributions from the electrostatic forces between the ions, from the repulsive forces associated with the overlap of electron shells, from the van der Waals forces, and from the zero-point energy.

LAURIC ACID. [CAS: 143-07-7]. Also called dodecanoic acid, formula $CH_3(CH_2)_{10}COOH$. A fatty acid that occurs in many vegetable oils and fats as the glyceride, especially in coconut oil and laurel oil. See also **Vegetable Oils (Edible)**. Combustible. It takes the form of colorless needles at room temperature. Specific gravity 0.833; mp 44°C; bp 225°C (100 millimeters pressure). Insoluble in water; soluble in alcohol and ether. It is derived by the fractional distillation of coconut oil. Lauric acid is used in alkyd resins; wetting agents; soaps; detergents; cosmetics; insecticides; food additives.

LAVA. Molten material that has poured out on the surface of the earth and, due to relief of pressure, may have lost much of its original gas and water content during its relatively rapid consolidation. The term lava is used for both the liquid and the consolidated state of the igneous material. Lava may be erupted either by volcanoes or from fissures. Flowing lava is shown in Fig. 1. The most extensive lava flows are fissure eruptions, such as the Columbia Plateau basalts in Oregon or the plateau basalts of the Deccan, India, which are derived from basic magma. Had this magma, either basic or acid, cooled slowly beneath the surface of the earth under great pressure and with all its original gases, the resulting rock would have had a coarser texture and somewhat different mineral content.

Fig. 1. Lava flow

LAVOISIER, ANTOINE, LAURENT (1743–1794). A French chemist generally regarded as the "father" of chemistry. His "Traite elementaire de chimie" (1789) listed 30 elements, clarified the nomenclature of acids, bases, and salts, and described the composition of numerous organic substances. He erroneously believed that oxygen is the characteristic element of acids. However, his fundamental work on combustion, as a result of which he identified and named nitrogen (azote), and on the separation of hydrogen from water by a unique reduction experiment carried out in a heated gun barrel, earned him a leading position among early chemists.

LAWRENCE, ERNEST O. (1901–1958). An American physicist who invented the cyclotron in 1929. Both the element lawrencium and the Lawrence Livermore Research Laboratory at the University of California were named after him.

See also **Cyclotron**.

LAWRENCIUM. [CAS: 22537-19-5]. Chemical element, symbol Lr, at. no. 103, at. wt. 257 (mass number of known isotope), radioactive metal of the Actinide series, also one of the Transuranium elements. ^{103}Lr was identified in 1961 by A. Ghiorso, T. Sikkeland, A. Larsh, and R. Latimer at the University of California at Berkeley.

This method used to produce and identify lawrencium was similar to that used in the later, direct-counting experiments performed in connection with the production of nobelium at Berkeley. About 3 micrograms of a mixture of californium isotopes were bombarded with boron ions accelerated in the heavy-ion linear accelerator. The atoms of lawrencium recoiled from the target into an atmosphere of helium, where they were electrostatically collected on a copper conveyor tape. This tape was then periodically pulled into place before radiation detectors to measure the emission rate and the energy of the alpha particles being emitted. By this means, it was possible to identify the lawrencium isotope ^{257}Lr, with a half-life of 8 seconds. At present, because of the short half-life and the lack of a suitable daughter isotope, available in the case of nobelium, it has not been possible to perform a chemical identification.

Another isotope, ^{256}Lr, half-life about 45 seconds, was reported by the Soviet Union in 1965. It was produced by impact of oxygen atoms (^{18}O) on americium (^{243}Am). It decayed by alpha-particle emission and electron capture to form ^{252}Fm. See also **Chemical Elements**.

Lawrencium has been found to behave quite differently from dipositive nobelium and, in fact, it is comparable to the tripositive elements that appear earlier in the Actinide series.

LAWSONITE. Named for Andrew Cowper Lawson (1861–1952), a Scottish-American geologist. This calcium aluminum silicate mineral, $CaAl_2(Si_2O_7)(OH)_2 \cdot H_2O$, is found as grains and veins within the metamorphic rocks, gneisses, and schists. It was found originally on the Tiburon Peninsula, San Francisco Bay, California, but also occurs in schistose rocks in France and New Caledonia. The mineral has a hardness of 7; specific gravity of 3.09. It is colorless, pale blue to bluish gray, translucent, with vitreous to greasy luster. The mineral crystallizes in the orthorhombic system.

LAZULITE. Lazulite is named from an Arabic word for *heaven* in allusion to its sky blue color. This mineral crystallizes within the monoclinic system, a basic phosphate of magnesium and aluminum, $MgAl_2(OH)_2(PO_4)_2$. Ferrous iron can substitute for the magnesium and the isomorphous mineral scorzalite is the product. Usually occurs massive but acute pyramidal crystals are not uncommon. Color is azure-blue to bluish-green, usually translucent (rarely transparent), with vitreous luster. It has a hardness of 5.5–6, with specific gravity of 3–3.1.

Lazulite is a rare mineral found principally within high-grade metamorphic rocks. Notable world crystal occurrences are Salzburg, Austria; Syria; Hörnsjöberg, Sweden; Madagascar; Brazil; and Graves Mountain, Georgia. When transparent, the mineral can be cut into gem stones.

LAZURITE. The mineral lazurite or lapis lazuli has been used since ancient times for jewelry and other ornamental purposes. Ground to powder it forms the pigment ultramarine, now, however, largely superseded by artificial preparations. Lapis lazuli is a mixture of minerals, lazurite being the chief component. This mineral is isometric, and chemically a sodium, calcium, aluminum sulfo-chlorosilicate. A general formula is $(Na, Ca)_8(Al, Si)_{12}O_{24}(S, SO_4)$. Lapis lazuli has a hardness of 5–5.5; specific gravity, 2.4; color, various shades of blue; luster, vitreous to greasy; translucent to opaque. Localities are Afghanistan, Siberia, Chile, and California.

LEAD. [CAS: 7439-92-1]. Chemical element, symbol Pb, at. no. 82, at. wt. 207.2, periodic table group 14, mp 327.5°C, bp 1740°C, density 11.35 g/cm^3, (20°C). Elemental lead has a face-centered cubic structure with an edge length of 4.950 Å.

Lead is a white to bluish-gray metal, soft, malleable, and slightly ductile; tarnishes in air, forming a film of oxide, forms oxide scum upon heating the molten metal in air; soluble in dilute HNO_3; HCP or H_2SO_4 attack lead only slightly, the extent depending markedly upon the concentration and the temperature; slowly dissolves in H_2O and consequently the use of lead constitutes a health hazard due to its toxic effect; attacked by solutions of organic acids or sodium hydroxide. Lead is one of the four most largely produced and utilized metals, and considerable scrap metal is recovered. Used (1) in construction and apparatus where workability is demanded, and definite resistance to corrosion is supplied by the metal, (2) as a constituent of various alloys, especially solder, type metal, pewter, and fusible alloys, (3) for storage battery plates, (4) for shot and bullets, and (5) as a protective coating for iron and steel.

Lead has four naturally occurring isotopes. In order of abundance, these are ^{208}Pb, ^{206}Pb, ^{207}Pb, and ^{204}Pb. There are ten unstable isotopes, 200–203, 205, and 209–214. See also **Radioactivity**. In terms of abundance, lead is scarcely represented in the earth's crust, the average composition of igneous rocks containing only 0.002% Pb by weight. In terms of cosmic abundance, an estimate made by Harold C. Urey in 1952, using silicon as a basis with the figure of 10,000, lead had an abundance figure of less than 0.02. In terms of presence in seawater, lead is 27th among the elements, with an estimated 14 tons per cubic mile (3 metric tons per cubic kilometer) of seawater. In this regard, it is comparable to tin, copper, arsenic, protactinium, and selenium.

The atomic weight varies because of natural variations in the isotopic composition of the element, caused by the various isotopes having different origins; ^{208}Pb is the end product of the thorium decay series, while ^{207}Pb and ^{206}Pb arise from uranium as end products of the actinium and radium series respectively. Lead-204 has no existing natural radioactive precursors. Electronic configuration $1s^2 2s$; &22$p^6 3s^2 3p^6 3d^{10} 4s^2 4p^6 4d^{10} 4f^{14} 5s^2 5p^6 5d^{10} 6s^2 6p^2$. Ionic radius Pb^{2+} 1.18 Å, Pb^{4+} 0.70 Å. Metallic radius 1.7502 Å. Covalent radius (sp^3) 1.44 Å. First ionization potential 7.415 eV; second, 14.97 eV. Oxidation potentials $Pb \longrightarrow Pb^{2+} + 2e^-$, 0.126 V; $Pb^{2+} + 2H_2O \longrightarrow PbO_2 + 4H^+ + 2e^-$, −1.456 V; $Pb + 2OH^- \longrightarrow PbO + H_2O + 2e^-$, 0.576 V; $Pb + 3OH^- \longrightarrow HPbO_2^- + H_2O + 2e^-$, 0.54 V. Other physical properties are given under **Chemical Elements**.

Lead is of interest as being the terminal product of radioactive decay. Thus, while ordinary lead has the atomic weight 207.19 (being composed of 1.37% ^{204}Pb, 26.26% ^{206}Pb, 20.8% ^{207}Pb and 51.55% ^{208}Pb), the isotopic composition, and hence the atomic weight, varies somewhat in lead from meteorites, from deep-seated rocks and from uranium ores (the last being somewhat less dense, as would be expected from the fact that ^{206}Pb is the end-product of the uranium series). These variations in isotopic composition of lead permit of calculations of the age of the earth (and the meteorites).

Lead Melting Point as a Standard

Melting, defined as the equilibrium transition between crystalline and liquid states, is of large concern in the development of the physical and materials sciences. To date, some of the purest crystals of silicon, diamond, and other technologically important materials have been produced from melts. Studies of melts also are of significance in understanding the interiors of terrestrial plants and, in fact, of Earth. In research at the University of California (Berkeley), studies of the effects of high pressure on the fusion temperature of lead have been underway. The advantages of studying lead are outlined by the investigators as: (1) the melting temperature of lead at ambient pressures is low and well determined, (2) lead is highly compressible and therefore should show the effects of pressure, (3) the behavior of lead under pressure is relatively simple, involving only one known polymorphic transition (from face-centered cube to hexagonal close-packed crystal structure), and (4) shock-wave experiments have been carried out previously to document the compression of both crystalline and molten lead at simultaneously high pressures and temperatures.

Occurrence and Processing

Galena, PbS, lead sulfide, is the source of over 95% of the lead currently produced. Bodies containing galena range from 3% to 30% lead. One of the most widely distributed sulfide minerals, galena frequently occurs along with sphalerite, ZnS. The lead-zinc ores processed usually contain recoverable quantities of copper, silver, antimony, and bismuth. Principal sources being worked are in Australia's Broken Hill area in New South Wales, the western United States, Canada, Mexico, Peru, former Yugoslav Republics, and the former Soviet Union. When groundwater reacts with galena, cerussite, $PbCO_3$, is formed; when galena is in contact with sulfate solutions generated by the oxidation of sulfide minerals, anglesite, $PbSO_4$, may be formed. See also **Anglesite**; **Cerussite**; and **Galena**.

In processing, the ore first is crushed, wet-ground, and classified to a point where it is at least 90% less than 200 mesh. Separation of the sulfide ore from the gangue is aided by flotation agents. The resulting concentrates contain from 45% to 60% lead, from zero to 15% zinc, and often a few ounces (~50 grams) of gold and up to 50 ounces (1.4 kilograms) of silver per ton. Copper content may be as much as 3%, arsenic, 0.4%, and antimony, 2%. The sulfur content (10 to 30%) is reduced by roasting in a Dwight-Lloyd sintering machine. This sulfur reduction is necessary because PbS is not reduced by carbon or carbon monoxide at blast-furnace temperatures. Once formed, the sinter, together with limestone and coke, is fed into a blast furnace. Further oxidation and electrolytic methods may be used to refine the lead. Lead is commercially produced to standards of very high purity. The minimum lead content permitted by specifications for Pig Lead (7 classifications) is 99.73%. Fully refined lead averaging 99.99% lead is obtainable. Large quantities are used for production of chemicals. At one time, primary uses for lead chemicals were in the production of paint pigments and lead tetraethyl gasoline additive.

Lead Metals and Alloys

Lead is soft and ductile and is readily worked by common methods, predominantly by rolling and extruding. Lead is easily formed and readily joined by welding (burning), or by soldering and can be bonded to steel, or used as a liner for steel, wood, concrete, and other materials. Lead is widely used in this manner because of its excellent resistant to atmospheric and soil corrosion, and attack by sulfuric and phosphoric acids. Lead generally does not resist the action of the organic acids, nor the oxidizing mineral acids, such as HNO_3. Lead is attacked by alkalies.

Due to its low melting point, pure lead will very gradually flow or creep at room temperature. Thus, lead sheeting used as a roofing material on old buildings will usually be thicker at the lower edge than at the upper edge. Other examples of creep occur under low sustained stresses due to the oil pressure in lead-covered power conducting cable, for example, or due to the weight in the case of a deep tank lined with sheet lead. To counter the effects of creep, lead containing 0.06% copper (*chemical lead* or *acid lead*) is preferred.

The addition of antimony in amounts up to 12% greatly improves the casting properties and increases the hardness very materially. These properties make possible the casting of intricately shaped antimonial lead storage-battery grids which, including the weight of the lead oxide paste applied to them, constitute the largest single use for the metal.

Tin and lead in various proportions form a highly useful series of alloys generally known as the soft solders which are used for joining copper, iron, nickel, lead, zinc and even glass. The solders can be applied by means of a soldering tool, by wiping, by hot-dipping, or by special machines as in the tin-can industry. Numerous compositions are used, the most popular of which are listed in the accompanying table.

Further additions of bismuth, cadmium, and antimony to the tin-lead alloys result in the low melting or "fusible" alloys widely used as safety

devices, the melting points of which can be varied to suit a wide range of requirements. The type metals of the printing industry are lead-tin-antimony alloys having the requisite hardness and good casting properties needed for high-fidelity reproduction.

Babbitt metals (white-metal bearing alloys) are generally classified as either tin-base or lead-base. The true tin-base Babbitts contain only tin, antimony and copper, and have been used for many years. The practice of adding up to 25% lead to the tin Babbitts to reduce their cost is to be avoided since the net result is an expensive series of alloys with inferior properties to the inexpensive lead-base Babbitts. The lead-base bearing alloys of the older type usually contain lead, antimony and tin, and while not considered the equal of the tin-base alloys for severe service have been widely employed due to their low cost. The lead-base alloy containing arsenic has found extensive use and has come to the fore of this group since it has successfully met many automotive and other severe service requirements. All of these alloys render their most efficient service when used in the form of a thin lining bonded to a bronze or steel shell. See Table 1.

Lead Eliminated from Free-cutting Alloys

Among the numerous efforts being made to eliminate lead from the environment, including the potable water plumbing systems, free-cutting copper alloys that contain no lead have been developed. As reported in late 1991, bismuth, as a replacement, has significant potential as a nontoxic alternative to lead to enhance the machinability of copper. When bismuth is used alone, however, the element embrittles copper because of its tendency to "set" grain boundaries. J.T. Plewes (see reference) ascribes this characteristic to the large difference in surface tension between copper and bismuth. It has been found that adding a third element in modest amounts removes this limitation of bismuth. Such elements include phosphorus, indium, and tin.

Chemistry of Lead

A number of oxides of lead are known, but not all are daltonide compounds. Thus, lead(I) oxide, Pb_2O, made by heating lead(II) oxalate, has been shown by x-ray analysis to be a mixture of the metal and lead(II) oxide, PbO. The latter is obtained by heating lead in air, which yields a yellow, rhombic material, which has a peculiar layer structure having each lead atom attached to four oxygen atoms all lying on the same side of it, forming a square pyramid with the lead at the apex. Each oxygen atom is surrounded tetrahedrally by four lead atoms. Another form of PbO, somewhat more stable and soluble in water, red in color, and tetragonal in structure, may be obtained along with the yellow form by alkaline dehydration of $Pb(OH)_2 \cdot PbO$ is amphiprotic, but only weakly acidic. Lead(IV) oxide, Pb_2O, is obtained by action of chlorine on alkaline solutions of lead(II) oxide or acetate. The reaction is $Pb(OH)_3^- + ClO^- \longrightarrow PbO_2 + Cl^- + OH^- + H_2O \cdot PbO_2$ can also be produced on a lead or platinum anode by electrolysis in acidic solution. Like the lower elements of main group 4, lead(IV) forms tetrahedral bonds exhibiting sp^3 hybridization. In its relatively more stable salts, however, the $6s^2$ electrons are unused, and Pb^{2+} ions are formed by loss of the $6p^2$ electrons. These facts explain the marked difference between the essentially covalent character of many of the tetravalent compounds and the essentially electrovalent character of the divalent compounds, as well as the peculiar structure of PbO and many other Pb(II) compounds.

The dioxide, Pb_2O, has rutile structure, and the compound is a strong oxidizing agent. It is also amphiprotic, giving unstable lead(IV) salts with acids, and orthoplumbates, $M_4^IPbO_4$, or metaplumbates, $M_2^IPbO_3$, upon fusion with alkalies. Lead dioxide dissolves in aqueous alkali with formation of the ion $Pb(OH)_6^{2-}$, the alkali salts of which are isomorphous with the corresponding stannates and platinates. Lead sesquioxide, Pb_2O_4, has been shown not to exist as a stable phase.

TABLE 1. REPRESENTATIVE LEAD AND TIN ALLOYS

Name	Pb	Sn	Sb	Cu	Bi	Ag	Cd	Typical application
				LEAD ALLOYS				
Chemical or acid lead	99.9			.06				Tank linings, coils, etc., power cable sheath.
Cable sheath	98.9		1.0					Telephone cable sheath.
Hard lead	96–92		4–8					Cast shapes, wrought sheet and pipe.
Battery grid metal	92–88	.25	8–12					Cast battery grids.
				SOLDERS				
Soft solder	50	50						General purposes, most popular solder.
Wiping solder	60	40						For wiping joints in cables, lead
	60	37.5	2.5					pipes, etc.
"Fine solder"	40	60						For making joints at low temperature.
Solder	95–97.5					5–2.5		High temperature solder.
				FUSIBLE ALLOYS				
Wood's metal	25	12.5			50		12.5	Melts in hot water at 154°F. Wets glass. Wide range of melting points possible with changes in composition for automatic sprinkler systems and other safety devices.
Matrix metal	28.5	14.5	9		48			For anchoring punches, etc., in jigs and fixtures. Expands on freezing.
Bending alloy	26.5	13.5			50		10	Filler for tubes, etc., during bending. Melts out in hot water.
				TYPE METALS				
Electrotype	93	3	4					
Linotype	84	4	12					
Stereotype	80.5	5.75	13.75					
Monotype	76	8	16					Single type.
				TIN BASE BABBITTS				
	89	7.5	3.5					General usage.
	83.3	8.3	8.3					Hard Babbitt.
				LEAD BASE BABBITTS				
	82.5	1.0	15	.5	1.0 As			General usage.
	80	5	15					General usage.
	75	10	15					General usage.

Notes: Figures given in percent. Wood's metal melts at ~68°C in water.

Lead orthoplumbate, Pb_2PbO_4, red lead, is similarly described as a salt, in this case an orthoplumbate of divalent lead, Pb_2PbO_4, because on treatment with nitric acid, two-thirds of the lead dissolves and one-third remains as PbO_2. It is prepared in the red form by atmospheric heating of PbO, and in a black form by reaction of PbO with pure oxygen. Red lead is formed of PbO_6 octahedra (with one common edge) linked by lead atoms covalently bonded to three oxygen atoms.

The lead dihalides are known for all four of the common halogens. They are not strictly ionic in the anhydrous state, but they dissolve in (hot) water to give Pb^{2+} ions, more or less hydrated. They are much less soluble in cold water. They also form complex compounds such as M_2PbCl_4, MPb_2Cl_5, M_4PbF_6, and $MPbF_3$, where M is an alkali metal. The compound formed, especially of the fluoroplumbates(II) depends somewhat on the alkali metal, some of which form/nondaltonide (berthollide) compounds. Of the lead tetrahalides, only PbF_4 and $PbCl_4$ are known, the fluoride being prepared by fluorination of PbF_2. The chloride, which easily loses chlorine, is made by careful acidification of a hexachloroplumbate(IV). $PbCl_4$ forms the complex compound ammonium hexachloroplumbate, $(NH_4)_2PbCl_6$, upon addition to its solution of solid ammonium chloride.

Lead(II) inorganic compounds and salts of organic acids are far more numerous than those of lead(IV), as is to be expected from the essentially covalent character of the latter. In addition to the oxides and halides already discussed, there are lead(II) compounds of essentially all of the common anions, including many basic compounds. Thus lead(II) chloride forms such basic compounds as $PbCl_2 \cdot Pb(OH)_2$, $PbCl_2 \cdot PbCl_2 \cdot 2PbO$, $PbCl_2 \cdot 3PbO$, and $PbCl_2 \cdot 7PbO$. In fact, a whole series of lead salts are derived from the hydroxide, some of which are double compounds, such as $PbX_2 \cdot 2Pb(OH)_2$ and some of which, of composition Pb(OH)X, have been shown to be dimeric of the general formula

$$\left[Pb \left(\begin{matrix} HO \\ \\ HO \end{matrix} \right) Pb \right] X_2$$

Other lead compounds include the following:

Acetates. Lead acetate, "sugar of lead," [CAS: 301-04-2], $Pb(C_2H_3O_2)_2 \cdot 3H_2O$, white crystals, soluble, formed by reaction of lead oxide and acetic acid, and then crystallization. Used (1) to furnish a soluble lead salt, (2) as a mordant in dyeing and printing textiles, (3) as a paint and varnish drier, basic lead acetate, white crystals, soluble, formed by reaction of lead acetate solution and lead oxide, and then crystallization. Used as a coagulating, clarifying, and deacidifying agent for many organic solutions.

Arsenate. Lead arsenate, [CAS: 10031-13-7], arsenate of lead $Pb_3(AsO_4)_2$, white precipitate, formed by reaction of soluble lead salt solution and sodium arsenate solution. Used as an insecticide. Banned or tightly controlled in some countries.

Azide. Lead azide, [CAS: 13424-46-9], PbN_6, white precipitate, formed by reaction of soluble lead salt solution and sodium azide solution (white solid, formed by reaction of sodamide $NaNH_2$ upon heating in nitrous oxide N_2O gas). Used as a detonator.

Borate. Lead borate $Pb(BO_2)_2$, white crystals, insoluble, by reaction of lead oxide and boric acid solution. Used in preparing special types of glass.

Carbonates. Lead carbonate $PbCO_3$, white precipitate, formed by reaction of soluble lead salt solution and sodium carbonate solution in the cold; basic lead carbonate, formed by reaction of (1) soluble lead salt solution and hot sodium carbonate solution, and (2) lead sheets, carbon dioxide and acetic acid, and pigment, the quality depending largely upon the conditions of the reaction.

Chromates. Lead chromate, "chrome yellow" $PbCrO_4$, yellow precipitate, by reaction of soluble lead salt solution and sodium dichromate or chromate solution, melting point of lead chromate 844 C. Used as a pigment; basic lead chromate, red solid, insoluble, formed by heating lead chromate and sodium hydroxide solution.

Nitrates. Lead nitrate, [CAS: 10099-74-8], $Pb(NO_3)_2$, white crystals, soluble, formed by reaction of lead oxide and nitric acid, and then crystallization, decomposes on heating leaving lead oxide residue. Used to furnish a soluble lead salt; basic lead nitrate, formed by reaction of lead nitrate solution and lead oxide.

Oxalate. Lead oxalate PbC_2O_4, white precipitate, formed by reaction of soluble lead salt solution and ammonium oxalate solution, yields lead suboxide on heating at 300°C out of contact with air.

Phosphate. Lead phosphate, [CAS: 7446-27-7], $Pb_3(PO_4)_2$, white precipitate, by reaction of soluble lead salt solution and sodium phosphate solution.

Sulfates. Lead sulfate, [CAS: 7446-14-2], $PbSO_4$, white precipitate, formed by reaction of soluble lead salt solution and sulfuric acid or sodium sulfate solution; basic lead sulfate, "sublimed white lead," white solid, formed (1) by reaction of lead sulfate and lead hydroxide in water (slow reaction), and (2) by roasting galenite in a current of air.

Sulfide. Lead sulfide, plumbous sulfide, [CAS: 1314-87-0], PbS, brownish-black precipitate, formed by reaction of soluble lead salt solution and hydrogen sulfide or sodium or ammonium sulfide, soluble in dilute nitric acid.

In the great majority of organometallic compounds of lead, the metal is tetravalent and covalently bonded, although the organolead group includes many compounds with both organic radicals and halogen atoms attached to Pb which are not to be described merely as covalent compounds. More than five hundred organometallic compounds of lead have been reported, many of which are named as substituted plumbanes, although PbH_4 is not a starting point in their production. Tetraethyl lead, $Pb(C_2H_5)_4$, is made from a sodium-lead alloy and ethyl chloride.

Like carbon and silicon, and to a lesser extent, germanium and tin, lead forms binary compounds with metals, such as Na_4Pb_7 and Na_4Pb_9. These materials are essentially salt-like, and contain polyplumbide anions. They are of theoretical interest, because they are intermediate in character between stoichiometric compounds (daltonide compounds) and intermediate phases. The two compounds cited dissolve in liquid ammonia, electrolyze in such solutions to give the metals, and apparently form ions such as $[Pb_7]^{4-}$ and $[Pb_9]^{4-}$ which readily form amine complexes.

Lead in Biological Systems—Toxicity

Lead has been identified as a biological system deterrent for decades. It is only recently, however, that studies pertaining to low-dosage exposures of lead have been published despite the fact that probably millions of words have appeared in various publications on the overall topic of lead poisoning.

From a qualitative standpoint, exposure to lead results in a clinical picture of hypertensive encephalopathy, neuropathy, and hemolytic anemia characterized by coarse basophilic stippling in red blood cells. The mechanism of lead's action on human tissue is complex. For one thing, lead blocks heme synthesis. This leads to a build-up of red blood cell protoporphyrin. Lead interferes with cell metabolism by causing a deficiency of pyrimidine 5'-nucleotidase. Lead attacks erythrocyte membrane phospholipids with resultant loss of potassium and interference with the sodium-potassium balance. Diagnosing lead poisoning may involve a determination of the free erythrocyte protoporphyrin level as well as determination of blood and urine levels. Once confirmed, further exposure to lead must be stopped immediately. Chelating compounds, such as $CaNa_2EDTA$, may be administered intravenously over an 8-hour period for several days. This may be followed by treatment with oral penicillamine for several days.

Lead poisoning can lead to chronic renal failure. In its effect on kidney function, lead acts much like cadmium. Chronic exposure to or ingestion of practically any heavy metal, such as lead, is the most common path to polyneuropathy. Where effects of heavy metals on the peripheral nervous system are suspected, many physicians will require testing for metal in hair, fingernails, serum, and urine of the patient. Habitual sniffing of leaded gasolines can lead to lead poisoning. Scientists have compared the lead concentration in the diets of present Americans (0.2 part per million) with the diets of prehistoric peoples (estimated to be less than 0.002 part per million). Some investigators believe that the presence of "natural" lead contamination has been grossly overestimated and that what has appeared to be natural has been the result mainly of a gradual build-up of lead pollution in the air derived from anthropogenic sources. The principal sources of atmospheric lead contamination include (1) natural sources, such as wind-blow volcanic dust, sea spray, forest foliage, and volcanic sulfur compounds; and (2) anthropogenic sources, such as lead alkyls (present in fuels), iron smelting, lead smelting, zinc and copper smelting, and the burning of coal. Much remains by way of research into the sources of lead contamination, including the contributions of atmospheric pollution, of food containers, and of food processing equipment.

In 1990, H.I. Needleman and co-researchers (University of Pittsburgh, Boston University, and Harvard University) reported their findings on the

long-term effects of exposure to low doses of lead in children. An abstract of the report is as follows:

> To determine whether the effects of low-level lead exposure persist, we reexamined 132 of 270 young adults who had initially been studied as primary school-children in 1975 through 1978. In the earlier study, neurobehavioral functioning was found to be inversely related to dentin lead levels. As compared with those we restudied, the other 138 subjects had somewhat higher lead levels on earlier analysis, as well as significantly lower IQ scores and poorer teachers' ratings of classroom behavior.
>
> When the 132 subjects were reexamined in 1988, impairment in neurobehavioral function was still found to be related to the lead content of teeth shed at the ages of six and seven. The young people with dentin lead levels >20 ppm had a markedly higher risk of dropping out of high school (adjusted odds ratio, 7.4; 95 percent confidence interval, 1.4 to 40.7) and of having a reading disability (odds ratio, 5.8; 95 percent confidence interval, 1.7 to 19.7) as compared with those with dentin lead levels <10 ppm. Higher lead levels in childhood were also significantly associated with lower class standing in high school, increased absenteeism, lower vocabulary and grammatical-reasoning scores, poorer hand—eye coordination, longer reaction times, and slower finger tapping. No significant associations were found with the results of 10 other tests of neurobehavioral functioning. Lead levels were inversely related to self-reports of minor delinquent activity.
>
> We conclude that exposure to lead in childhood is associated with deficits in central nervous system functioning that persist into young adulthood.

An interesting professional critique of the Needleman report is summarized by J. Palca (reference listed).

The lead elimination and clean-up problem has numerous parallels with the asbestos pollution problem. The main problem is not one of finding substitutes for these substances, because lead-free paints, for example, have been available for several years, just as substitute insulating materials for asbestos have been found. As pointed out in an excellent article by Pollack (reference listed), the problem (or dilemma) lies with the cleanup of old structures that have such materials installed; and to what limits must one go, within the limitations of financial resources, to remove such materials; and, once removed, how to dispose of them safely. While removing all lead-painted surfaces from schools, for example, ultimately can provide assurance that children will not be exposed to the long-term effects of lead, a great deal of new exposure to workmen and the immediate neighborhoods of such removal projects can occur. Modern technology has designed equipment to protect the safety of restoration or demolition crews, but there remains the enforcement of their using such equipment. One crux of the problem is that posed by the apparent effects of lead in very low dosages. Such pollutants of low concentration, as may be typified by the creation of dust and windborne aerosols, definitely exacerbates the problem. Obviously, the problem becomes one more hampered by socioeconomic measures than by technology.

LEAVENING AGENTS. The generation of carbon dioxide for use as dough leavening is produced by reacting sodium carbonate (baking soda) with one of several leavening acids. In the case of an acidic phosphate salt (with two replaceable hydrogen atoms), the reaction is:

$$MH_2PO_4 + 2\ NaHCO_3 \longrightarrow MNa_2PO_4 + 2\ H_2O + 2\ CO_2$$

where M can be a hydrogen or an alkali metal ion. Claims for use of acidic phosphate salts, in addition to formation of carbon dioxide, are the buffering effects for providing an optimal pH for the baked product, as well as interactions with protein constituents of flour, with resulting optimal elastic and viscosity properties of the dough batter.

Other leavening acids used in modern bakeries include sodium aluminum sulfate, $Na_2SO_4 \cdot Al_2(SO_4)_3$; sodium aluminum phosphate hydrate (and anhydrous); potassium acid tartrate, $KHC_4H_4O_6$ (cream of tartar); and glucono-delta-lactone. The baker is concerned with (1) *dough rate of reaction* (DRR), a measure of the rate at which the leavening acid reacts with the baking soda during both the mixing stage and the holding period after mixing (bench action); and (2) *neutralizing value* or neutralizing strength, i.e., the weight of leavening acid required to neutralize a given weight of sodium bicarbonate. This value is used to compute the amount of leavening acid required to yield the needed amounts of leavening gas as well as its effect upon the pH of the baked goods.

Properties of the principal leavening acids are given in Table 1, which shows the most appropriate baking applications for each.

Baking powders, as prepared for the home baker and for use in premixes, usually incorporate, along with sodium bicarbonate, one of the following leavening acids: (1) potassium hydrogen tartrate (2 parts for 1 part sodium bicarbonate); (2) tartaric acid (infrequent), 1 part; (3) calcium hydrogen phosphate (crystallized), 1.5 parts; or (4) sodium aluminum sulfate or ammonium aluminum sulfate, 1.8 parts. With 7 parts by weight of this finely powdered mixture, there is usually mixed about 3 parts by weight of starch to diminish the effects of moisture in storage. In some cases, dry powdered egg albumin is added to decrease the loss of carbon dioxide upon wetting the flour and baking powder mixture when used. For some purposes, ammonium carbonate can be used alone, since upon heating this material furnishes both ammonia and carbon dioxide gases to make

TABLE 1. PROPERTIES OF LEAVENING ACIDS

Chemical name and formula	Abbreviation	Relative speed at room temperature	Neutralizing value[1]
Sodium aluminum phosphate (anhydrous)	SALP	Medium	110
Sodium aluminum sulfate, $Na_2SO_4 \cdot Al_2(SO_4)_3$	SAS	Slow	100
Monocalcium phosphate (anhydrous), $CaH_4(PO_4)$	MCP	Slow	83
Monocalcium phosphate (monohydrate), $CaH_4(PO_4) \cdot H_2O$	MCP · H_2O	Quite fast	80
Sodium acid pyrophosphate, $Na_2H_2P_2O_7$	SAPP	Medium	72
Glucono-delta-lactone, $C_6H_{10}O_6$	GDL	Slow	55
Potassium acid tartrate, $KHC_4H_4O_6$	—	Medium to fast	50
Dicalcium phosphate dihydrate, $CaHPO_4 \cdot 2H_2O$	DCP	Very slow	33
Sodium aluminum phosphate hydrate	SALP · H_2O	Slow	100

[1] Values in this column indicate the parts of sodium bicarbonate that will be neutralized by 100 parts of the leavening acid under nominal conditions. Values vary with composition of dough.

the product light. These gases escape from the product during the baking process. In selecting a baking powder, one must keep in mind the speed with which the components react at room temperature: alum-containing baking powders act slowly; phosphate baking powders have a medium speed; and tartrate baking powders act quickly to produce carbon dioxide. Hence, when using the latter type, it is necessary to bake quickly after mixing to eliminate the loss of too much gas.

Within the last several years, advantage has been taken of mixing different leavening acids in premixes and household baking powders. Because the use of emulsifiers in most cake mixes reduces the need for early leavening action, it is common practice to use combinations of slow-acting leavening acids that retain much of their leavening reaction for the baking stage. In mixes, the leavening process must be regarded as a system because, in addition to gas generation, the leavening system controls the pH of the finished product and thus affects crumb and crust color, the intensity of flavor, as well as other properties. For various cakes, the optimum pH values are: white cakes, 6.9–7.2; yellow cakes, 7.2–7.5; chocolate or devil's food cakes, 7.1–8.0. Monocalcium phosphate (anhydrous) and sodium aluminum phosphate are frequently used together in white and yellow cake mixes; monocalcium phosphate and sodium acid pyrophosphate or dicalcium phosphate dihydrate are used in chocolate cake mixes. Generally, the combination will be comprised of 10–20% fast-acting leavening acid and 80–90% slow-acting leavening acid.

For pancake and waffle mixes, a common blend of leavening acids is 20–30% monocalcium phosphate monohydrate or monocalcium phosphate (anhydrous), combined with 70–80% sodium aluminum phosphate. A batter of this type can be prepared several hours in advance if retained under refrigeration. It has been observed that such a batter will sour before a serious loss of leavening power occurs.

Prepared biscuit mixes made of flour, shortening, and salt usually contain 30–50% monocalcium phosphate (anhydrous) and 50–70% sodium aluminum phosphate or sodium acid pyrophosphate. Self-rising flours and corn meals usually contain flour or corn meal, salt, soda, and leavening acid. Usually used in these products are combinations of sodium aluminum phosphate and monocalcium phosphate (anhydrous).

Refrigerated doughs available for preparation of biscuits, dinner rolls, and various sweet rolls, usually contain flour, water, shortening, nonfat milk solids (or dried whey solids), sugar (or corn sugar), salt, soda, and a leavening acid. Long-term refrigerated storage requires that only slow-acting leavening acids be used, frequently the sodium acid pyrophosphates. The latter have the disadvantage of possibly producing orthophosphates under certain conditions. The orthophosphates have a rather disagreeable, astringent flavor.

Unleavened Products

The principal unleavened bakery product is pie crust, which is low in moisture and high in fat content. The ingredients and method of preparation prevent the formation of a continuous gluten network through the dough mass. The porosity associated with leavened products is not desirable because the crust literally acts as a container and requires some strength.

LE CHÂTELIER'S PRINCIPLE. Let us perturb a system that is initially in stable equilibrium to a neighboring nonequilibrium state. Since the initial equilibrium is supposed to be stable, the system will return to an equilibrium state.

Theorems governing the behavior of perturbed systems are often known as *theorems of constraint or theorems of moderation*. The best known thermodynamic theorem of moderation is that of Le Châtelier-Braun, which in the form stated by Le Châtelier is:

"Any system in chemical equilibrium undergoes, as a result of a variation in one of the factors governing the equilibrium, a *compensating* change in a direction such that, had this change occurred alone it would have produced a variation of the factor considered in the *opposite direction*."

However, this principle suffers from a number of important exceptions. It is therefore preferable to study the "moderation" starting from the usual thermodynamic formalism without invoking a special principle.

LECITHIN. Lecithin and other phospholipids are of universal occurrence in living organisms. They are constituents of biological membranes and are involved in permeability, oxidative phosphorylation, phagocytosis, and chemical and electrical excitation.

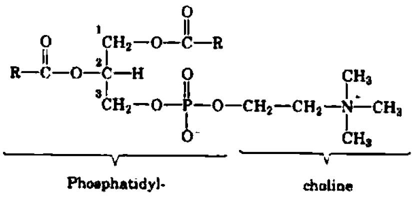
Lecithin is not only used in the strict scientific sense to describe pure phosphatidylcholine (Fig. 1), but also to describe crude phospholipid mixtures containing phosphatidylcholine (PC), phosphatidylethanolamine (PE), phosphatidylinositol (PI), other phospholipids, and a variety of other compounds such as fatty acids, triglycerides, sterols, carbohydrates, and glycolipids. Commercial lecithin is currently available in more than 40 different formulations varying from crude oily extracts from natural sources to purified and synthetic phospholipids. Many of these products are defined according to the stage of the purification process from which they are obtained and fall into three broad categories (Table 1) varying in their constituents both qualitatively and quantitatively.

Industrial lecithins from a variety of sources are utilized. The main sources include vegetable oils (e.g., soybean, cottonseed, corn, sunflower, rapeseed) and animal tissues (egg and bovine brain). However, egg lecithin and in particular soy lecithin are by far the most important in terms of quantities produced, so much so that the term soy lecithin and commercial lecithin are often used synonymously.

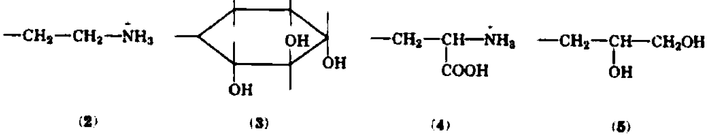
Physical Properties

Commercial crude lecithin is a brown to light yellow fatty substance with a liquid to plastic consistency. Its density is 0.97 g/mL (liquid) and 0.5 g/mL (granule). The color is dependent on its origin, process conditions, and whether it is unbleached, bleached, or filtered. Its consistency is determined chiefly by its oil, free fatty acid, and moisture content. Properly refined lecithin has practically no odor and has a bland taste. It is soluble in aliphatic and aromatic hydrocarbons, including the halogenated hydrocarbons; however, it is only partially soluble in aliphatic alcohols. Pure phosphatidylcholine is soluble in ethanol.

Commercial lecithin is soluble in mineral oils and fatty acids but is practically insoluble in cold vegetable and animal oils. It is insoluble



(1)



(2) (3) (4) (5)

Fig. 1. Chemical structure of phosphatidylcholine (PC) (1) and other related phospholipids. $R-C(=O)-O-$ represents fatty acid residues. The choline fragment may be replaced by other moieties such as ethanolamine (2) to give phosphatidylethanolamine (PE), inositol (3) to give phosphatidylinositol (PI), serine (4), or glycerol (5). If H replaces choline, the compound is phosphatidic acid. The corresponding IUPAC-IUB names are (1), 1,2-diacyl-*sn*-glycero(3)phosphocholine; (2), 1,2-diacyl-*sn*-glycero(3)phosphoethanolamine; (3), 1,2-diacyl-sn-glycero(3)phosphoinositol; (4), 1,2-diacyl-sn-glycero(3)-phospho-L-serine; and (5), 1,2-diacyl-*sn*-glycero(3)phospho(3)-*sn*-glycerol

but infinitely dispersible in water. Commercial lecithin is a wetting and emulsifying agent. Lecithin is one of the very few natural and edible surface-active agents of this type that is soluble or dispersible in oil.

Chemical Properties

In general, the presence of fatty acid groups in the phospholipid molecule permits reactions such as saponification, hydrolysis, hydrogenation, halogenation, sulfonation, phosphorylation, elaidinization, and ozonization.

Manufacture and Processing

Crude soy lecithin is obtained as a by-product during the degumming process of soy oil. Only a minor proportion of the total lecithin that is potentially available in the vegetable processing industry is produced.

Purification Processes

Separation of neutral and polar lipids, so-called deoiling, is the most important fractionation process in lecithin technology. A classic solvent for the deoiling is acetone.

Due to the possible environmental problems with acetone, new technologies are being developed for the production of deoiled lecithins like an ethanol-based extraction and fractionation or a process involving treatment of lipid mixtures with supercritical gases or supercritical gas mixtures.

Commercial Grades

There are six common grades of lecithin available including (*1*) clarified lecithins, (*2*) fluidized lecithins; (*3*) compounded lecithins; (*4*) hydroxylated lecithins; (*5*) deoiled lecithins and (*6*) fractionated lecithins. Fractions with different phosphatidylcholine content are commercially available. Besides these common commercial grades, more special products are available, e.g., enzymatically modified lecithin and phospholipids, semisynthetic phospholipids, and acetylated lecithins.

Economic Aspects

The total commercial lecithin potential if all vegetable oils were degummed worldwide would be 552,000 t. Although soybean, sunflower, and rape lecithins are available in the market, the principal commercial interest is only in soybean lecithin. The annual worldwide production is 130,000 t.

Health and Safety Factors

The phospholipids are biodegradable, but their presence in streams and water resources, especially in the form of soap stock, is undesirable. Fatty acid recovery from phospholipids is less than with neutral oils because of the lower fatty acid content. There are no known health hazards involved in the production of commercial lecithin from crude vegetable oils because the phospholipids are nonvolatile and are a nonirritating food material.

Uses

The worldwide uses of lecithin break down as follows: margarine, 25–30%; baking/chocolate and ice cream, 25–30%; technical products, 10–20%; cosmetics, 3–5%; and pharmaceuticals, 3%.

Cosmetics and Soaps. One to five percent lecithin moisturizes, emulsifies, stabilizes, conditions, and softens when used in products such as skin creams and lotions, shampoos and hair treatment, and liquid and bar soaps. Since the introduction of Capture in 1986, liposomes produced from phospholipids are commercially available worldwide.

Pharmaceuticals. Lecithin and especially purified phosphatidylcholine can act as excipients in pharmaceutical (drug) formulation to enhance and control the bioavailability of the active component. Moreover, phosphalidylcholine can be utilized as a diedelic source, as it involved in the cholesterol metabolism and the metabolism of fats in the liver; also, it can be utilized as a precursor of brain acetylcholine, as neurotransmitter.

LEDUC'S RULE. States that the volume occupied by a gas mixture is equal to the sum of the volumes occupied separately by each constituent at the same temperature and pressure as the mixture.

LEE, YUAN T. (1936–). Awarded the Nobel prize in chemistry in 1986 jointly with John C. Polanyi and Dudley R. Herschbach for their contributions concerning the dynamics of chemical elementary processes. A former student of Herschbach, Lee refined molecular-beam and laser techniques, combining them with theory to perform definitive studies of reactions of individual complex molecules. Lee received his Doctorate from the University of California at Berkeley in 1965.

LEHN, JEAN-MARIE PIERRE (1939–). Awarded the Nobel prize for chemistry, together with Donald J. Cram, in 1987 for work in elucidating mechanisms of molecular recognition, which are fundamental to the enzymic catalysis, regulation, and transport. He also studied three-dimensional cyclic compounds that maintained a rigid structure, accepting substrates in a structurally preorganized cavity. Lehn named these compounds cryptands, while Cram called them cavitands. Awarded Doctorate by the University of Strasbourg, France in 1963.

LELOIR, LUIS F. (1906–1987). A French-born biochemist who won the Nobel prize for chemistry in 1970 for work in biosynthesis of carbohydrates. He discovered chemical compounds that affect the storage of chemical energy in humans and animals. He headed the Department of Biochemistry at the University of Buenos Aires for many years.

LEPIDOLITE. This member of the mica group of minerals is a silicate of potassium, lithium and aluminum, sometimes with sodium, fluorine, or rarely rubidium. A general formula is $K(Li, Al)_3(SiAl)_4O_{10}(F, OH)_2$. Crystals of lepidolite are monoclinic but often pseudo-hexagonal; cleavage, basal and perfect, being susceptible of splitting into thin laminae; hardness, 2.5–4; specific gravity, 2.8–3.3; luster, pearly; color, reddish to violet, grayish-blue, gray to white. A variety carrying rubidium is yellowish-gray; translucent. It usually is found as granular to scaly masses, in short stocky prisms or less often in easily cleavable sheets. Lepidolite is characteristic of pegmatite veins, frequently being associated with other lithium-bearing minerals such as tourmaline, spodumene, amblygonite, and others. It occurs in the Ural Mountains, the Czech Republic and Slovakia, the Island of Elba, and Madagascar, where it is often found in large sheets. In the United States, it is found in the pegmatites of New England, California, South Dakota, and New Mexico. The name lepidolite is derived from the Greek, meaning scale. See also **Lithium**.

LEPTONS. The electron, muon, and two kinds of neutrino are collectively called *leptons*. The leptons are considered to be point-like particles without structure and thus truly elementary. Leptons can interact with other particles through the weak interactions. Electrons and muons also can interact through electromagnetic and gravitational forces, but they appear to be without capability of interaction through the strong (nuclear) forces. The neutral members, the electron neutrino, the muon neutrino, and their antiparticles have extremely weak interaction with matter and do not participate in electromagnetic interactions. Leptons make excellent probes in particle physics experiments. The other major family of subatomic particles is referred to as *hadrons*. See also **Electron**; **Muon**; **Neutrino**; and **Particles (Subatomic)**.

The name *lepton* from its derivation means "light," referring to the fact that the masses of the leptons are all lighter than that of the lightest meson. The properties of the electron are discussed in that entry; here it will merely be noted that the term *electron* is used to denote the negative electron (often called the "negatron" when ambiguity might arise). Its antiparticle is the positron (also called positive electron).

LEUCITE. The mineral leucite is a metasilicate of potassium and aluminum corresponding to the formula $KAlSi_2O_6$. It is isometric at a temperature of about 600°C (1112°F) and pseudoisometric at lower temperatures, at which leucite is tetragonal but retains an external isometric crystal form, usually trapezohedral. It has a conchoidal fracture; is brittle;

hardness, 5.5–6; specific gravity, 2.47–2.50; luster, vitreous; color, white or some shade of gray; translucent to opaque. It is commonly found in the more recent lavas of high alkali content. Leucite is seldom reported from plutonic rock types. It is a relatively rare mineral. It is found plentifully at Vesuvius and Monte Somma and elsewhere in Italy, and Germany in the Tertiary volcanic district of the Eifel. In the United States, leucite has been found in the Leucite Hills of Wyoming, the Highwood Mountains of Montana, and as pseudomorphs (pseudoleucites) representing a mixture of nepheline, orthoclase, analcime, and aegerine from New Jersey, Arkansas, and Montana. Its name is derived from the Greek word leukos, referring to its white color.

LEVENE-HUDSON PHENYLHYDRAZIDE RULE. The direction of rotation of the phenylhydrazides of the sugar acids indicates the configuration of the hydroxyl on the α-carbon atom. If the phenylhydrazide rotates to the right, the hydroxyl on the α-carbon is to the right, and vice-versa. The rule was shown to be valid for salts, amides, and corresponding acylated nitriles. In connection with the rule, Hudson mentioned that, "the sugar benzylphenylhydrazones rotate to the left when the asymmetric α-carbon atom of the configuration has its hydroxyl to the right, and vice-versa."

LEVOROTATORY COMPOUNDS. Having the property when in solution of rotating the plane of polarized light to the left or counterclockwise. Levorotatory compounds may have the prefix *l*-to distinguish them from their dextrorotatory or *d*-isomers, but the minus sign (−) is preferred.

See also **Asymmetry (Chemical)**; **Isomerism**.

LEWIS ACID. Any molecule or ion (called and electrophile) that can combine with another molecule or ion by forming a covalent bond with two electrons from the second molecule or ion. An acid is thus an electron acceptor. Hydrogen ion (proton) is the simplest substance that will do this, but many compounds such as boron trifluoride, BF_3, and aluminum chloride, $AlCl_3$, exhibit the same behavior and are therefore properly called acids. Such substances show acid effects on indicator colors and when dissolved in the proper solvents.

LEWIS BASE. A substance that forms a covalent bond by donating a pair of electrons, neutralization resulting from reaction between the base and the acid with formation of a coordinate covalent bond. It is also called a nucleophile.

See also **Lewis Electron Theory**.

LEWIS ELECTRON THEORY. A theory involving acid and base formation, neutralization, and related phenomena on the basis of exchange of electrons between substances and the formation of coordinate bonds. It represented an important advance in chemical theory, largely replacing earlier concepts. Advanced in 1923 by Gilbert N. Lewis, it contributed much to the development of coordination chemistry in which the base is represented by the ligand and the acid by the metal ion.

LEWIS, GILBERT N. (1875–1946). An American chemist, native of Massachusetts, professor of chemistry at MIT from 1905 to 1912 after which he became dean of chemistry at the University of California at Berkeley. His most creative contribution was the electron-pair theory of acids and bases, which laid the groundwork for coordination chemistry. He was also a leading authority on thermodynamics.

LEWIS, WARREN P. (1882–1974). Born in Laurel, Maryland, graduated from MIT in 1905, and received is Ph.D. from the University of Breslau, Germany in 1908. He became professor of chemical engineering at MIT in 1910. He is often regarded as the "father" of chemical engineering in the U.S., as his outstanding books and other publications did much to establish the fundamental principles of this field.

LEYDEN TEMPERATURE SCALE. A low-temperature thermometer scale based on a boiling point of hydrogen equal to −252.74°C and of Oxygen equal to −182.95°C.

LIBBY, WILLARD P. (1908–1980). An American chemist, famous for his role in the development of radiocarbon dating, a process which revolutionized archaeology.

After the start of World War II he worked on the Manhattan Project at Columbia University with Nobel laureate Harold Urey. Libby was responsible for the gaseous diffusion separation and enrichment of Uranium-235 which was used in the atomic bomb on Hiroshima.

In 1945 he became a professor at the University of Chicago. In 1954, he was appointed to the U.S. Atomic Energy Commission, and in 1959, he became Professor of Chemistry at University of California, Berkeley, a position he held until his retirement in 1976. He also started the first Environmental Engineering program at UCLA in 1972.

Libby won the Nobel prize for chemistry in 1960, for his method to use carbon-14 for age determination in archaeology, geology, geophysics, and other branches of science.

LIEBIG, JUSTUS Von (1803–1873). A German chemist who founded the *Annalen*, a world-famous chemical journal. He was a great teacher of chemistry, training such men as Hofmann, August Whilhelm, who did basic work on organic dyes. Liebig contributed original research in the fields of human physiology, plant life, soil chemistry, and was first to discover chloroform, chloral, and cyanogen compounds. He was the first to recommend the addition of nutrients to soils and thus may be considered the originator of the fertilizer industry.

LIFE, ORIGIN (Biogenesis). The succession of chemical events that led up to the appearance of living organisms on earth about 3.3 billion years ago. According to one theory, substantiated by experimental evidence, this occurred as follows. The inorganic compounds originally present were carbides, water, ammonia, and carbon dioxide. The carbides reacted with water to form methane, which in turn reacted with ammonia and water vapor as a result of an electric impulse to form amino acids, porphyrins, and nucleotides (or their precursors). All these compounds have been created artificially in the laboratory. It has further been shown that amino acids and nucleotides can be concentrated into proteins (and probably nucleic acids) by the action of zinc-bearing clays, which were present along the shores of the primeval oceans. Little or no free oxygen existed in the primordial atmosphere, which consisted chiefly of reducing gases. The complex chemical reactions that eventually resulted in the formation of DNA took place in an anaerobic aqueous environment, and the earliest living organisms developed in a nutrient solution in which free oxygen finally appeared as the result of photosynthesis by blue-green bacteria. Another theory advances the idea that essential life chemicals such as purines and amino acids were formed under primitive conditions from aqueous solutions of hydrogen cyanide. Both of these theories are based on research carried out by highly competent biochemists.

LIGAND. Any atom, radical, ion, or molecule in a complex (poly-atomic group) which is bound to the central atom. Thus, the ammonia molecules in $[Co(NH_3)_6]^{3+}$, and the chlorine atoms in $[PtCl_6]^{2-}$ are ligands. Ligands are also complexing agents, as for example, EDTA, ammonia, etc. See also **Chelates and Chelation**.

Ligand field theory incorporates elements from the valence bond theory of Pauling and the molecular orbital method of Hund, Mullikan, and others. As pointed out by Mortimer, the chemists of the late nineteenth century had difficulty in understanding how "molecular compounds" or "compounds of higher order" are bonded. The formation of a compound such as $CoCl_3 \cdot 6NH_3$, was baffling, particularly in this case since simple $CoCl_3$ does not exist. In 1893, Alfred Werner proposed a theory to account for compounds of this type. Werner wrote the formula of the cobalt compound as $[Co(NH_3)_6]Cl_3$. Werner assumed that the six ammonia molecules are symmetrically coordinated to the central cobalt atom by "subsidiary valencies" of cobalt, while the "principal valencies" of cobalt are satisfied by the chloride ions. Werner devoted over 20 years preparing and studying coordination compounds and perfecting and proving his theory. Although modern work has amplified his theory, it has required relatively little modification.

In ligand field theory, one is concerned with the origin and the consequences of splitting the inner orbitals of the central metal by the surrounding ligands. The most satisfactory correlations have been demonstrated with the first transition series, in which the $3d$-orbitals are split into different energy levels. To appreciate the effect of a ligand field, imagine that a symmetrical group of ligands is brought up to a charged ion from a distance. First, the electrostatic repulsions between the ligand electrons and those in the d-orbitals of the metal will raise the energy of

all five d-orbitals equally. Then, as the ligands approach to within bonding distances, the repulsion interactions will take on a directional character that will vary with the particular d-orbitals under consideration. This arises because of the different shapes and orientations of the five d-orbitals in space along a Cartesian coordinate system. The splitting of the orbitals for a given central metal ion is dependent on the set of ligands.

Applications of ligand field theory to many transition metal complexes have played an important role in the interpretation of visible absorption spectra, magnetism, luminescence, and paramagnetic resonance spectra.

LIGNIN. Approximately 25% of the content of most woods is lignin. Lignin concentration in wood substance is greatest in the middle lamella (the zone around each individual fiber cell), decreasing in concentration through the cross section of the fiber, reaching a concentration of about 12% at the inner layer of the fiber adjacent to the fiber cavity, or lumen. Lignin and hemicellulose cement the fiber cells together, providing rigidity to the fibrous wood structure. In the destructive distillation of wood, the methanol produced is derived from the lignin. In the manufacture of paper pulp, it is necessary to remove the lignin, usually accomplished by treatment of the wood fibers with such agents as sulfur dioxide, calcium bisulfite, and sodium sulfate/sodium sulfide solutions. Sodium hydroxide is sometimes used. An important byproduct of the paper pulp industry is dimethyl sulfoxide, $(CH_3)_2SO$ which is produced from the lignin released during wood pulping by the Kraft process. Dimethyl sulfoxide has a number of industrial uses—as an intermediate in organic syntheses, as a solvent in spinning synthetic fibers, and in some pharmaceuticals.

The wall material of plant cells is one of their distinguishing characteristics. As a result, lignin, cellulose, and other wall constituents have been studied in many plant tissue cultures. Phenylpropanoids, for example, have been shown to be precursors of lignin formation in white pine, *Sequoia*, lilac, rose, carrot, and geranium tissue cultures. Moreover, the biosynthesis of lignin has been shown to be affected by kinetin, boron, and major elements, such as calcium.

Lignin is a major source of vanillin.

LIGNITE AND BROWN COAL. Lignite and brown coal are common names for coals having properties intermediate between peat and bituminous coal as a result of limited coalification. In general, brown coal designates a geologically younger, i.e., less coalified, material than the firmer, fibrous lignite. In many English-speaking countries, the consolidated coals are termed *lignite*. In many English-speaking countries, the consolidated coals are termed lignite, and unconsolidated coals are termed brown coal. In Australia, and in Germany and a number of other European countries, the generic term brown coal is used for the whole class, including some coals that are included in the ASTM classification as subbituminous. Lignite signifies the firmer, fibrous, woody variety. Herein lignite is used as the comprehensive term.

Selection of coal for a particular use requires a knowledge of composition greater than that supplied from the ASTM classification. Progress is being made toward classifying all kinds of coal, including lignite, by correlating properties with composition and other qualities.

Lignite is less valuable than coals of higher rank, primarily because its much higher (30–70% as mined) water content and high chemically combined oxygen content result in a relatively low heating value (LHV). In the past, the expense of shipping limited the market largely to the vicinity of the mine. However, in the United States the low sulfur content of lignite has made long distance shipments economically feasible, in order to limit sulfur oxide emissions at electric power generation plants. The increasing worldwide demand for energy together with desire for national self-sufficiency has increased the importance of low heating value coals.

Geology

Lignite was deposited relatively recently (ca 2.5–60 × 10^6 yr ago), mainly during the Tertiary era. U.S. deposits include those in the Dakotas, Alaska, Montana, and Wyoming. The Miocene period provided the brown coal deposits that are up to 300 m thick in the Latrobe Valley of Victory in Australia.

Composition, Properties, and Analysis

Macroscopic Appearance. Lignitic coals vary from brown to dull black when moist, although the color may appear considerably lighter when the coal is dried. Breakage is easiest for the unconsolidated coals. Strength and toughness increase as coalification increases.

Physicochemical Structure. Water-filled pores and capillaries of differing diameters permeate the organic gel material that makes up asmined lignite.

Properties. The apparent density of lignite is 0.8–1.35 g/cm^3, which is lower than values given for higher ranking coals. Therefore, greater volume is required for storage, transportation, and lignite reactors than is needed for an equivalent weight of more mature coals. Lignite generally has lower elasticity and greater plasticity than more mature coals. The tar yield is usually higher for lignite than for more mature coals. Tar yields are important in determining selection for carbonization and for liquid fuel production by pyrolysis.

Oxidation. The high reactivity of lignites with oxygen requires special care during mining, transportation, and storage to avoid spontaneous combustion from heat generation.

Resources and Production

The importance of a coal deposit depends on the amount that is economically recoverable by conventional mining techniques. The world total recoverable reserves of lignitic coals were 3.28 × 10^{11} metric tons at the end of 1990, of which ca 47% was economically recoverable as of 1992. These estimates of reserves change as geological survey data improve and as the resources are developed.

The extent of lignite production is generally not proportional either to total resources or to known economic reserves. Lack of energy alternatives is a strong motive to developments in lignite production.

Main Deposits and Production Areas. The eastern European reserves of lignitic coals provide the primary solid fuel for the eastern part of Germany, the former Czechoslovakia, Hungary, the former Yugoslavia, and Bulgaria. The importance of lignite as an energy source is great enough in Germany to permit long-range planning that includes removal and relocation of towns or villages situated on deposits in order to permit more complete recovery of the lignite resource. Hard coal is more important in most of the western European countries, with the exception of Austria and Italy.

In the U.S., lignite deposits are located in the northern Great Plains and in the Gulf states. Subbituminous coal is found along the Rocky Mountains. The lignite deposits of North Dakota and Montana extend into Canada as far as Saskatchewan. Canadian deposits are also located in Alberta, Yukon, the Northwest Territories, Ontario, and Manitoba.

Production. The mining or winning of lignitic coal typically involves deposits near the surface. The open-cast, open-cut, or stripmining techniques employed involve mobile equipment built to provide a range of capacities to over 200,000 m^3/d. The rate of production can be increased rapidly, and the amount of labor per ton of coal mined is less than for underground mining. The quality of the coal, ratio of overburden thickness to seam thickness, stratigraphy, and distance to location of consumption are important in determining the cost to the consumer.

Concern about spontaneous ignition has led some operators to try to match the mining and consumption rates, so that there is little if any reserve, as in minemouth power generation stations. When the coal must be stockpiled, careful stacking minimizes oxygen reaction and overheating. To limit drying, spraying with cold water is useful.

For short distances from the mine, transportation is by truck or conveyer belt. Rail transportation is generally used for greater distances. Slurry pipelines are being considered as an alternative. Drying can be accomplished by evaporative, hydrothermal, or other thermal processes.

Health and Safety Factors

The principal hazards involve the tendency of the coal toward spontaneous combustion as the coal dries, especially at the exposed seam.

Economic Aspects

The price of lignite per mined ton or per heat unit is lower than that for higher rank coals. The market for all coals is primarily as boiler fuel for electric power production. Prices are generally established by contracts between utility and supplier before mining begins. Because of its sulfur content, lignite is becoming more important.

Uses

Most of the world's coal supply is used for combustion to generate steam for electric power production. This is especially true of lignitic coals. Other uses for lignite, such as briquetting, for domestic and industrial fuels; carbonization, to provide coke and liquid by-products; gasification, to provide gaseous fuels; chemical feedstocks, for making fertilizers and other liquid fuels; and direct liquefaction are being developed.

LIME AND LIMESTONE. The term *lime* includes a variety of chemicals manufactured from limestone or derived from chemical processes that utilize calcium compounds. According to the composition of the parent limestone, lime may be designated as *high calcium lime* or *dolomitic lime*. Both *quicklimes*, CaO and CaO · MgO, and *hydrated limes*, CaO · H_2O, $Ca(OH)_2$ · MgO, and CaO · MgO · $2H_2O$, are conventionally called lime. Precise terminology requires complex wording, e.g., *dolomitic quicklime* to denote CaO · MgO. The various lime oxides and hydroxides are among the lowest-cost and most widely used sources of alkali for the chemical and metallurgical industries. About 80% of the lime used in the United States is used by the chemical and related industries, mostly as quicklime. About 10% is dead-burned dolomite, and less than 10% goes into construction uses, mostly as hydrate. Very little lime is imported into or exported by the United States.

Limestone

[CAS: 1317-65-3]. This is a rock containing chiefly calcium carbonate and variable quantities of magnesium carbonate. Limestone is classified along the lines of lime as previously mentioned. *High-calcium limestone* contains 5% or less of $MgCO_3$ and occurs in two mineral forms, calcite and aragonite. See also **Aragonite**; and **Calcite**. *Dolomitic limestone* usually contains over 35% $MgCO_3$, with the remainder $CaCO_3$. See also Dolomite. *Magnesian limestone* is predominantly $CaCO_3$, but contains from 5 to 35% $MgCO_3$. All limestones evolve carbon dioxide and bubble in dilute hydrochloric acid. Dolomite reacts only with dilute HCl, while calcite will decompose in cold dilute HCl.

Limestones vary greatly in color and texture, the latter ranging from dense and hard limestone, e.g., marble or travertine, which can be sawed and polished, to soft, friable forms, e.g., chalk and marl. Chalk is a very fine-grained white limestone, while marl is an impure deposition product that contains clay and sand. Texture, hardness, and porosity appear to be functions of the degree of cementation and consolidation during the formation of these materials. Color variations arise from the presence of impurities. Some impurities, such as sulfur and phosphorus, make limestone unattractive for metallurgical uses.

A high percentage of all limestone is quarried; the balance is mined underground. Although limestone occurs widely, good chemical- and metallurgical-grade limestone is less plentiful. Along the seacoasts, oyster or clam shells are dredged as a source of $CaCO_3$. Limestone is normally processed through a series of crushing, screening, and grinding operations. Because of transportation costs, the proximity of limestone sources to points of use is highly desirable. The major uses of limestone are in construction (asphalt filler, road stone, riprap, and bituminous aggregate); in Portland cement; in agriculture; and in metallurgy.

Precipitated $CaCO_3$ is produced in a number of chemical processes. Sometimes it is economical to dry and calcine the byproduct to regenerate CaO or $Ca(OH)_2$. Some precipitated $CaCO_3$ is made to specific particle size and shape, whiteness, and purity for use as functional filler for paper coatings, paint, and polymers. These products command a premium price as compared with pulverized limestone fillers.

Manufacture of Lime

The basic processes are calcination and hydration. Commencing with high-calcium limestone, the reactions are:

$$CaCO_3 + \text{heat} \rightleftharpoons CaO + CO_2 \qquad (1)$$

$$CaO + H_2O \rightleftharpoons Ca(OH)_2 + \text{Heat} \qquad (2)$$

If dolomitic limestone is used, the reactions are:

$$CaCO_3 \cdot MgCO_3 + \text{heat} \rightleftharpoons CaO \cdot MgO + 2\,CO_2 \qquad (3)$$

$$CaO \cdot MgO + H_2O_{(liq)} \rightleftharpoons Ca(OH)_2 \cdot MgO + \text{heat} \qquad (4a)$$

or

$$CaO \cdot MgO + 2\,H_2O_{(gas)} + \text{pres} \rightleftharpoons Ca(OH)_2 \cdot Mg(OH)_2 + \text{heat} \qquad (4b)$$

High-calcium limestone dissociates at 900°C (1650°F) in 100% carbon dioxide atmosphere at 1 atm pressure. Under similar conditions, dolomitic limestone dissociates over 727–900°C (1340–1650°F). The heat of reaction required to convert $CaCO_3$ to CaO is about 2.8 million Btu per ton (0.64 million kg-Cal/metric ton) of CaO. In practice, heat input may vary from 4 to 10 million Btu/ton (0.9 to 2.3 million kg-Cal/metric ton) of lime. Calcination of limestone particles proceeds by a receding-surface mechanism. To attain reasonable rates of heat transfer into the center of the rock or pebble-sized stone, operating temperatures in lime kilns are 980–1260°C (1800–2300°F). Reaction rate is increased and opportunity for recarbonation of the oxide is decreased by rapid removal of CO_2 from the kiln.

Except for very old mixed-feed vertical kilns, lime kilns operate with countercurrent flow of raw material and heat. Modern lime kilns utilize coolers to preheat air by recuperating heat from the hot quicklime. Lime kilns may be fired directly with coal, oil, or gas.

Two major types of lime calciners are the rotary (Fig. 1) and the vertical kiln. In North America, rotary kilns are widely used for lime calcination, whereas in Europe vertical kilns are most popular. Rotary kilns typically have higher output [up to 600 tons (545 metric tons)/day] and lower labor cost. Vertical kilns can be designed for higher fuel efficiency and lower capital investment. They handle down to about ¾-in. (19-cm) stone, but

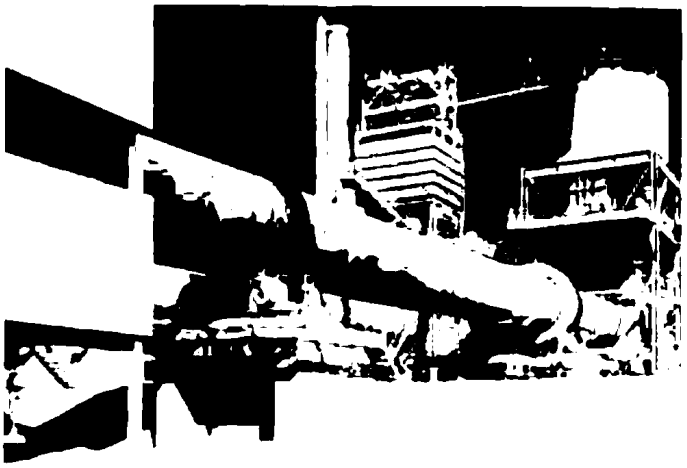

Fig. 1. Large rotary lime kiln designed to operate 24 hours per day year around. Rugged construction is required for handling abrasive limestone rock at very high temperature

normally the rock feed is at least 3 × 6 in. (7.5 × 15 cm). Rotary kilns can handle down to $\frac{1}{4}$-in. (0.6 cm) stone.

The long-established use of lime is as a structural material in masonry mortars, wall plasters, sand-lime brick, and for soil stabilization. Double-hydrated dolomitic lime or specially processed high-calcium lime mixed with gypsum plaster is troweled on interior walls or ceilings to provide a hard, white, finished surface. It is mixed with cement and sand to make exterior plaster or stucco. Mason's mortar used to lay up bricks or blocks usually contains lime. Lime provides plasticity, water retention, and easy troweling. Sand-lime bricks are more popular in Europe than in the United States. About 10% hydrated lime is mixed with graded sand and water, pressed into shape, and put into autoclaves for 4–8 hours at 150–205°C (300–400°F). The reaction product, calcium silicate, results in a strong, white brick. Dead-burned dolomite, formed by calcining dolomite at about 1650°C (3000°F) to convert MgO to periclase, is used as a *refractory*. Lime is used in the sulfate process for making paper. In the seawater process for producing magnesium metal, lime reacts with $MgCl_2$ to precipitate $Mg(OH)_2$. Calcium metal is made from lime by reducing CaO with coke. In water treatment, hydrated lime can be added to remove temporary hardness, or in the lime-soda process to remove permanent hardness. Dolomitic lime removes silica from boiler feedwater due to silica absorption by $Mg(OH)_2$. For acid neutralization of industrial wastes, lime is widely used.

LIMONITE. The mineral limonite, hydrated oxide of iron, corresponds to the formula $Fe_2O_3 \cdot nH_2O$, but is often very impure due to the admixture of sand and clay. It is not found crystallized but grades from loose porous material to compact masses. Its hardness is variable but pure material is 5–5.5; specific gravity 3.6–4; usual luster, dull to earthy but may be silky to submetallic; color, various shades of yellowish-brown, sometimes nearly black; streak, yellowish-brown; opaque. Limonite is a secondary mineral from the alteration of various other iron-bearing ores or minerals; it is of widespread occurrence and used both as an ore of iron and as a pigment. Limonite has been formed in marshy and boggy areas and is frequently called bog iron ore. Limonite is an important ore of iron in Lorraine, Luxemburg, Bavaria and Sweden. It is found in Saxony, Austria and England. In the United States, limonite is found particularly in Connecticut, Massachusetts, Pennsylvania, New York, Virginia, Tennessee, Georgia and Alabama, but these deposits are of little economic importance at the present time.

LINOLEIC ACID. [CAS: 60-33-3]. Also called linoleic acid, formula $CH_3(CH_2)_4$ HC:CHCH$_2$CH:CH(CH$_2$)$_7$COOH. This is a polyunsaturated fatty acid (two double bonds) existing in both conjugated and unconjugated forms. It is a plant glyceride essential to the human diet. It is found in linseed oil, safflower oil, and tall oil. See also **Vegetable Oils (Edible)**. At room temperature linoleic acid is a colorless to straw-colored liquid. Specific gravity 0.905 (15/4°C); mp −5°C; bp 228°C (at 14 millimeters pressure). Insoluble in water; soluble in most organic solvents. Combustible. Sources are the oils previously mentioned. Linoleic acid is used in soaps; special driers for protective coatings; emulsifying agents; pharmaceuticals; livestock feeds; and margarine.

LINOLENIC ACID. [CAS: 463-40-1]. Also called 9,12,15-octadecatrienoic acid, formula $CH_3CH_2CH{:}CHCH_2CH{:}CHCH_2CH{:}CH(CH_2)_7COOH$. This is a polyunsaturated fatty acid (three double bonds). It occurs as the glyceride in many seed fats. It is an essential fatty acid in the diet. See also **Vegetable Oils (Edible)**. At room temperature, linolenic acid is a colorless liquid; soluble in most organic solvents; insoluble in water. Specific gravity 0.916 (20/4°C); mp −11°C; bp 230°C. Combustible. Linolenic acid finds use in various pharmaceuticals and drying oils.

LIPIDS. A heterogenous group of substances which occur ubiquitously in biological materials. They may be categorized as a group by their extractability in nonpolar organic solvents, such as chloroform, carbon tetrachloride, benzene, ether, carbon disulfide, and petroleum ether. Structural types within the group range from simple, straight-chain hydrocarbon molecules to complex ring structures with varying side chains. A useful classification of the lipids is: (1) fatty acids; (2) neutral fats; (3) phosphatides; (4) glycolipids; (5) aliphatic alcohols and waxes; (6) terpenes; and (7) steroids. See also **Steroids**.

Many lipids, especially the phospholipids, have a strong tendency to form complexes with each other and with various substances. Complex formation is due to the electrostatic attraction of polar groups and to the mutual solubility of the long hydrocarbon chains. Thus, the lipoproteins and proteolipids are complexes of proteins and a variety of lipids, such as cholesterol, phospholipids, glycerides, and glycolipids. The lipids are linked to the proteins by several types of forces. Electrostatic forces, Van der Waals forces, hydrogen bonding, and hydrophobic bonding hold these complexes together. Because of their attraction for water, the polar groups of the protein and phospholipid arrange themselves on the outside of the complex, while the hydrocarbon groups of the lipids are folded into the center. Thus, there is presented to the aqueous phase those groups which have an affinity for water. This arrangement accounts for the solubility of the complexes in water. The phospholipids, owing to their polar groups, act as water solubilizers for the nonpolar lipids. The arrangement may be different in the proteolipids of the brain and nerves, since they are not soluble in water. In these complexes, the lipids may completely envelop the protein.

Knowledge of lipid metabolism has increased at an accelerated rate during the past few decades. The detailed biochemical reactions whereby the fatty acids are synthesized and oxidized; how phospholipids, glycolipids, and cholesterol are synthesized; and how lipids are absorbed and transported have been elucidated. Fatty acids are synthesized from acetyl coenzyme A and malonyl coenzyme A thiol esters. The vitamin biotin plays a vital part in the fixing of carbon dioxide to form malonyl coenzyme A, an important intermediate in fatty acid synthesis. The hormone insulin also favors fatty acid synthesis. The oxidation of fatty acids occurs as their coenzyme A esters in the Krebs cycle of the mitochondria. Cholesterol is biosynthesized from acetyl coenzyme A. Cholesterol in humans is converted to bile acids, fecal sterols, and to steroid hormones. The synthesis of lecithin is mediated via phosphatidic acid and diglyceride precursors. Cytidine nucleotides play a role in the transfer of choline (as phosphorylcholine) to a diglyceride to form lecithin. Uridine nucleotides act to transfer sugar residues in the synthesis of glycolipids.

The transport of lipids in the blood plasma is effected by complex formation with proteins to yield lipoproteins. The liver is the major organ for the synthesis of the lipoproteins. Analysis of serum lipoprotein patterns is important in the understanding of vascular disease (atherosclerosis). The clearing of lipemic blood, such as may occur after a heavy fat meal, is brought about by enzyme known as lipoprotein lipase. This enzyme yields free fatty acids which combine immediately with the plasma albumin to form complexes known as NEFA (nonesterified fatty acids). NEFA act as important transport vehicles for transport of triglycerides and the levels of blood NEFA are very sensitive to hormonal control and neural control. Certain hormones, such as epinephrine, stimulate the membrane-bound adenyl cyclase which converts ATP (adenosine triphosphate) to cyclic AMP (adenosine monophosphate). The latter stimulates adipose tissue lipase and mobilizes depot fat.

The excess utilization of lipids and excess oxidation of fatty acids causes an increase in acetoacetic acid in the body. This condition is known as *ketosis* and can lead to *acidosis*. This situation is common in severe diabetes and can occur whenever carbohydrate utilization is severely decreased.

Research continues in an effort to gain a more thorough understanding of how lipoproteins are synthesized; how lipids are arranged and combined with proteins to form cell membranes; what specific role lipids play in transport across cell membranes; how hormones act to regulate lipid metabolism; the biochemical basis of such abnormal lipid metabolic states as Gaucher's disease, Niemann-Pick's disease, etc.; how lipids per se permeate cell membranes; and how many phenotypic lipoproteins occur in serum.

LIPMANN, FRITZ (1899–1986). A German-born biochemist who won the Nobel Prize in 1953 for the discovery of coenzyme A (CoA). He earned doctorates at the University of Berlin in both chemistry and medicine. He worked at Cornell and Harvard Universities. He founded the biochemistry department of Brandeis University and later joined the faculty of Rockfeller University.

LIPSCOMB, WILLIAM N. (1919–). An American chemist who won the Nobel prize for chemistry in 1976 for his studies on the structure and bonding mechanisms of boranes. Much of the research concerned structure and function of enzymes and natural products in organic and theoretical chemistry. He studied at the Universities of Kentucky, California, and Minnesota.

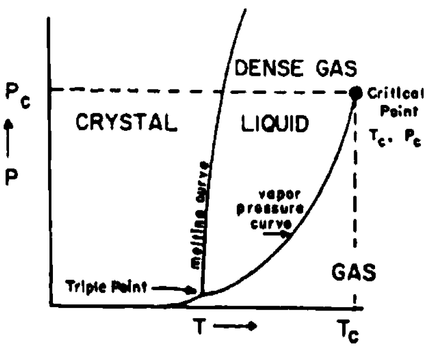
LIQUATION. 1. The separation of two or more compounds of a mixture by heating to a temperature at which one component melts, leaving the others as solids.

2. The separation of a more readily fusible substance from a less fusible one by controlled heating.

LIQUID. Matter in a fluid state but relatively incompressible. An ideal liquid offers no permanent resistance to a shear stress but is incompressible. It has then a constant volume and incompletely fills any container of less than this volume. A real liquid is appreciably compressible, and the liquid state of a substance might be defined as the denser, and less compressible, phase of the two-phase fluid system which can exist in equilibrium at temperatures below the critical temperature. X-ray diffraction experiments show that, near the melting-point, the molecules of a liquid show a considerable degree of short-range order and that, in small volumes, they are arranged much as in a solid crystal. This crystalline structure persists over volumes comparable with the intermolecular distances, but cannot be traced beyond. This local or short-range order means that the average molecule is at any moment surrounded by a number of molecules occupying nearly the same relative positions as they would in the solid state. The degree of short-range order is described by the radial distribution function.

This concept of a liquid as an imperfect crystal requires that the molecules in a liquid are packed sufficiently loosely for comparatively free movement, i.e., the energy required to move a molecule from a lattice site to a vacant space is not large compared with thermal energies. Under these conditions, shear flow of the liquid resembles closely the high temperature creep of crystalline solids. A number of theories of the liquid state have this concept as their starting point.

With a few exceptions, including helium, the accompanying universal phase diagram applies for all pure compounds. The triple point is the single point at which all three phases (crystal, liquid, and gas) are in equilibrium. The triple point pressure is normally below atmospheric. Those substances, such as carbon dioxide, where $P_t = 3.885$ millimeters, $T_t = -56.6°C$, sublime without melting at atmospheric pressure. From the triple point, the melting curve defines the equilibrium between crystal and liquid, usually rising with small but positive dT/dP, and presumably always with positive dT/dP at sufficiently high P values. The line is



Universal phase diagram.

believed to extend infinitely without a critical point (it has been followed to $T \cong 16T_c$ for helium, and calculations indicate that hard spheres would show a gas-crystal phase change). The gas-liquid equilibrium line, the vapor pressure curve, has dT/dP always positive and greater than the melting curve. The vapor pressure curve always ends at a critical point, $P = P_c, T = T_c$, above which the liquid and gas phase are no longer distinguishable. Since the liquid can be continuously converted into the gas phase without discontinuous change of properties by any path in the $P - T$ diagram passing above the critical point, there is no definite boundary between liquid and gas. Two liquids of similar molecules are usually soluble in all proportions, but very low solubility is sufficiently common to permit the demonstration of as many as seven separate liquid phases in equilibrium at one temperature and pressure (mercury, gallium, phosphorus, perfluoro-kerosene, water, aniline, and heptane at 50°C, 1 atmosphere).

LIQUID CHROMATOGRAPHY. An analytical method based on separation of the components of a mixture in solution by selective adsorption. All systems include a moving solvent, a means of producing solvent motion (such as gravity or a pump), a means of sample introduction, a fractionating column, and a detector. Innovations in functional systems provide the analytical capability for operating in three separation modes: (1) liquid–liquid: partition in which separations depend on relative solubilities of sample components in two immiscible solvents (one of which is usually water); (2) liquid–solid: adsorption where the differences in polarities of sample components and their relative adsorption on an active surface determine the degree of separation; (3) molecular size separations which depend on the effective molecular size of sample components in solution.

Solvents, often referred to as carriers, include isooctane, methyl ethyl ketone, acetone/chloroform, tetrahydrofuran, hexane, and toluene.

Packing materials in columns of various lengths include silica gel, alumina, glass beads, polystyrene gel, and ion exchange resins.

High-performance liquid chromatography (HPLC) is the term applied to new and more effective instrumental techniques developed in recent years that have greatly increased the scope of this analytical method. It can now be applied to biological as well as chemical research. Among the separations possible are peptides (by reverse phase chromatography), proteins and enzymes (hydrophobic and size exclusion modes of chromatography), amino acids, and inorganic and organometallic compounds (neutral species, including, clusters, by adsorption and size exclusion, and ionic species including coordination compounds). A comparatively recent development is the use of supercritical fluids as solvents, e.g., carbon dioxide and sulfur hexafluoride.

LIQUID CRYSTALLINE MATERIALS. Liquid crystals represent a state of matter with physical properties normally associated with both solids and liquids. Liquid crystals are fluid in that the molecules are free to diffuse about, endowing the substance with the flow properties of a fluid. As the molecules diffuse, however, a small degree of long-range orientational and sometimes positional order is maintained, causing the substance to be anisotropic as is typical of solids. Therefore, liquid crystals are anisotropic fluids and thus a fourth phase of matter. There are many liquid crystal phases, each exhibiting different forms of orientational and positional order, but in most cases these phases are thermodynamically stable for temperature ranges between the solid and isotropic liquid phases. Liquid crystallinity is also referred to as mesomorphism.

Many thousands of organic substances, some rigid-rod polymers, and other macromolecules exhibit liquid crystallinity. The general common molecular feature is either an elongated or flattened, somewhat inflexible molecular framework, which is usually depicted as either a cigar- or disk-shaped entity. The orientational and positional order in a liquid-crystal phase is only partial, with the intermolecular forces striking a very delicate balance involving both attractive and repulsive interactions. As a result, liquid crystals are extraordinarily sensitive to external perturbations, e.g., temperature, pressure, electric and magnetic fields, shearing stress, or foreign vapors. For this reason, liquid crystals are used to design practical devices to either monitor ambient changes of various kinds or to transduce an environmental fluctuation into a useful electrical or optical output.

Besides being used in the scientific study of cooperative phenomena and complex fluid phases, liquid crystalline phenomena have received a good deal of attention due to the possibility of practical applications. Liquid crystals are widely used in electrooptic displays. Other applications include radiation and pressure sensors, optical switches and shutters, and thermography. The liquid crystalline structures formed by amphiphilic molecules form the basis for emulsions and are studied thoroughly by researchers in the food, drug, and oil industries. Polymers that form an anisotropic fluid phase are important in the fabrication of lightweight, ultrahigh strength, and temperature-resistant fibers, and are beginning to be used in electrooptic displays. Liquid crystals also appear to play an important role in the structure and biochemical function of living tissue, where the characteristic combination of order and flow mobility is particularly suited to life processes. Certain disease states, e.g., atherosclerosis, sickle cell anemia, or cancer, may be associated with physical changes in the liquid-crystalline order within biological structures.

Orientational and Positional Order in Fluids

Solids of mesogenic (liquid-crystal forming) molecules melt to form fluids in which some of the long-range molecular order is retained. At the simplest level, the elongation or flattening of the mesogenic molecules prevents the immediate dissolution of the parent, solid-state order. The loss of positional order of the centers of mass of the molecules in the parent solid may be either partial or complete upon melting, but some degree of orientational order is always retained. The fluid retains many solid-like properties, which are finally eliminated when the substance passes into the normal, isotropic liquid phase at a higher temperature (a second melting point). Solid-like features return if the substance is cooled from the isotropic state; this intermediate state is usually thermodynamically reversible, but in some cases it only forms upon cooling. Partial dissolution of solid-state order also may occur in certain substances by the use of solvents. In this case the molecules are either orientationally ordered in the solvent (some macromolecules), or form aggregates, in which the molecules exhibit long-range positional and/or orientational order. Liquid crystals that are established solely by the adjustment of temperature are referred to as thermotropics, whereas those that form through the addition of a solvent are called lyotropics.

Orientational Distribution Function and Order Parameter. In a liquid crystal a snapshot of the molecules at any one time reveals that they are not randomly oriented. There is a preferred direction for alignment of the long molecular axes. This preferred direction is called the director, and it can be used to define an orientational distribution function, $f(\theta)$, where $f(\theta)\sin\theta d\theta$ is proportional to the fraction of molecules with their long axes within the solid angle $\sin\theta d\theta$.

It is useful to describe the amount of orientational order with a single quantity. X-ray, uv, optical, ir, and magnetic resonance techniques are used to measure the order parameter in liquid crystals.

Positional Distribution Function and Order Parameter. In addition to orientational order, some liquid crystals possess positional order in that a snapshot at any time reveals that there are parallel planes which possess a higher density of molecular centers than the spaces between these planes. If the normal to these planes is defined as the z-axis, then a positional distribution function, $g(z)$, can be defined, where $g(z)dz$ is proportional to the fraction of molecular centers between z and $z + dz$. Since $g(z)$ is periodic, it can be represented as a Fourier series (a sum of a sinusoidal function with a periodicity equal to the distance between the planes and its harmonics). To represent the amount of positional order, the coefficient in front of the fundamental term is used as the order parameter. The more the molecules tend to form layers, the greater the coefficient in front of the fundamental sinusoidal term and the greater the order parameter for positional order.

Bond Orientational Order. In some cases, although the lattice of points of high density of molecular centers parallel to the planes are not correlated from layer to layer, the two principal directions of the lattice are the same for all layers. In these materials, the interactions between the planes do not prevent the planes from translating relative to each other, but do prevent them from rotating relative to each other.

Thermotropic Liquid Crystals

Thermotropic liquid crystals result from the melting of mesogenic solids due to an increase in temperature. Both pure substances and mixtures form thermotropic liquid crystals. In order for a mixture to be a thermotropic liquid crystal, the different components must be completely miscible. Examples include nematic liquid crystals (*p*-methoxybenzylidene-*p*′-*n*-butylaniline (MBBA); *p*-azoxyanisole (PAA); *p*-*n*-hexyl-*p*′-cyanobiphenyl; di-4-methoxyphenyl-*trans*-1,4-cyclohexane-dicarboxylate; and *p*-quinquephenyl), cholesteric liquid crystals ((−)-2-methylbutyl 4-(4′-methoxybenzylideneamino)cinnamate), and smectic liquid crystals (ethyl 4-(4′-phenylbenzylideneamino)benzoate; ethyl 4-(4′-ethoxybenzylideneamino)-cinnamate; *p*-*n*-octyloxybenzoic acid; 4-(4′-*n*-octadecyloxy-3′-nitrophenyl) benzoic acid; diethyl *p*-terphenyl-*p*, *p*″-carboxylate; 2-(*p*-pentylphenyl-5-(*p*-pentyloxyphenyl)-pyrimidine; and 4-ethyl-4′-butyloxybenzylodeneaniline). Much more is known about calamitic (rod-like) liquid crystals then discotic (disk-like) liquid crystals, since the latter were discovered only recently.

Nematic. In a nematic liquid crystal, the long axes of the molecules remain substantially parallel, but the positions of the centers of mass are randomly distributed. Therefore, there is orientational order and a nonzero orientational order parameter, but there is no positional order.

If the molecules of a liquid crystal are optically active (chiral), then the nematic phase is not formed. Instead of the director being locally constant as is the case for nematics, the director rotates in helical fashion throughout the sample. Within any plane perpendicular to the helical axis the order is nematic-like. In other words, as in a nematic there is only orientational order in chiral nematic liquid crystals, and no positional order.

Smectic. Smectic liquid crystals are distinguished from nematics by the presence of some positional order (a tendency to form layers) in addition to orientational order. The direction of preferred orientational order is perpendicular to the layers in a smectic A liquid crystal and at an angle with the layer normal in a smectic C liquid crystal.

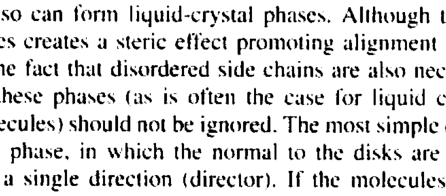
In much the same way as a chiral compound forms the chiral nematic phase instead of the nematic phase, a compound with a chiral center forms a chiral smectic C phase rather than a smectic C phase. In a chiral smectic C liquid crystal, the angle the director is tilted away from the normal to the layers is constant, but the direction of the tilt rotates around the layer normal in going from one layer to the next.

Frustrated Phases. Chiral molecules normally form chiral phases, but in some cases this is done in an interesting way. For example, it is not

unusual for a chiral molecule to form a smectic *A* phase, which is not chiral. If the molecule is highly chiral, however, twist is sometimes introduced into the smectic *A* phase by an array of grain boundaries which are perpendicular to the smectic *A* layers and parallel to the director. In one compound the normal to the layers is rotated by roughly 17° on either side of a grain boundary and the grain boundaries are separated by about 24 nm, giving this twist grain boundary (TGB) phase a pitch of a little more than 500 nm. In a sense the frustration of an achiral phase of chiral molecules has been relieved by the introduction of these twist grain boundaries.

Discotic Phases. Molecules which are disk-shaped rather than elongated also form thermotropic liquid-crystal phases. Usually these molecules have aromatic cores and six lateral substituents, although the predominance of six lateral substituents is solely historical; molecules with four lateral substituents also can form liquid-crystal phases. Although the flatness of these molecules creates a steric effect promoting alignment of the normal to the disks, the fact that disordered side chains are also necessary for the formation of these phases (as is often the case for liquid crystallinity in elongated molecules) should not be ignored. The most simple discotic phase is the nematic phase, in which the normal to the disks are preferentially aligned along a single direction (director). If the molecules are chiral or if a chiral dopant is added to a discotic liquid crystal, a chiral nematic discotic phase can form.

Metallomesogens. It is also possible to synthesize compounds based on metal atoms which possess liquid-crystal phases. The series based on dithiolene complexes (**1**), where M = Ni, Pd, or Pt, contains a number of compounds which show the liquid-crystal phases typical of rod-like molecules.



(**1**)

Disk-shaped molecules based on a metal atom possess discotic liquid-crystal phases.

Lyotropic Liquid Crystals. Some molecules in a solvent form phases with orientational and/or positional order. In these systems, the transition from one phase to another can occur due to a change of concentration, so they are given the name lyotropic liquid crystals. Of course temperature can also cause phase transitions in these systems, so this aspect of thermotropic liquid crystals is shared by lyotropics. The real distinctiveness of lyotropic liquid crystals is the fact that at least two very different species of molecules must be present for these structures to form.

Amphiphilic Molecules. In just about all cases of lyotropic liquid crystals, the important component of the system is a molecule with two very different parts, one that is hydrophobic and one that is hydrophilic. These molecules are called amphiphilic because when possible they migrate to the interface between a polar and nonpolar liquid.

Even more interesting phenomena occur when amphiphilic compounds are put into water–oil mixtures. If the oil concentration is low, the amphiphilic molecules form micelles and the oil collects inside the micelles. As the oil concentration is increased, the micelles continue to swell with oil until it is safe to say that the system is really composed of volumes of water and volumes of oil separated by a single amphiphilic layer. This type of system is called an emulsion, and thus amphiphiles can serve as emulsifiers.

When a highly polar liquid, a slightly polar liquid, and an amphiphile are mixed together at the right temperature and in the right concentrations, the micelles which form are not spherical. Within this vary narrow concentration range, the micelles are rod-shaped for one part of this range and disk-shaped for another part. In either case the micelles themselves orient their symmetry axes (the long axis for the rod-shaped micelles and the short axis for the disk-shaped micelles) just like a thermotropic liquid crystal.

Polymorphism

A liquid crystal compound in more cases than not takes on more than one type of mesomorphic structure as the conditions of temperature or solvent are changed. In thermotropic liquid crystals, transitions between various phases occur at definite temperatures and are usually accompanied by a latent heat.

An exception to the rule that lowering the temperature causes transitions to phases with increased order sometimes occurs for polar compounds which form the smectic A_d phase (a layered structure formed by molecular dimers). Decreasing the temperature causes a transition from nematic to smectic A_d, but a further lowering of the temperature produces a transition back to the nematic phase (called the reentrant nematic phase). Electric or magnetic fields also may induce mesomorphic phase transitions.

Synthesis

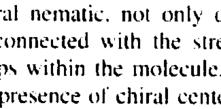
Just because a molecule is long, narrow, and meets the requirement of geometric anisotropy does not ensure that it will have a liquid crystal phase. The particular phase structure that occurs in a compound, i.e., smectic, nematic, or chiral nematic, not only depends on the molecular shape but is intimately connected with the strength and position of the polar or polarizable groups within the molecule, the overall polarizability of the molecule, and the presence of chiral centers.

Molecular interactions that lead to attraction include dipole–dipole interactions, dipole-induced dipole interactions, dispersion forces, and hydrogen bonding.

In order for dipole–dipole and dipole-induced dipole interactions to be effective, the molecule must contain polar groups and/or be highly polarizable. Ease of electronic distortion is favored by the presence of aromatic groups and double or triple bonds. These groups frequently are found in the molecular structure of liquid crystal compounds. The most common nematogenic and smectogenic molecules are of the type shown in Table 1. In general, if the X link is rigid, a liquid crystal phase is favored.

The importance of unsaturation is illustrated by the fact that 2,4-nonadienoic acid forms a liquid-crystal phase, whereas the *n*-aliphatic carboxylic acids do not. The two double bonds enhance the polarizability of the molecule and bring intermolecular attractions to a level that is suitable for mesophase formation. The overall linearity of the molecule must not be sacrificed in potential liquid-crystal candidates. Bulky, even if highly polarizable, functional groups or atoms that are attached anywhere but on the end of a rod-shaped molecule are usually less favorable for liquid-crystal formation.

In the case of carboxylic acids, hydrogen bonding can induce liquid-crystal phases by lengthening the molecular unit through dimerization:



On the other hand, hydrogen bonding may lead to nonlinear molecular associations that disrupt the parallelism. Hydrogen bonding associations may also be so strong that by the time the solid reaches its melting point the thermal energy is too intense to permit substantial order to remain within the fluid.

Although it is difficult to predict exactly which type of liquid-crystal phase will be formed by a molecule meeting the general requirements, rough trends can be recognized. The presence of functional groups that lead to strong lateral interactions, e.g., dipoles operating across the long

TABLE 1. SOME CENTRAL LINKAGES FOUND IN LIQUID CRYSTALLINE COMPOUNDS

−(nothing)	biphenyls

molecular axis, favor the layered smectic structure. When these structural elements are not present but the molecule is otherwise suitable for mesomorphism, i.e., is long and narrow, the nematic phase is likely. Longer terminal groups favor the smectic phase over the nematic phase. An asymmetric center on the molecule causes the chiral nematic and chiral smectic *C* phases in place of the nematic and smectic *C* phases.

Goals in liquid crystal synthesis include the design of room temperature thermotropics which are stable, colorless liquid crystalline over a wide range of temperature, and operate at low voltage and power levels.

A good deal of synthesis effort has been devoted to chiral liquid crystals, especially those with chiral smectic *C* phases. The chiral smectic *C* phase is ferroelectric, which gives it properties quite useful for applications. Perhaps the most important property of these phases is that a lateral dipole can produce a spontaneous polarization.

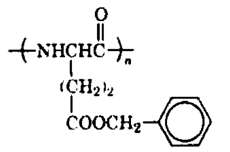
Polymer Liquid Crystals

Both polymer melts and polymer solutions sometimes form phases with orientational and positional order. Thermotropic polymer liquid crystals possess at least one liquid crystal phase between the glass-transition temperature and the transition temperature to the isotropic liquid. Lyotropic polymer liquid crystals possess at least one liquid crystal phase for certain ranges of concentration and temperature.

Polymer Melts. When a rigid, polarizable monomer forms wither a mainchain polymer with flexible segments in between or a side-chain polymer with flexible segments between the rigid segments and the flexible main chain, liquid-crystal phases are usually stable.

Examples of polymers which form anisotropic polymer melts include petroleum pitches, polyesters, polyethers, polyphosphazines, α-poly-*p*-xylylene, and polysiloxanes. Synthesis goals include the incorporation of a liquid crystal-like entity into the main chain of the polymer to increase the strength and thermal stability of the materials that are formed from the liquid-crystal precursor, the locking in of liquid crystalline properties of the fluid into the solid phase, and the production of extended chain polymers that are soluble in organic solvents rather than sulfuric acid.

Polymer Solutions. Perhaps the most extensively studied macromolecular liquid crystals are the synthetic polypeptides, such as poly(γ-benzyl L-glutamate) (PBLG). PBLG is a homopolymer of the L-enantiomorph of a single amino acid with the following repeat unit.



PBLG adopts the α-helical conformation in a number of solvents as a result of intramolecular hydrogen bonding and favorable stacking of the pendent side chains. Thus the polymer assumes an extended, relatively rigid geometry and may become ordered spontaneously at sufficiently high concentrations. The formation of this lyotropic liquid crystal phase occurs at a critical volume fraction of polymer ϕ' which is inversely proportional to the length-to-diameter ratio of the macromolecule.

A variety of aromatic and extended-chain polyamides that spontaneously form a mesophase in concentrated solutions also have been synthesized.

The polyamides are soluble in high strength sulfuric acid or in mixtures of hexamethylphosphoramide, *N,N*-dimethylacetamide, and LiCl. The liquid-crystal phase is optically anisotropic and the texture is nematic. The nematic texture can be transformed to a chiral nematic texture by adding chiral species as a dopant or incorporating a chiral unit in the main chain as a copolymer.

Applications. The polyamides have important applications. The very high degree of polymer orientation that is achieved when liquid crystalline solutions are extruded imparts exceptionally high strengths and moduli to polyamide fibers and films. DuPont markets such polymers, e.g., Kevlar, and Monsanto has a similar product, e.g., X-500, which consists of polyamide and hydrazide-type polymers. Liquid-crystal polymers are also used in electrooptic displays.

Liquid Crystals in Biological Systems

Many biological systems exhibit the properties of liquid crystals. Considerable concentrations of liquid crystalline compounds have been found in many parts of the body, often as sterol or lipid derivatives. A liquid crystal phase has been implicated in at least two degenerative diseases, atherosclerosis and sickle cell anemia. Living tissue, such as muscle, tendon, ovary, adrenal cortex, and nerve, show the optical birefringence properties that are characteristic of liquid crystals. The liquid crystal state has been identified in many pathological tissues, particularly in areas of large lipid deposits. Massive deposits of liquid crystalline cholesterol derivatives have been found in the kidneys, liver, brain, spleen, marrow, and aorta walls. Certain living sperms possess a liquid crystalline state.

Cell Membrane. The fluid mosaic model of the cell membrane is one in which the phospholipids provide the basic order and integrity of the cell through amphiphilic interaction with the aqueous environment.

Microfilaments and Microtubules. There are two important classes of fibers found in the cytoplasm of many plant and animal cells that are characterized by nematic-like organization. These are the micro-filaments and microtubules which play a central role in the determination of cell shape, either as the dynamic element in the contractile mechanism or as the basic cytoskeleton.

Liquid Crystalline Structures. In certain cellular organelles, deoxyribonucleic acid (DNA) occurs in a concentrated form. Striking similarities between the optical properties derived from the underlying supramolecular organization of the concentrated DNA phases and those observed in chiral nematic textures have been described. Concentrated aqueous solutions of nucleic acids exhibit a chiral nematic texture *in vitro*.

LIQUID CRYSTAL POLYMERS. These materials (LCPs) exhibit a highly ordered structure in the melt, solution, and solid states. A tightly packed and highly ordered morphology particularly susceptible to orientation during processing is characteristic. Commercial applications for LCP resins include chemical pumps, tower packings, coil bobbins, connectors, sockets, etc. for electronic components, and various automotive parts. LCPs have an excellent combination of chemical and flame resistance, dimensional stability, and ease of processing. Their thermal stability makes them suitable for dual ovenable cookware and where thermal resistance for both conventional and microwave oven service is important.

Compared with other polymeric materials, LCPs have very high unidirectional properties. *Vectra*™ (Celanese Corp.) resins are primarily aromatic polyesters based on *p*-hydroxybenzoic acid and hydroxynaphthoic acid monomers. *Xydar*™ (Celanese Corp.) injection molding resins are polyesters based on terephthalic acid, *p, p'*-dihydroxybiphenyl and *p*-hydroxybenzoic acid. Differences in monomers are primarily responsible for the differences in specific properties and end uses. The fibrous nature of the polymers imparts good impact strengths.

LIQUID CRYSTALS. Liquids that have the structural character of cybotactic liquids (see also **Cybotaxis**), but which are considerably more viscous, with viscosities extending from that of a light glue to that of a glassy solid. They also exhibit much more definite evidences of structure than the cybotactic liquids.

Liquid crystals must be geometrically highly anisotropic—usually long and narrow—and revert to an isotropic liquid through thermal action (thermotropic mesomorphism) or by the influence of a solvent (lyotropic mesomorphism). Several thousand organic compounds are now known which meet these criteria, but significant molecular features found in

thermotropic liquid crystals are among the following. The molecule will be elongated and rectilinear; if "flat segments," e.g. benzene rings, are present its liquid crystallinity will be enhanced. The molecule will be rigid along its long axis and double bonds will be common in this direction. The simultaneous existence is seen in the molecule of strong dipoles and easily polarizable groups. Of lesser importance are weak dipolar groups at the extremities of the molecule.

The present day classification of thermotropic liquid crystals is threefold. *Smectic liquid crystals*, such as *p*-ethyl azoxybenzoate, have their molecules arranged in definite strata, a variety of molecular arrangements being possible within each stratification. In *smectic Type A* crystals, the molecules may be considered to "stand on end" with their long axes perpendicular to the plane of the layer but with their centers irregularly spaced. When the molecular centers adopt hexagonal close packing, the crystals are considered *smectic Type B*, and when they adopt a titled form of Type A, they are classified as *smectic Type C*. See Fig. 1.

In *nematic liquid crystals*, the molecular structures possess a high degree of long-range orientation order, but no long-range translational order. The molecules are spontaneously oriented with their long axes approximately parallel, but without the stratification seen in smectic crystals. Nematic liquid crystals like *p*-azoxyanisole are generally optically uniaxial, positive, and strongly birefringent, and some are composed of hundreds of molecules (cytotactic groups), the molecular centers in each group arranged in layers. See Fig. 2.

Lyotropic liquid crystals possess at least two components. One of these is water and the other is amphible (a polar head group attached to one or more long hydrocarbon chains). In the lamellar form, water molecules are sandwiched between the polar heads of adjacent layers while the hydrocarbon tails lie in a nonpolar environment. Lyotropic liquid crystals have very complex structures, but occur abundantly in nature, particularly in living systems. See Fig. 3.

Polarized light is the most powerful tool for investigating liquid crystals, all of which exhibit characteristic optical properties. A smectic liquid crystal transmits light more slowly perpendicular to the layers than parallel to them. Such substances are said to be optically positive. Nematic liquid crystals are also optically positive, but their action is less definite than that of smectic liquid crystals. However, the application of a magnetic field to nematic liquid crystals lines up their molecules, changing their optical properties and even their viscosity.

Both smectic and nematic crystals split a beam of ordinary light into two polarized components whose transverse vibrations are at right angles to each other. This is the well-known phenomenon of double refraction. Cholesteric liquid crystals exhibit the phenomenon of circular dichroism. That is, they break a beam of ordinary light into two components, one with the electric vector rotating clockwise and the other with it rotating counterclockwise. The first is usually transmitted, and the second is the one to be reflected. It is this property that gives cholesteric crystals their characteristic iridescent colors when illuminated by white light.

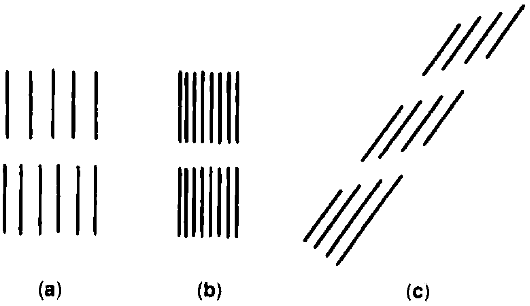

Fig. 1. Smectic liquid crystals: types (a), (b), and (c)

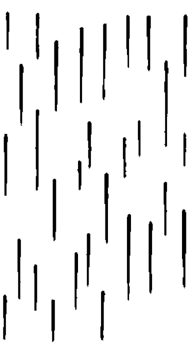

Fig. 2. Nematic crystals

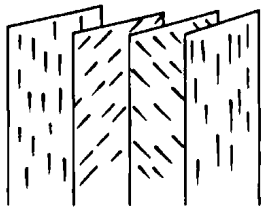

Fig. 3. Cholesteric crystals

This ability to exhibit colors is one of the most useful attributes of liquid crystals. Many cholesteric substances behave as liquid crystals only in a certain temperature range. Above it they are colorless, but as they are cooled through it they assume a succession of colors, running down the spectrum from red to violet and finally becoming colorless. However, at this final stage they still retain their molecular orientation, but it is that of smectic liquid crystals rather than cholesteric. Some cholesteric liquid crystals do not exhibit all the colors mentioned and others, which are naturally colored, simply change to another color on heating or cooling. Since the exact temperatures at which these color changes occur are invariable, these substances can be used for measuring temperatures; in fact, combinations of them cover the range from −20 to +250°C.

Useful applications have been found for the varied effects of these crystal changes. One of the first came from the property of selectively reflecting visible light; because this is temperature-dependent, the property can be used as a temperature detector, and in gel form liquid crystals have been used for the early detection of those cancers which cause hot spots in the body. Applications of the smectic modifications arise from their ferroelectric properties; this phase can function as a fast-switching light-valve device with memory. This kind of application requires some

control on the pitch of the polarized helix, which is obtained by blending together materials. Most twisted nematic field effect liquid crystal displays make use of a 90° twist between transparent conductive electrodes and crossed polarizers, as shown in Fig. 4. As randomly polarized light enters the device, only that portion which is vertically polarized may pass through the front polarizer. This, in turn, is rotated another 90° through the rear polarizer. If a reflective surface is placed behind the rear polarizer, the light will be passed back through the cell, its polarization again being rotated. By applying a voltage to the transparent electrodes, the molecules of the crystal will leave the nematic structure and align with the field, as shown in Fig. 5. Then the incoming light is no longer polarized—so extinction occurs and the area of extinction is defined very sharply by the shape of the electrode pattern, producing a dark area on a light reflective background. The reverse can also be achieved by using parallel rather than crossed polarizers. Fig. 6 shows a cross section of a typical display. A polymeric seal contains the liquid crystal material and holds the glass substrates together and the whole is laminated to the assembly.

LIQUID JUNCTION. To avoid the unknown liquid junction potential in measuring the potential of a half-cell against a reference electrode, the two half-cells are frequently connected via a salt bridge, usually a concentrated solution of potassium chloride. Since its anion and cation have almost the same velocity, a negligible diffusion potential is set up across the liquid junctions at the ends of the bridge.

LIQUID STATE. Because of the theoretical and practical importance to the era of electronics, which commenced nearly a half-century ago, the solid state of matter has become better known and understood than the physics of fluids (liquids and gases). Much practical engineering knowledge has been amassed pertaining to substances in the fluid state, but much research of a fundamental nature on fluids remains to be finished. Particularly, the transition of liquids to solids (and vice versa) at the theoretical level has not been fully explored and explained.

Prestigious scientists have commented on the mysteries that confront them. Russell J. Donnelly (University of Oregon) has observed, "Most flows of fluids, in nature and in technology, are turbulent. Since much of the energy expended by machines and devices that involve fluid flows is spent in overcoming the drag caused by turbulence, there is a strong practical motivation to understand the phenomenon. The study of turbulent flows, however, is one of the most formidably difficult subjects in physics and engineering. At present (1988), there is no substantial aspect of turbulent flow that can be understood fully from first principles."

Steve Granick (University of Illinois) has commented (1991), "Apart from structure, what are the dynamics of liquids in intimate contact with a solid boundary? This question has proven to be one of the most baffling aspects of liquids, in spite of long-standing interest."

Sir Samuel F. Edwards (Cavendish Laboratory, University of Cambridge) noted (1987), "Liquids are everywhere in our lives, in scientific studies and in our everyday existence. The study of their properties, in terms of the molecules of which they are made, has been the graveyard of many theories put forward by physicists and chemists. The modern student of liquids places his faith in the computer, and simulates molecular motion with notable success, but this still leaves a void where simple equations should exist, as are available for gases and solids. There is a powerful reason for the failure of analytical studies of liquids, i.e., the difficulty experienced in finding simple equations for simple liquids. We can explain the origin of the trouble and show that it does not apply to what at first might seem a much more complex system, that of polymer liquids where, instead of molecules like H_2O or C_6H_6, one has systems of molecules like $H_2(CH_2)_{10,000}$ or $H_2(CHC_6H_6)_{2,000}$ which behave like sticky jellies and yet have complex properties that can be predicted successfully."

Jacob N. Israelachvili and Patricia M. McGuiggan (University of California, Santa Barbara) observe, "The subtleties that can occur in the last few nanometers as two surfaces, particles, or solute molecules approach each other in a medium can be quite remarkable. Sometimes the forces are well described by 'continuum' or 'mean-field' theories, such as the DLVO (Derjaguin, Landau, Verwey, and Overbeck) theory, but more often they are not. Important fundamental questions remain concerning the origin of long-range attractive and repulsive hydration forces in water, the spontaneous nucleation of a bulk liquid or vapor phase between two surfaces close together, and the nature of entropic-fluctuation forces between two fluid-like interfaces. The elucidation of these interactions both at the fundamental level and when applied to specific systems (where a number of different interactions may be occurring simultaneously) present a challenge to experimentalists and theoreticians. On the purely experimental side, new techniques are constantly being introduced for extending the range and scope of surface force measurements. For example, one may anticipate that the atomic force microscope will soon provide the first direct measurements of the forces between molecules, as opposed to between surfaces."

General Properties of Liquids

A liquid is matter in a fluid state that is relatively incompressible. An *ideal liquid* offers no permanent resistance to a shear stress, but is incompressible. A liquid has a constant volume and incompletely fills any container of less than this volume. A *real liquid* is appreciably compressible, and the liquid state of a substance might be defined as the denser and less compressible phase of the two-phase fluid system that can exist in equilibrium at temperatures below the critical temperature. X-ray diffraction experiments show that, near the melting-point, the molecules of a liquid show a considerable degree of short-range order and that, in small volumes, they are arranged much as in a solid crystal. This crystalline structure persists over volumes comparable with the intermolecular distances, but cannot be traced beyond. This local or short-range order means that the average molecule is at any moment surrounded by a number of molecules occupying nearly the same relative positions as they would in the solid state. The degree of short-range order is described by the radial distribution function.

This concept of a liquid as an imperfect crystal requires that the molecules in a liquid are packed sufficiently loosely for comparatively free movement, i.e., the energy required to move a molecule from a lattice site to a vacant space is not large compared with thermal energies. Under these conditions, shear flow of the liquid resembles closely the high temperature creep of crystalline solids. A number of theories of the liquid state have this concept as their starting point.

With a few exceptions, including helium, the universal phase diagram shown in Fig. 1 applies for all pure compounds. The triple point is the single point at which all three phases (crystal, liquid, and gas) are in equilibrium. The triple point pressure is normally below atmospheric. Those substances, such as carbon dioxide, where P_t = 3,885 millimeters, T_t = −56.6°C, sublime without melting at atmospheric pressure. From the triple point, the melting curve defines the equilibrium between crystal and liquid, usually rising with small but positive dT/dP, and presumably always with positive dT/dP at sufficiently high P values. The line is believed to extend infinitely without a critical point (it has been followed to $T \cong 16T_c$ for helium, and calculations indicate that hard spheres would show a gas-crystal phase change). The gas-liquid equilibrium line, the vapor pressure curve, has dT/dP always positive and greater than the melting curve. The vapor pressure curve always ends at a critical point, $P = P_c$,

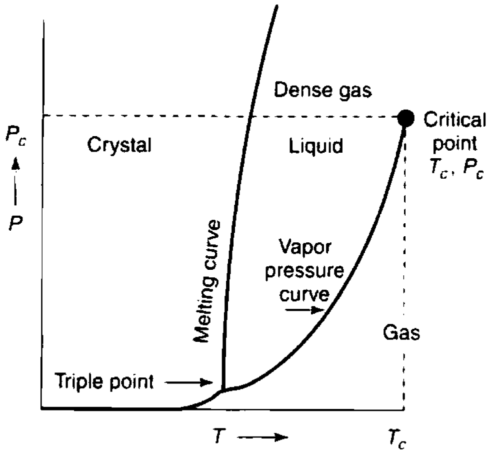

Fig. 1. Universal phase diagram

$T = T_c$, above which the liquid and gas phase are no longer distinguishable. Since the liquid can be continuously converted into the gas phase without discontinuous change of properties by any path in the $P - T$ diagram passing above the critical point, there is no definite boundary between liquid and gas. Two liquids of similar molecules are usually soluble in all proportions, but very low solubility is sufficiently common to permit the demonstration of as many as seven separate liquid phases in equilibrium at one temperature and pressure (mercury, gallium, phosphorus, perfluorokerosene, water, aniline, and heptane at 50°C, 1 atmosphere).

Stability Limits[1]. With the exception of helium and certain apparent exceptions discussed below, Fig. 1 gives a universal phase diagram for all pure compounds. The triple point of one P and one T is the single point at which all three phases, crystal, liquid, and gas, are in equilibrium. The triple point pressure is normally below atmospheric. Those substances, e.g., CO_2, $P_t = 3885$ mm, $T_t = -56.6$°C, for which it lies above, sublime without melting at atmospheric pressure.

From the triple point, the melting curve defines the equilibrium between crystal and liquid, usually rising with small but positive dT/dP, and presumably always with positive dT/dP at sufficiently high P values. The line is believed to extend infinitely without a critical point (it has been followed to $T \cong 16T_c$ for He, and calculations indicate that hard spheres would show a gas-crystal phase change). The gas-liquid equilibrium line, the vapor pressure curve, has dT/dP always positive and greater than the melting curve. The vapor pressure curve always ends at a critical point, $P = P_c$, $T = T_c$ above which the liquid and gas phase are no longer distinguishable. Since the liquid can be continuously converted into the gas phase without discontinuous change of properties by any path in the $P - T$ diagram passing above the critical point, there is no definite boundary between liquid and gas.

The term *liquid* is commonly reserved for $T < T_c$, and "dense gas" is used for $T > T_c$. However, certain properties, such as the ability to dissolve solids, change rather abruptly at the critical density. In many respects, the dense gas resembles the low-temperature liquid of the same density more closely than it does the dilute gas.

The slope, dT/dP, of all phase equilibrium lines obeys the thermodynamic Clapeyron equation:

$$dT/dP = \Delta V/\Delta S = T\Delta V/\Delta H \tag{1}$$

with ΔV, ΔS, and ΔH the differences, for the two phases, of volume, entropy, and heat content or enthalpy, respectively. The quantity ΔH is the heat absorbed in the phase change at constant P. Since always $S_{cr} < S_{liq} < S_{gas}$, and usually $V_{cr} < V_{liq} < V_{gas}$, one usually has $dT/dP > 0$; the relatively rare cases, including water, for which $V_{liq} < V_{cr}$ at low pressures leads to $dT/dP < 0$ for the melting curve near the triple point.

Figure 1 gives the $P - T$ boundaries of the stable liquid phase. Clean liquids can readily be superheated or supercooled, and, in vessels having walls to which the liquid adheres, they can be made to support negative pressures of several tens of atmospheres. Thus the properties of the metastable liquid can be investigated outside the limits shown in the diagram.

Two apparent exceptions to the universality of the phase diagram of Fig. 1 deserve mention. First, many of the more complicated molecules decompose at temperatures below melting or boiling, and the diagram is unobservable. Secondly, some liquids, notably glycerine and SiO_2 and many multicomponent solutions, supercool so readily that crystallization is difficult to observe. In these cases, there is a continuous transition on cooling to a glass, which has the elastic properties of an isotropic solid. The structure of the glass is qualitatively that of the high-temperature liquid, lacking long-range order. Since glass and liquid are not sharply differentiated, the term *liquid* is sometimes used to include glasses, although common parlance reserves *liquid* for the state in which flow is relatively rapid.

Quantum Liquids. The one real exception to the phase diagram of Fig. 1 is that of helium, Fig. 2. Both isotopes, ^{4}He and ^{3}He, have no triple point, the liquid is stable to 0 K below about 20 atm for ^{4}He and below about 30 atm for ^{3}He. The liquids have zero entropy at 0 K in both cases. This is also the only case in which isotopic mixtures form two liquid phases at equilibrium, the isotopic solution separating below 1 K. The isotope ^{4}He has itself two phases, He I above the dotted λ-line of the diagram, and He II with remarkable properties of superfluidity, second sound, etc., below the λ-line. The phase transition along the λ-line is second order; that is, whereas S and V are continuous, heat capacity and compressibility change discontinuously across the λ-line.

Although no completely satisfactory single theory of liquid helium has yet been formulated, one can say that most of the remarkable properties are qualitatively understood and are due to the predominance of quantum effects, including the difference in the statistics of the even and odd isotopes. Thus helium is the one example in nature of a quantum liquid, all other liquids showing only minor deviations from classical behavior.

Structure. Considerable confusion in the description of liquid structure exists, due primarily to difficulties of precise formulation of verbal concepts. The geometric arrangement of any small number (say 10 to 12) of close-lying molecules resembles the arrangement in the crystal, but the order rapidly disappears as larger groups are considered. Long-range order is lacking. The fact that numerical theories based on a lattice or cell structure have some success is evidence only that most properties depend on the configuration of near neighbors alone. Insofar as the arrangement of nearest neighbors is describable in terms of that of the crystal, the structure of the normal liquid is probably characterized best by a somewhat closer spacing than the crystal of the same molecules. The reduced density arises from a considerable number of vacancies in the lattice; the coordination number, or number of nearest neighbors, is lower than in the crystal. The exception is water, in which the low coordination number, 4, of the crystal, is increased by interstitial molecules in the liquid, leading to a higher density of the liquid.

Structural descriptions of this nature usually lack the possibility of precise formulation. It is, however, possible to define for any disordered array of molecules in three-dimensional space an arrangement of contiguous cells, each containing one and only one molecule, the faces of the cells being the loci of the midpoints of neighboring molecules. The statistics of the fraction of cells with n faces and of the distances of the

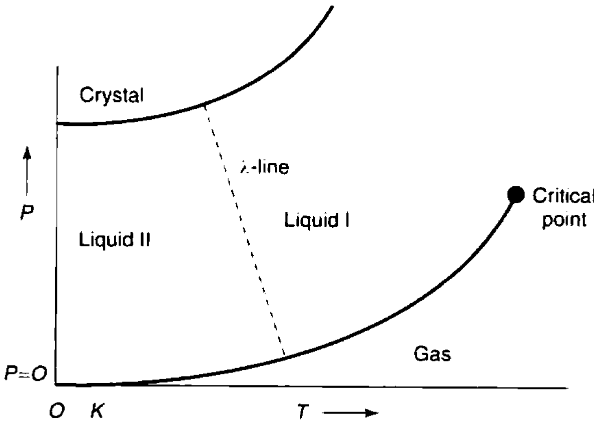

Fig. 2. Quantum liquid exception to phase diagram of Fig. 1

[1]The following several paragraphs by Joseph E. Mayer are part of a large article that appears in "The Encyclopedia of Physics" (Robert M. Besancon, Editor), Van Nostrand Reinhold, New York, 1984.

faces from the molecules would give the fraction of molecules having a given number of nearest neighbors and the distance distribution of these in a precisely defined manner. Neither present experimental information nor present theories lend themselves to analysis in such terms.

The only clearly defined manner of describing liquid structure in use at present involves the concept of a set of probability density functions, ρ_n, for ascending numbers, n, of molecules. The function ρ_n depends on the vector coordinates $\mathbf{r}_1, \mathbf{r}_2, \ldots \mathbf{r}_n$ of n molecules, and

$$\rho_n \mathbf{r}_1, \mathbf{r}_2, \ldots, \mathbf{r}_n, d\mathbf{r}_1, \ldots, d\mathbf{r}_n$$

is defined as being the probability that in the liquid of definite P and T, there will be, at any instant of time, one molecule at each position, $\mathbf{r}_i$, within the volume element, $d\mathbf{r}_i$. For a fluid, unlike a perfect single crystal, $\rho_i(\mathbf{r})$ is a constant independent of $\mathbf{r}$ and equal to the number density: the number, ρ, of molecules per unit volume. The first significant member of the set is then the pair density function, $\rho_2(\mathbf{r}_1, \mathbf{r}_2)$, which depends only on the distance, $\mathbf{r} = |\mathbf{r}_1 - \mathbf{r}_2|$, between the two molecules. At large distances $\rho_2(\mathbf{r} \rightarrow \infty) = \rho^2$. This function can be found experimentally from the x-ray scattering intensities of the liquid (it is the three-dimensional Fourier transform of the scattering intensity at angle θ vs $(4\pi/\lambda)/\sin;\ (\theta/2)$). A typical plot is shown in Fig. 3. The area under the ill-defined first peak integrated over $4\pi\mathbf{r}^2 d\mathbf{r}$ is the average number of nearest neighbors, and is of order 10 to 11 for normal liquids.

The quantity of dimensions of energy,

$$W_n(\mathbf{r}_1, \ldots, \mathbf{r}_n) = -kT \ln[\rho^{-n}\rho_n(\mathbf{r}_1, \ldots, \mathbf{r}_n)]$$

can be shown to be the potential of average force of n molecules located at the positions $\mathbf{r}_1, \ldots, \mathbf{r}_n$. That is, if there are n molecules at these positions, there will be some average force, f_{xi}, along the x-coordinate of molecule i. This average is the sum of the direct force due to the other $n - 1$ plus the average of a fluctuating force due to the others, whose average position is affected by that of the n specified ones. This average force is

$$f_{xi} = -(\partial/\partial x_i)W_n(\mathbf{r}_i, \ldots, \mathbf{r}_n)$$

One frequently assumes that W_n is a sum of pair forces only,

$$W_n(\mathbf{r}_i, \ldots, \mathbf{r}_n) = \sum_{n \geq i}\sum_{j \geq i}{}' W_2(\mathbf{r}_{ij})$$

although this assumption is known to be only approximate. With this assumption, the pair average force potential, $W_2(\mathbf{r}_{ij})$, can be computed as the solution of an integral equation, and the solutions agree quite well with the experimental curves.

The knowledge of the complete set of functions ρ_n plus that of the intermolecular forces would permit the computation of all equilibrium properties of the liquid, and indeed if the intermolecular forces are the sum of pair forces, only a knowledge of ρ_2 at all P, T values is necessary. An adequate, although numerically difficult, theory of the transport properties also exists, using the equilibrium functions, ρ_n. At present, only qualitative success is obtained in the completely *a priori* use of the equations.

Associated Liquids. The description given above is adequate only for liquids composed of spherically symmetric molecules or molecules that are nearly so. These constitute the so-called normal liquids, which obey reasonably well the law of corresponding states, for which the entropy of vaporization at the boiling point has the Trouton's rule value of approximately 21 cal/deg. For molecules containing large dipole moments, or those forming mutual hydrogen bonds, the concept of the probability

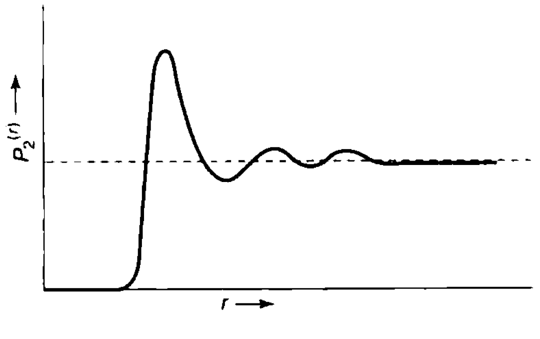

Fig. 3. Fourier transform of scattering intensity

density functions must be extended to include angles or other internal degrees of freedom in the coordinates. Such inclusion is conceptually easy, but incredibly complicates the already difficult numerical evaluation of any equations. However, certain qualitative statements may be made.

Liquids composed of molecules with large dipole moments are frequently referred to as associated. Although in some instances relatively stable dimer or definite polymer units of relatively fixed orientation may exist, in many cases, notably water, it is extremely doubtful if an exact knowledge of the structure would reveal any distinguishable entities of associated molecules other than that of the whole liquid. In such cases, one would, however, expect that certain mutual angular orientations between neighboring molecules will be highly preferred, whereas in the dilute gas this will not be the case. The effect of this restriction on the internal coordinates will be to decrease the entropy of the liquid markedly compared to the gas. This effect is qualitatively the same as in association, and the properties of these liquids, particularly the high entropy of vaporization, will simulate those of a liquid composed of definite associated complexes.

Traditional Views of Forces Between Surfaces in Liquids

For many years, four kinds of forces have been recognized to operate between surfaces or particles in liquids:

1. *Van Der Waals forces*—Normally, these are monotonically attractive and occur between all molecules. See also **Van Der Waals Forces**.
2. *Repulsive electrostatic (double-layer) forces*—These forces are apparent when ionizable surfaces have a net electric charge, the common case in water.
3. *Structural, hydration, or solvation forces*—These forces may be attractive, repulsive, or oscillatory and depend upon the structuring or ordering of liquid molecules. (Solvation may be defined as the adsorption of a microlayer of film of water or other solvent on individual dispersed particles of a solution or dispersion.)
4. *Repulsive entropic (steric or fluctuation) forces*—As defined by Israelachvili and McGuiggan, these are "forces which arise from the thermal motions of protruding surface groups (such as polymers or lipid head groups) or from the thermal fluctuations of flexible fluid-like interfaces (or surfactant or lipid bilayers)."

Although, in a vacuum, only the Van Der Waals forces are important; in liquids, all forces may operate simultaneously. In liquids, it is extremely difficult to separate the effects of each of the aforementioned forces.

In the 1950s, the DLVO theory was based largely upon forces (1) and (2) defined above. The DLVO theory became the basis for studying the properties of colloidal and biocolloidal systems.

Electrorheological Fluids

Complications continue in the theoretical exploration of liquid behavior, but, in attempting to learn about the complexities, leads toward a more fundamental understanding of liquids may emerge. One of these complexities is a class of fluids referred to as *electrorheological*.

In a normal setting, these liquids are liquid in the conventional sense, but, when they are subjected to a strong electric field, they become solids. A common example is a mixture of cornstarch and vegetable oil. The viscous, sticky starting mixture of these two components can be converted into a hardened solid material with the application of an appropriate electric field. In recent years, through random researching, investigators have found numerous combinations of materials that qualify as electrorheological fluids, but to date no satisfactory explanation of the effect from a theoretical standpoint has been developed. The effect of the ER effect can be observed readily by microscopic examination. In a normal liquid or in an electrorheological mixture not in an electric field, examination shows particles moving in random fashion throughout a container, as may be expected. But, when a field is applied, long strands of particles appear to be "solidly" linked together, thus providing rigidity to the mix. No retentivity is involved, however, because liquid normalcy is returned immediately upon cessation of the electric field. This action intrigues a number of designers of equipment, as in the electronics and valve fields, where such materials may be used in future circuits, valves, and any number of other "on-off" devices.

Artificial Magnetic Fluids. The concept of magnetizable liquids dates back over several decades. The first breakthrough occurred in the mid-1960s, with the production of stable colloids of subdomain solid

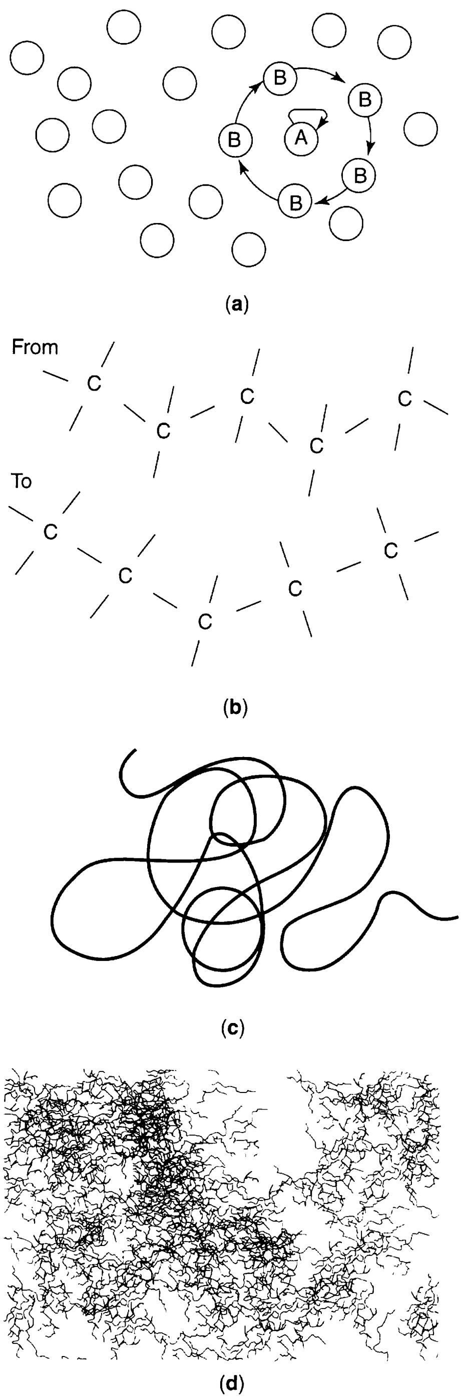

Fig. 4. Sketches by Edwards for schematically illustrating the behavior of polymer liquids. (**a**) Central molecule A moves around a (temporary) average position, occasionally escaping the barrier of the molecules B when some fluctuation of their positions permits it to do so. But, in addition to this single molecule motion, the molecules B can move around cooperatively, one of many cooperative motions that the observer may "invent." The numerous possibilities immediately derail the formulation of a simple theory. As explained by Edwards, "If the motion only involved one molecule at a time, quite a reasonable theory can be put together, but it will always be inadequate to describe the whole motion, and possibly, this always will be the case. The very apparatus of mathematical equations cannot handle this level of complexity, even though the human mind has no difficulty in seeing where the trouble is. The best current way to deal with this problem is to put all the molecules onto the computer and study their molecular dynamics." Continual changes are possible, and the long-chain molecule can be regarded as a flexible string in continual motion. A single coil may be drawn, as shown in (**c**). A computer model could be generated to show many polymers projected onto a plane, as indicated in (**d**). Edwards observes, "So the liquid looks like a seething pit of wriggling motion, a kind of living spaghetti, but with less smooth shapes than real spaghetti. How can one describe such a system? How do the molecules move, and how does the material flow?" (*Sketches after Sir Samuel F. Edwards*)

ferromagnets, which variously were called magnetic fluids, magnetizable fluids, or simply ferrofluids. These may be prepared by size reduction or precipitation. It has been a rather remarkable feat to grind bulk material down to a size of 100 micrometers. Grinding is done in the presence of a dispersing agent and a solvent. In chemical precipitation, iron(II) and iron(III) ions in aqueous solution are coprecipitated in the molar ratio of about 2:1 using ammonium hydroxide. To maintain the magnetic product in a small colloidal size range, a peptization step is included in which the particles are transferred to a heated organic phase containing the dispersing agent. The behavior of these artificial fluids offers techniques for achieving efficient heat and mass transfer, drag reduction, wetting, fluidization, sealing, damping, and other process and product potential uses.

Polymer Liquids

Sir Samuel F. Edwards of the Cavendish Laboratory, previously mentioned, observes, "Polymer liquids are liquid because the temperature is high enough to change the configuration of the molecules easily." See Fig. 4.

Scientists and engineers experienced in the production and application of polymeric liquids have learned from thousands of examples of how polymeric liquids behave, and can even classify some of them into behavioral families. But the complexity of these substances to date has eluded the achievement of precise designs and predictive behavior.

Mixing of Liquids

In the chemical process industries and in food manufacturing, the mixing of liquids is an important and frequently used operation. Over the years, the mixing operation has been poorly understood and essentially remains so. Progress in equipment design has been achieved mainly through the development of extensive empirical information rather than upon the creation of precise mathematical and theoretical relationships. J.M. Ottino (University of Massachusetts) observes, "There are many fundamental questions regarding mixing in slow three-dimensional flows, and unfortunately some of the intuition we have obtained from our study of two-dimensional flows does not necessarily carry over to flows in three

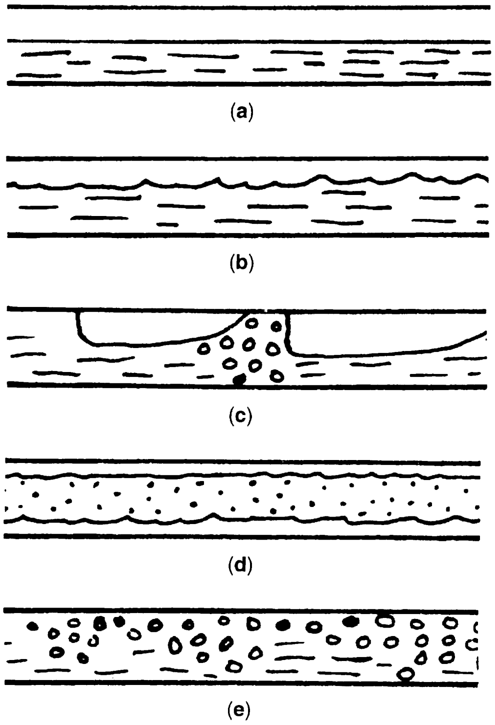

Fig. 5. Types of two-phase flow in a horizontal pipeline: (**a**) Stratified smooth flow where gas velocity is low. Liquid flows along bottom portion of pipelines with essentially a smooth surface. (**b**) Stratified flow with a wavy surface, the waviness caused by increased gas flow velocity. (**c**) Liquid bridges the pipeline cross section, thus causing slugs or plugs of liquid, which move at a velocity approximately that of the flowing gas. (**d**) Annular flow, in which the liquid essentially flows as an annular film on the pipe wall while gas flows as in a central core of the pipe. (**e**) Dispersed bubble flow usually results when liquid flow rates are high and gas rates are low. Because of comparative density differences, most bubbles are found above the pipe center line. Conditions vary somewhat when the pipeline is in a vertical orientation. (*After Cindric, Gandhi, and Williams*)

dimensions." The Ottino reference listed describes studies of chaotic and nonchaotic flows in laboratory setups.

Multiphase Fluid Flow

It is quite common in industrial and cross-country liquid transport problems to encounter mixtures of liquids, vapors, and gases—that is, the presence of two phases of matter. As pointed out by D.I. Koch (Cornell University), "Research programs in this area at Cornell involve studies that fall outside of the traditional realm of chemical engineering, including blood flow in capillaries, the transport of contaminants in groundwater, the dynamics of geothermal reservoirs, enhanced oil recovery, the processing of fibrous composites, melt-spinning processes, and the growth of silicon crystals."

As previously mentioned in this article, liquid behavior presents an immense variety of puzzling problems that are difficult to comprehend and hence difficult to forecast precisely. As just one example, in the study of large drops of liquid at high flow rates, the inertia of the drops and the surrounding fluids play an important role. When such drops are propelled toward one another, they may coalesce into a single drop or may rebound like a pair of elastic balls, a phenomenon that is partially (but not fully) dependent upon the comparative velocities of the two drops.

In traditional industrial two-phase flow situations, as occur in process piping, engineers classify flow patterns, as indicated in Fig. 5. This type of classification and the development of empirical data from past experimentation and practice assist much in simplifying the problems from a practical, if not from a theoretical, standpoint. Multiphase flow behavior considerations are essential in calculating pipe diameters, pumping capacities, and energy consumption. Multiphase flows also exhibit different characteristics when being pumped uphill or flowing downhill. See also **Fluid and Fluid Flow**.

LITHIUM. [CAS: 7439-93-2]. Chemical element, symbol Li, at. no. 3, at. wt. 6.941, periodic table group 1, mp 180.54°C, bp 1342°C (at 760 torr), density 0.534 g/cm^3 (20°C). Lithium is lightest in weight of all the chemical elements that are solid at standard conditions. Elemental lithium in the solid phase has a body-centered cubic crystal structure. In comparison with other members of the alkali metal series, lithium has the smallest ionic radius, the highest ionization potential, the highest electronegativity, and the greatest heat capacity. Generally, lithium is the least reactive of the alkali metals. Lithium is a silver-white metal, harder than sodium, but softer than lead. It is tough and may be drawn into wire or rolled into sheets. The element tarnishes rapidly in air and often is preserved under naphtha. The reaction with H_2O is vigorous, producing LiOH (lithium hydroxide) and hydrogen. There are two naturally occurring isotopes, ^{6}Li and ^{7}Li. They are not radioactive. Two radioactive isotopes have been identified, ^{5}Li and ^{8}Li, both with very short half-lives, measured in fractions of seconds. Among elements occurring naturally in the earth's crust, lithium ranks 28th with an estimated average content of about 10–20 ppm. In terms of content in seawater, lithium ranks 17th with an estimated content of approximately 950 tons of lithium per cubic mile of seawater. The element was first identified by Johann August Arfvedson in 1817 in the laboratory of Berzelius. The name of the element is accredited to Berzelius.

First ionization potential 5.39 eV. Oxidation potential $Li \longrightarrow Li^+ + e^-$, 3.02 V. Other physical properties of lithium are given under **Chemical Elements**.

The main sources of lithium are pegmatites and brines. The most important pegmatite mineral is *spodumene*, $LiAlSi_2O_6$, which contains a theoretical content of 8.03% Li_2O. *Petalite*, $LiAlSi_4O_{10}$, contains between 4 and 4.5% Li_2O. *Lepidolite*, a complex mica, contains between 3 and 4% Li_2O. See also entries on **Lepidolite**; **Petalite**; and **Spodumene**. Brines contain normally a few hundred to a few thousand parts per million (ppm) of lithium. The only commercial source of spodumene in North America is located in North Carolina. Abundant resources of lithium pegmatites occur in Canada, the African continent, and unconfirmed sources in Russia and China. Significant quantities of lithium (as carbonate) are produced from the brines of Clayton Valley, Nevada. A recently discovered, lithium-rich brine deposit has been located in the Atacama desert of Chile. More detail on lithium resources is given in the next entry.

There are three major processes for extracting lithium from pegmatite ores. (1) An acid process, wherein the spodumene concentrate, after calcining at about 1095°C, is reacted with sulfuric acid, followed by water leaching of the resulting lithium sulfate, Li_2SO_4. The sulfate is then converted to the carbonate with soda ash. (2) An alkaline process, wherein the ore is reacted with lime or limestone at high temperatures followed by water leaching of the resulting lithium hydroxide. (3) A base exchange method, whereby the ore is reacted with an alkaline chloride or sulfate at a high temperature in an aqueous phase to yield a soluble lithium salt. The sulfuric acid leaching method is the only commercial process for extraction of lithium from spodumene in practice today.

Lithium metal was first prepared by Sir Humphry Davy in 1818 by electrolyzing lithium oxide. At about that same time, Brande also isolated the metal. In 1855, R. Bunsen and A. Matthiessen prepared gram amounts by electrolyzing fused lithium chloride. Modest commercial quantities were first made in Germany during World War I when the metal was considered as a potential alloying material. Limited production did not commence in the United States until the early 1930s. Present commercial methods were pioneered by Guntz in 1893 and involve electrolyzing a low-melting mixture of LiCl and KCl. Graphite anodes and mild steel cathodes are used. Lithium is formed at the cathode and rises to the surface, from which it is skimmed periodically. Pure lithium chloride is added to the bath as required. Chlorine gas is liberated at the anodes. The process yields a lithium metal of about 99.8% purity. The metal normally is cast into ingots of different sizes, but is also available as extruded rod, ribbon, or wire. The metal also is available as "sand"—fine dispersions in the 10–30 μm range.

Lithium in Metallurgy and Alloys

In metallurgy, lithium metal is used as a deoxidizer, desulfurizer, and degasifier in the production of a number of molten metals, notably copper and copper alloys. Lithium also is an ingredient of an increasing number of alloys, particularly with aluminum. Early alloys included aluminum alloy

X2020 (1% Li), which is a structural alloy with improved high-temperature strength. In another early Li alloy, about 14% Li is alloyed with magnesium in the LA 141 alloy, designed for very light-weight structural applications, notably in aerospace applications.

In late 1989, a new proprietary (Martin Marietta Corp.) family of weldable, high-strength Al-Li alloys was introduced. With a 690-MPa (100 × 10^3 psi) yield strength, the material is claimed to be twice as strong as the previous leading Al-Li alloys. This alloy was developed specifically for space launch systems. The alloy is claimed to maintain a high strength under thermal conditions ranging from cryogenic to elevated temperatures. A primary use is for fuel and oxidizer tanks, where its weldability is a marked advantage. Sheet, plate, extrusion, and ingot products of the new alloy also are available.

The addition of lithium to aluminum castings has been found to be particularly advantageous. Lithium produces a lower density and higher stiffness over conventional aluminum alloys used in aerospace applications. Lithium has one of the highest solubilities of any aluminum alloying element. About 4.2% Li can be dissolved in Al at the 602°C (1116°F) eutectic temperature. The hardness of Al-Li alloys improves with aging temperature. Al_3Li precipitates are formed, producing higher hardness. Yield strength also increases with higher aging temperature and higher Li content.

Lithium alloyed with silver has been used for fluxless brazing.

Lithium Batteries. For many years, lithium has been considered for use in batteries, particularly with the growing emphasis on the electric car. See also **Batteries**.

Chemistry and Compounds

Lithium has the highest ionization potential (i.e., Li $\longrightarrow$ Li^+ in the vapor) of the alkali metals. However, the measured value of its oxidation potential against a normal aqueous solution of its ion is 3.02 V, which does not differ from those of the other main group I metals by as much as the difference in ionization potentials. That difference, attributed to the high heat of hydration of Li^+, explains why lithium is a vigorous reductant in aqueous systems, but reacts slowly with H_2O, and not at all with dry oxygen except above 100°C.

The single 2*s* electron in the outer shell of lithium is easily removed to form the positive ion, and stability of the remaining $1s^2$ electron pair requires too high a potential (75.62 eV) for any further ionization (by chemical means) so that lithium is exclusively monovalent in its compounds.

Because of the reactivity of lithium with water to form its hydroxide, LiOH, and hydrogen, its properties when dissolved in other solvents have been studied extensively. It does not decompose liquid NH_3, but does form a blue solution, which decomposes to yield its amide, $LiNH_2$, and hydrogen, when catalyzed by metallic salts. With the elements of main groups 2 to 7, lithium in liquid NH_3 reacts to form binary compounds, which may vary from simple halides, as with the halogens, to intermetallic phases, as with cadmium and mercury. Lithium amide in liquid NH_3 is regarded in the same class as a hydroxide in aqueous solution.

Many other lithium compounds not obtainable in aqueous solution can be produced from the solution of lithium in liquid ammonia. Thus the acetylide is obtained by action of acetylene.

$$C_2H_2 + LiNH_2 \longrightarrow LiC_2H + NH_3$$

$$2LiC_2H \longrightarrow Li_2C_2 + C_2H_2$$

The amide, as stated above, is produced by catalyzed decomposition of the liquid NH_3 solution, and the nitride, Li_3N, by heating the amide or by direct combination of the elements.

Lithium salts exhibit general high solubility and a high degree of dissociation in other nonaqueous solvents than liquid ammonia, such as liquid sulfur dioxide and acetic acid.

Like the other alkali metals lithium forms compounds with virtually all of the anions, inorganic as well as organic. The lithium salts are in many instances different in their solubility properties from the corresponding salts of the other alkali metals. Thus lithium fluoride, phosphate, and carbonate are the least soluble alkali metal fluoride, phosphate, and carbonate, the solubilities for the other alkali metals increasing with increasing ionic radius. Lithium chlorate and dichromate are, on the other hand, the most soluble alkali chlorate and dichromate, the solubilities for the other alkali metals decreasing with increasing ionic radius. These differences are partly explained, as was that in the oxidation potential, by the considerable hydration of the lithium ion, which also explains the fact that lithium salts generally crystallize as hydrates. Lithium salts, probably because of the small size of the lithium ion, do not form mixed crystals with the other alkali salts, but they do form double salts, notably the two series of lithium-sodium and lithium-potassium sulfates.

Lithium forms several organic compounds. Most of them are lithium salts or lithium acid salts of organic acids or other oxygen-connected lithium compounds. The number of lithium-carbon bonded compounds that have been reported is very small including, in addition to the carbide, methyllithium, CH_3Li, ethyllithium, C_2H_5Li, *n*-propyllithium, C_3H_7Li, *n*-butyllithium, C_4H_9Li, benzyllithium, $C_6H_5 \cdot CH_2Li$, and methylenedilithium $LiCH_2Li$.

The alkyllithium compounds are usually colorless, soluble in organic solvents, and capable of distillation or sublimation. They are nonelectrolytes and are widely used in synthetic organic chemistry, since, like other lithium compounds, they resemble in their properties the corresponding magnesium compounds.

Lithium carbonate. [CAS: 554-13-2]. Li_2CO_3, mp 72.6°C, slightly soluble in H_2O. Used in glass, enamel, and ceramic formulations, in the electrowinning of aluminum, and in the manufacture of other lithium compounds. The compound also has been used in the treatment of manic-depressive psychoses.

Lithium hydride. [CAS: 7580-67-8]. LiH, mp 686.4°C, reacts vigorously with H_2O. With NH_3, it forms the amide. The compound is used to produce $LiAlH_4$ and other double hydrides. Lithium hydride is an excellent light-weight source of hydrogen. One pound yields 45 cubic feet of hydrogen (one kilogram yields 2.8 cubic meters of hydrogen) at standard conditions. The compound also can serve as a light-weight shield for thermal neutrons.

Lithium hydroxide monohydrate. [CAS: 1310-65-2]. $LiOH \cdot H_2O$ loses water at 101°C. LiOH melts at 450°C. The compound is soluble in water. The compound is used in the formulation of lithium soaps used in multipurpose greases; also in the manufacture of various lithium salts; and as an additive to the electrolyte of alkaline storage batteries. LiOH also is an efficient, light-weight absorbent for carbon dioxide.

Lithium bromide. [CAS: 7550-35-8]. LiBr, mp 550°C, soluble in H_2O or alcohols. The compound is very hygroscopic and forms four hydrates. Major use has been in absorption-refrigeration air-conditioning systems in which H_2O is the refrigerant—strong LiBr is used to absorb H_2O vapor.

Lithium chloride. [CAS: 7447-41-8]. LiCl, mp 608°C, soluble in H_2O or alcohols. Very hygroscopic and forms four hydrates like the bromide. The compound is a component of brazing fluxes for aluminum and magnesium. It is used in dehumidification systems, as an additive to the electrolyte of dry cells for low-temperature applications; and it is used in low-freezing fire-extinguishing systems; as an ingredient of fused-salt baths to lower fusing temperature; and, as a coating, in humidity-sensing instruments.

Lithium fluoride. [CAS: 7789-24-4]. LiF, mp 848°C, soluble in H_2O (slight). Used in enamel and glass formulations; as a component of welding and brazing fluxes; in the electrowinning of aluminum; and as an ingredient of molten salts.

Lithium in Biological Systems

Although much remains to be learned, there is considerable evidence that lithium can play an active role (positive and negative) in biological systems. Possibly most widely known is the use of lithium salts, notably lithium carbonate, in the therapy for mania (a condition where the patient is mentally and physically hyperactive, associated with an elevated mood and disorganized behavior). Frequently associated with mania is the broad swinging of the patient's mood (*bipolar disorder*). Studies have shown that persons with mania have a defect in the transmissions of impulses between and along nerve cells in the brain, which depends upon the regulated movement of ions across the membranes of those cells. Lithium antagonizes synaptic transmission of catecholamines in the brain by inhibiting norepinephrine and dopamine release. This is the result of weakly increasing their re-uptake by the presynaptic neuron and by decreasing storage. Lithium also interferes with the ability of several hormones to stimulate adenylate cyclase, a property that is believed to decrease the action of catecholamines at the postsynaptic receptor sites.

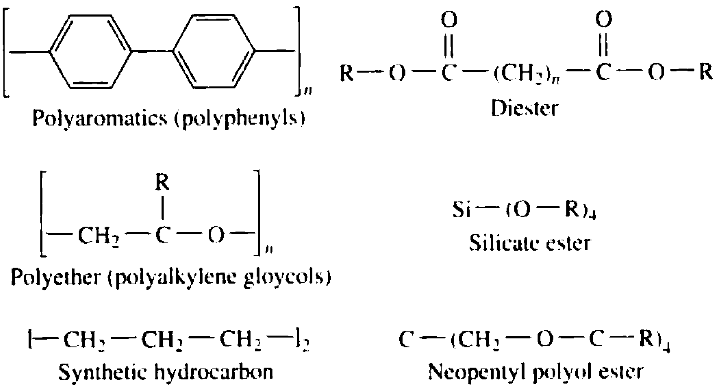
LITTLE, ARTHUR D. (1863–1935). Born in Boston, Little was a pioneer in the field of industrial research and chemical consulting. Originally an authority on paper technology, he established a consulting industrial chemical laboratory in 1886, which has since become a large institution of worldwide reputation, located in Cambridge, MA. It has served as a prototype of many industrially oriented consulting firms that have become a significant factor in the growth of research in the last half century. It has made significant contributions in such fields as flavors, food chemistry and acceptability, paper chemistry, and rubber chemistry, as well as in corporate management.

LOW-TEMPERATURE TECHNOLOGY. See **Cryogenics**.

LUBRICANT. A material used to diminish friction between the moving surfaces of machine parts; also to decrease friction between a cutting tool and the material being cut. A wide variety of materials is used for manufacturing lubricants. Animal lubricants are obtained from the fat of common animals and can be classified as hard fats (stearin) and soft fats (lard) or naturally occurring combinations. Vegetable lubricants include rape seed oil, cottonseed oil, soybean oil, castor oil, and linseed oil. They range in properties from solid to liquid. Petroleum and mineral oil lubricants, because of their greater stability, are usually preferred for machine applications. Lubricants range from light oils to very heavy solid greases. Graphite, a solid, is also used as a lubricant.

Because of increased requirements for lubricants, including higher temperature and pressure applications, greater durability, and tolerance to wide changes in ambient temperature conditions, numerous synthetic lubricants have been developed. These include synthetic hydrocarbons, carboxylic acid esters, silicones, polyethers (polyalkylene glycols), phosphate esters, silicate esters, highly fluorinated compounds, and polyaromatics (polyphenyls and polyphenyl ethers). In selecting a lubricant, the following characteristics are considered: (1) lubricity and antiwear properties; (2) fluid range; (3) viscosity index; (4) additive response of base oil; (5) oxidation stability; (6) thermal stability; (7) hydrolytic stability; (8) fire resistance; (9) compatibility with petroleum products; (10) compatibility with paints, plastics, and elastomers; and (11) cost.

Over a number of years, the early polyol esters, the formulas of some of which are shown below, appeared to be adequate for coping with the increasing rigorous properties required for increasingly difficult lubrication problems. They continue to be used, but some professionals in the field have developed a number of proprietary formulations that are claimed to be superior to the polyolesters.



More attention has been given to tribology, the scientific discipline of friction, wear, and lubrication. The underlying principles of tribology have been investigated intensively by a number of research groups, including the U.S. Naval Research Laboratory and physicists at the Georgia Institute of Technology, Atlanta, Georgia. Researchers are attempting to develop a better theoretical basis for understanding the processes that occur when two solid bodies move past each other at close to overlapping distances. Most of this new knowledge has stemmed from working models as well as from computer models. Researchers at the Georgia Institute of Technology have used a large Cray computer to predict what occurs when the tip of a thin nickel needle, for example, is pressed repeatedly onto a flat gold surface. The investigators initially employed quantum mechanics for answering such questions as adhesion, cohesion, and the making and breaking of chemical bonds. Researchers at the Naval Research Laboratory have used an atomic force microscope as a tool to check their experiments. The present goal is to model more complex systems. As pointed out by one researcher, "To make progress in the molecular engineering of lubricants, you need to know the molecular details of the process."

LUBRICATING AGENTS. There are two fundamental classes of lubricating agents—natural and synthetic.

Lubricating oils are fluids whose function is the reduction of friction and wear between solid surfaces (generally metals), in relative motion. This function is accomplished in either of two ways: (1) by formation of adsorbed films on the two opposed surfaces, which can be more easily sheared than the solid substrate, or (2) by interposition of a fluid film between the two opposed surfaces. In the former case the shear strength of the film, and in the latter, the viscosity of the fluid determine the magnitude of the work which must be done to maintain the opposed surfaces in relative motion. In most cases, bearings are designed to operate under fluid film conditions and thus the viscosity of an oil is its most important property in classifying it for lubricating purposes. The range of viscosities required is approximately 1 centistoke at 100°F (38°C) for high-speed, lightly loaded spindle bearings to approximately 4000 centistokes at 100°F (38°C) for some gear units. The great majority of oils used fall within a much narrower viscosity range of about 20–200 centistokes.

Aside from the primary function of friction and wear control, lubricating oils are often called on to serve other purposes, such as corrosion prevention, electrical insulation, power transmission and cooling. This last is particularly important in metal cutting and grinding.

As petroleum consists of a highly complex mixture of hydrocarbons and other organic compounds, the raw material must be carefully processed to separate the fractions which are desired for lubricating purposes. This is

generally accomplished by a combination of fractional distillation, solvent extraction and adsorption treatments to obtain various cuts which are blended if necessary, to produce the desired viscosity. A typical sequence of operations would be:

(1) Preliminary distillation of the crude petroleum to strip off volatile matter, i.e., dissolved gases and light hydrocarbons through the fuel oil range.

(2) Secondary vacuum distillation to separate the various lubricating oil fractions, which in some cases, may include the *residuum*. Since hydrocarbons tend to undergo thermal decomposition above 600°F (316°C), the distillation is generally carried out under vacuum to enable the higher-boiling fractions to be distilled.

(3) Solvent extraction to remove waxes, unsaturates, aromatics, asphalt, and nonhydrocarbon material.

(4) Contact with an adsorbent, e.g., activated clay, for final removal of polar impurities.

(5) Incorporation of special-purpose additives and blending to obtain the desired viscosity.

The lubricating oil fractions thus obtained consist of some of the largest and most complex hydrocarbon molecules to be found in crude petroleum. Their molecular weight ranges from about 250–1000 or more, based on structures containing 20–70 carbon atoms. They may be classified broadly as (1) straight-chain paraffins, (2) branched chain paraffins, (3) naphthenes (one or more saturated 5 or 6 membered rings with paraffin side chains), (4) aromatics (benzene ring structures with paraffinic side chains), and (5) mixed aromatic-naphthene-paraffin.

Of the above classes, the most desirable are the branched chain paraffins and the naphthenes. The refining processes are directed to increasing the concentration of these and removal of the others, as well as of organic compounds containing sulfur, oxygen, and nitrogen which are found in varying proportions in all crude petroleum.

Most hydrocarbons in the lubricating oil range are subject to low-temperature oxidation (180°F; 82°C and above) by atmospheric oxygen, particularly under the influence of catalysts such as metals (copper is particularly active), moisture, and occasionally nonhydrocarbon impurities. The paraffinic types show the greatest resistance to oxidation, followed by the naphthenes and the aromatics. An empirical rule states that the rate of oxidation approximately doubles for each 20°F (11°C) rise in temperature. Thus, in practice where long life of the oil is desired, bearing temperatures are held to around 150°F (66°C) as a maximum. In an internal combustion engine where temperatures at the sliding surfaces of the order of 400–500°F (204–260°C) are encountered, shorter life will result, e.g., 100 hrs. in an engine, compared with several years in a water-wheel generator.

Besides viscosity, the viscosity-temperature variation of lubricating oils is a most important property. It has been found that this behavior can be accurately expressed by the relation: $\log_{10}\log_{10}(v + 0.8) = b\log_{10}(t\,°F + 460) + c$ where v is the viscosity in centistokes, t the temperature in °F, and b and c are constants. In most cases an oil with the smallest viscosity-temperature variation is considered the more desirable. As a generalization, it may be said that the oils with the highest paraffin-to-naphthene ratios have the smallest change, while low paraffin-to-naphthene ratios correspond to a higher viscosity-temperature change. However, it is possible to dissolve materials in oil (e.g., olefinic polymers) which will effect a decrease in this variation.

While most bearings depend on the viscosity of the oil for the formation of a lubricating film (0.0001" to 0.002"; 0.0025 to 0.051 mm thick), there are many cases where this is not feasible and successful lubrication depends on the formation of very thin films (10 to 10^3 Å thick). This was generally thought to occur through preferential adsorption by the solid surface of polar compounds (e.g., napththenic acids, sulfur compounds) present in small amounts in the oil.

Another factor possibly contributing to the lubricating ability of very thin films is the variation of viscosity with pressure. The viscosity-pressure relationship is approximately $\log_{10} v = kP + c$ where P is the pressure and k and c are constants. Thus, at very high unit pressures of the order of 10^5 psi (690 MPa), viscosity increases of the order of 1000–10,000 times are encountered. This can account for a significant increase in load-carrying capacity. More recent work on rolling contact bearings has shown that these extremely high viscosities may be partially responsible for the observed formation of true hydrodynamic lubricating films in the 10^{-6} to 10^{-5} inch (0.00254–0.000254 mm) range.

Though the major portion of industrial lubricants is derived from petroleum, a small but significant portion is being obtained from other sources.

(1) Natural liquid fatty esters, such as lard oil, palm oil, sperm oil, etc. These are good lubricants but have poor chemical stability.

(2) Synthetic hydrocarbons, prepared by polymerization of olefinic hydrocarbons; these have good stability when saturated and good viscosity-temperature coefficients.

(3) Polyalkylene glycol oils, made by reaction of alcohols with polymerized ethylene and propylene glycols. They are either water-soluble or -insoluble. Fair stability (improved with additives), good viscosity-temperature coefficient, and good lubricating qualities.

(4) Synthetic esters, (a) primarily esters of dibasic acids such as adipic and sebacic, though in Europe some monobasic acid esters have been prepared and used; (b) organic esters of phosphoric and silicic acid, which have some advantage of being more fire-resistant than the other organic compounds but which are subject to hydrolysis on exposure to water.

(5) Silicone oils, which are linear and cyclic siloxane polymers of the formula $(-SiR_2O)_n$. They generally possess good thermal and oxidative stability, and good viscosity-temperature coefficients. When $-R$ is a hydrocarbon substituent their lubricating ability is poor. This can be somewhat improved by the introduction of aromatic halogen in $-R$.

(6) Halogenated hydrocarbons (chlorinated or fluorinated). These have good lubricating properties but very poor viscosity-temperature relations. The fluorinated materials are extremely stable.

(7) Perfluorinated polyalkylene glycols which have better viscosity-temperature behavior and temperature resistance.

(8) Polyphenyl ethers are very stable organic fluids which can be used in the 500–700°F (260–371°C) temperature range although, like the silicones, they do not have good boundary lubrication properties. These reportedly, however, can be improved with suitable additives.

Generally speaking, these synthetic materials are at present used primarily as specialty lubricants where the need for a particular property outweighs high cost, e.g., diesters as military aircraft engine lubricants. As synthetic processes are improved more extensive application may be expected.

Synthetic Lubricants

Chemistry has been the guiding science in creating the various classes of chemical lubricants. Each class is named in terms of the chemical structure involved and each has at least one property that is unobtainable with naturally occurring materials. In varying degrees and combinations, synthetic lubricants provide excellent lubricity over extremely wide temperature ranges, high thermal and oxidative stability, fire-resistance, and outstanding resistance to nuclear radiation. Other noteworthy advantages of synthetic lubricants are the ease with which physical or performance properties can be altered by chemical modification or the incorporation of additives. The facility with which modifications can be achieved makes it possible for the chemists to tailor individual members of the family to meet exactly the requirements of a particular application. Compromises in properties are likewise made to obtain a satisfactory lubricant at lowest cost.

Polyglycols. $RO(CH_2CHR'O)_xR''$, where R's can be hydrogen and/or organic groups. Terminal groups determine the type of polyglycol such as diol, monoether, diether, ether-ester, etc. Various alkylene oxides including mixtures are the basic raw materials. The major attributes of the polyglycols are viscosity-temperature characteristics, volatility of products of decomposition, relatively low cost, and the wide variety of properties (water-soluble to organic-soluble) obtainable by structural variations. Major uses are as lubricants in automotive hydraulic brake fluids and water-based hydraulic fluids, as compressor lubricants, textile lubricants and rubber lubricants, and in greases where the polyglycol is the carrier for solid lubricants.

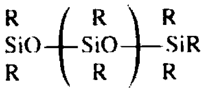
Phosphate Esters. $R'OP(O)(OR'')(OR''')$ where at least one R represents an organic group while the remaining represent organic groups or hydrogen. These products are prepared from phosphorus oxychloride or phosphoryl chlorides plus phenols, alcohols or their sodium salts. The tertiary phosphate esters are often classified as triaryl, trialkyl, and alkyl aryl phosphates. The primary and secondary phosphates are used extensively as lubricant additives in various chemical forms. Phosphate esters are best known for their fire-resistant characteristics, and as a result

have found extensive application as industrial and aircraft lubricants and hydraulic fluids.

Dibasic Acid Esters. These can include both simple and complex materials. The simple dibasic acid esters, ROOCR′COOR″ are made by reacting a dibasic acid, such as sebacic acid, with a primary branched alcohol, such as ethyl hexanol. Complex esters are prepared by reacting a dibasic acid with a polyglycol, such as polyethylene glycol, and capping the chain with a branched primary alcohol or a monobasic acid. The outstanding characteristics of the dibasic acid esters are favorable viscosity-temperature characteristics, excellent lubricating ability, and high stability. Because of this combination of properties, these products are now used as lubricants in almost all aircraft turbine engines.

Chlorofluorocarbons. The polymerization or telomerization of chlorotrifluoroethylene is the route to these relatively low-molecular-weight synthetic lubricants. Manufacture involves elaborate polymerization techniques and stabilization methods to eliminate all of the hydrogen and terminal chlorine introduced into the polymer chain by peroxide fragments or the chain transfer agent. The major characteristics of the chlorofluorocarbons are chemical inertness and thermal stability. Industrial and aerospace applications involving exposure to corrosive or oxidizing atmospheres are the largest uses for these lubricants.

Silicones.



where the R's may be the same or different organic groups. The properties are varied by the use of different types of organic substituents; the most popular are methyl, phenyl, and chlorophenyl groups. Recent advances involve fluorine-containing substituents. Manufacture entails the preparation of organochlorosilane intermediates, hydrolysis and condensation of these intermediates, and polymer finishing. In addition to good stability and low volatility, silicones have the best viscosity-temperature characteristics of any lubricant. Although they perform well under many conditions of lubrication, silicone lubricants are generally unsatisfactory for situations involving sliding contact of steel-on-steel. The many and varied uses include lubricating electric motors, precision equipment, plastic and rubber surfaces, and as greases for antifriction bearings.

Silicate Esters. ROSi(OR′)(OR″)(OR‴), where the R's may be similar or dissimilar groups. The best-known types are the tetraalkyl, tetraaryl, and mixed alkylaryl orthosilicates. The classic means of preparation is through the reaction of phenol or alcohol with silicon tetrachloride. A closely related group of products, the hexaalkoxy- and hexa-aryloxydisiloxanes, is also generally included in the silicate esters classification. These products, the so-called "dimer silicates," are conveniently made by the reaction of an alcohol or phenol with hexachlorodisiloxane. Notable characteristics of the silicate esters are low volatility, low-temperature fluidity, and thermal stability. The hydrolytic stability varies from poor to good, depending upon chemical structure. The products are used as high-temperature heat-transfer fluids, wide-temperature range hydraulic fluids, electronic coolants, and automatic weapon lubricants.

Neopentyl Polyol Esters. These polyesters are prepared by the esterification of 5-carbon polyfunctional alcohols with mono-functional acids. Because the beta carbon of the starting alcohol does not contain hydrogen, these esters are superior in thermal stability to the diesters. Most of the other characteristics are similar to those of the diesters. As a result of their superior stability, the neopentyl esters are finding increasing use as the lubricant for aircraft turbine engines.

Polyphenyl Ethers. Both alkyl-substituted and unsubstituted polyphenyl ethers are included in this class of synthetic lubricants. General preparation involves the Ullman ether synthesis. The unsubstituted polyphenyl ethers have outstanding thermal, oxidative and radiation resistance, however, poor low-temperature characteristics are a major drawback. Alkyl substitution improves low-temperature viscosity, but detracts from stability. Most lubricant uses are developmental in nature and involve aircraft and aerospace applications.

Lubrication

Lubrication is the process of separating two rubbing solid surfaces by means of a layer which is effectively "softer" than either surface. Depending upon circumstances, the "soft" layer (the lubricant) may be a gas, a liquid, a solid, or a combination of various phases. The many ways of accomplishing lubrication can be conveniently grouped into two categories: hydrodynamic and solid lubrication.

Hydrodynamic Lubrication. The separation of moving surfaces by a "fluid" (gas, liquid, or gel) is accomplished according to the laws of hydrodynamics. One of the surfaces "swims" on the lubricant, i.e., it is lifted through the simultaneous possession of velocity relative to the lubricating fluid and of an acute angle of attack. This so-called glider bearing is the basis of design of nearly all fluid-lubricated bearings, including the journal bearing, which is just a circular glider bearing.

The basic relation which expresses the load-carrying ability of a glider bearing can be given in the form:

$$W/\eta U = a(r/h) \tag{1}$$

where W is the load on the glider, U the velocity of the glider relative to the stator, h is the minimum distance between the rubbing surfaces, r is a dimension characterizing the angle of attack, a is a numerical coefficient (somewhere between 1 and 10) and η is the viscosity of the lubricating fluid under the temperature and pressure conditions of the application. The energy expenditure required for the service performed by the lubricant film is usually expressed in terms of the friction coefficient, f, defined as the ratio of the frictional force required to move the glider (or the journal) to the load carried by it. For the case under discussion:

$$f = K\sqrt{\eta U/W} \tag{2}$$

where K is a numerical coefficient which depends upon the geometry of the system and varies between about 2 and 6.

While Equations (1) and (2) provide only a qualitative guide— the detailed calculations for specific bearings are quite complicated— they clearly indicate that the only variable at the disposal of the chemist, the viscosity, will be chosen such as to give the maximum load-carrying ability of the bearing consistent with a reasonable amount of frictional energy lost in the lubricant.

The low friction losses (f is usually of the order 10^{-3}) and the naturally wear-free operation generally make the maintenance of hydrodynamic lubrication the primary aim of bearing design. This goal is attained perfectly only with journal and with glider (pad) bearings and to some extent in roller bearings. It can be achieved by a special mechanism (thermal expansion of the flowing fluid) in parallel thrust bearings. Its attainment is uncertain (and not readily subject to calculation) in ball bearings and in gear lubrication.

Since the viscosity of readily available fluid varies over a 10^{10}-fold range between gases and the thickest liquids, and the temperature and pressure coefficients of viscosity vary similarly over an about 10^4-fold range, the choice of a suitable lubricant is usually determined by the ancillary conditions of temperature, volatility, chemical stability, etc. The use of sulfuric acid as lubricant for oxygen compressors is a typical illustration of a choice dictated by chemical conditions. The evaporation and deterioration of liquid lubricants in high energy particle fluxes and/or in hard vacua ($< 10^{-9}$ torr) has led to increased use and rapid development of gas lubricated bearings. These call generally for extremely high and therefore very costly standards of workmanship. Hence the use of gas lubrication is at present largely restricted to precision instruments and to military and space applications.

The most important source of lubricants is petroleum. There is hardly a chemical species (esters, ethers, sulfides, metal-or-ganic compounds, etc.) which has not contributed to the array of synthetic lubricants now available. Some chemicals, such as the perfluorocarbon compounds and the siloxane polymers were originally synthesized for just this service.

Elastohydrodynamic Lubrication. Well designed and equally well built machine elements with very smooth bearing surfaces permit the imposition of very high bearing loads. The resulting elastic deformation of the bearing may then change the geometry of the load-bearing surfaces substantially. Hence the elastic properties of the load-bearing materials enter the bearing calculations. The change of lubricant properties with pressure, temperature, and with the duration of exposure to the pressure and shear regime also enter the bearing calculations. The required viscoelastic properties of lubricants at high-frequency deformations are only beginning to be determined.

Hydrostatic Lubrication. Slow-moving or even static "gliders" can be separated from the bearing surface by a fluid film if the hydrostatic pressure required to carry the load is provided by an external source, as for instance

by a pump. The very large journals of turbo generators, or heavy thrust bearing pads are generally lifted by these means before the onset of rotation in order to avoid scoring damage to the valuable bearings. Exceedingly low friction coefficients are obtained in these hydrostatic bearings, the most spectacular being that of the Mt. Palomar 200-inch (508 cm) telescope mirror pad bearings, where $f = 0.000004$, such that the 500-ton (450 metric ton) structure is easily moved by a $\frac{1}{2}$ HP clock motor.

Solid Lubrication. While fluid film separation of rubbing surfaces is the most desirable objective of lubrication, it is often unattainable, especially when bearings are too small or unsuitable for liquid lubricants. Even bearings built for full fluid lubrication during most of their operating periods experience solid-to-solid contact when starting and stopping.

Solid surfaces in rubbing contact are characterized by friction coefficients varying between 0.04 (Teflon on steel) and >100 (pure metals *in vacuo*). Solid lubrication, in contrast to fluid lubrication, is generally accompanied by a certain amount of wear of the rubbing parts. Optical inspection of the surfaces after rubbing reveals macroscopic (i.e., bulk) damage of the metal both when unlubricated and when lubricated. Quantitative differences between the two cases are easily measured radiographically when a radioactive glider has been used. In this manner it is found that effective solid lubrication can reduce the amount of wear—compared to the dry case— by a factor as high as 10^5.

Typical solid lubricants are the soft metals lead, indium, and tin, the layer lattice crystals graphite and molybdenum disulfide, many soft organic solids, such as metallic soaps, and waxes as well as the crystalline polymers Teflon (polytetrafluorethylene), polythene (polyethylene), and nylon. The integral bonding of these solids to the surface of the hard solid to be lubricated is essential for good performance. The bonding is accomplished either by alloying (copper-lead bearing metals), by flash coating, by introduction of the lubricating solid into the interstices of the sintered metal bearing (Teflon emulsion into sintered bronze), by chemical coating (phosphate coatings), or by anchorage to a phosphate or bonded plastic coating.

Special cases of solid lubrication are boundary and EP (extreme pressure) lubrication. In both cases the solid lubricant is formed by chemical reaction of special compounds, usually applied as oil solutions, with the metallic rubbing surfaces. Typical boundary lubricants are the fatty acids which react with the metal surface to form metallic soaps which then carry the load. Strongly adsorbed but nonreacting substances of linear structure, such as long chain fatty alcohols, can also act as boundary lubricants but only under very mild conditions.

Under the very severe conditions, sometimes encountered in automobile transmissions and especially in hypoid gear differentials as well as in machining operations, only those substances act as lubricants which contain chemically active chlorine, sulfur, or phosphorus to form the corresponding iron chloride, sulfide or phosphide by instantaneous attack on the surface hot spots resulting from the collisions of surface asperities. The chemical stability of these so-called E.P. agents is designed to permit activity at the temperature near the rubbing surface, say 200°C and above, but not be corrosive under normal conditions.

Mixed Film Lubrication. Mixed film lubrication is almost invariably the true state of affairs when boundary and EP lubrication are encountered, i.e., an appreciable fraction of the load is carried by the fluid film in the "valleys" of the surface while the asperities in contact are permitted to carry the balance of the load without seizure through the beneficent intervention of the boundary or EP lubricant. The very important breakin process of rubbing surfaces consists in the controlled reduction of the number and the size of the surface asperities so that fluid lubrication will prevail for most of the time.

"Real" Lubrication. In "real" lubrication of machinery, such as automotive engines, turbines, etc., the lubricating oil has to perform many functions besides lubrication. The most important of these is the cooling of the bearings. It also has to keep internal combustion engines clean by dispersing the partial combustion products of the fuel and its own degradation products, it has to carry chemicals to counteract wear, and—in common with many other lubrication applications— it must prevent corrosion of the equipment and be inhibited against its own deterioration in service. A relatively large amount of synthetic organic chemicals is therefore carried by many oils to perform the additional functions which one must expect from a modern lubricant.

Ideally one should always have full fluid separation of rubbing surfaces. But in inaccessible locations, or reactive environments, or under conditions of very slow motion or of intermittent operation, recourse must be had to solid lubrication.

LUMINESCENCE. A characteristic nonthermal emission of electromagnetic radiation by a material upon some form of excitation. Some luminescent materials are called phosphors. E. Wiedemann defined the term in 1888 as "all those phenomena of light not solely conditioned by the rise in temperature."

Whereas the output from blackbody radiators consists of broad-band emissions which follow the Stefan-Boltzmann temperature relationships, luminescence emission from phosphors consists of relatively narrow bands, which do not follow the blackbody laws. Thus, light emission due solely to the temperature of a source is referred to as *incandescence*, while *luminescence*, unlike incandescence, is a function of the specific material involved. Although *fluorescence* and *phosphorescence* are sometimes used synonymously with luminescence, a more rigid definition of *fluorescence* would be luminescence having a persistence (afterglow) shorter than about 10^{-8} second, with *phosphorescence* being longer than 10^{-8} second.

The luminescence process itself involves (1) absorption of energy; (2) excitation; and (3) emission of energy, usually in the form of radiation in the visible portion of the spectrum. The *type* of luminescence is usually defined by the excitation means, i.e., *cathodo*luminescence where excitation is by cathode rays, as in a television kinescope. The most commonly encountered types of luminescence are listed in Table 1.

The luminescent material may be considered as a transformer of energy, i.e., from ultraviolet photons to photons of lower energy; from cathode rays to photons; from electric fields to photons, etc. An inorganic luminescent material, or phosphor, usually consists of a crystalline host material to which is added a trace of an impurity (activator and coactivator).

Chemiluminescence

Numerous chemical reactions produce heat, but relatively few release their energy as light. This latter phenomenon is termed *chemiluminescence*. As pointed out by researchers at the University of Wales College of Medicine, Cardiff. "Absorption of energy by an atom or molecule raises an electron to a higher energy level. This is known as an 'excited state' and is inherently unstable. When the electron drops back to its ground state the energy must either be transferred to another atom or molecule, be released as heat or be emitted as light. The decay of the electron to ground state is very fast, occurring within 1–10 nanoseconds (10^{-9}–10^{-8} second)."

In chemiluminescence, the chemical reaction raises an electron to a higher level, which then decays back to the ground state, releasing a photon of light, the energy of which is predictable by Einstein's equation. When the energy drop is large, the light is blue; if small, the light is red. Inasmuch as the electronic excitation-decay process is extremely fast, the intensity of light in chemiluminescence is determined by the kinetics of the chemical reaction.

The distinction of chemiluminescence from fluorescence results from two factors:

1. When an atom or molecule fluoresces, it remains chemically unchanged and can be immediately be reexcited once light emission has occurred.

TABLE 1. TYPES OF LUMINESCENCE

Luminescence Type	Excitation Source	Example
Photoluminescence	Photons	ZnS Ag
Cathodoluminescence	Cathode Rays	$Zn_2SiO_4 \cdot Mn$
Electroluminescence	Electric Fields	Zn (S · Se) · Cu
Chemiluminescence	Chemical Reactions	Oxidation of Luminol
Bioluminescence	Biochemical Reactions	Luciferin
Triboluminescence	Mechanical Disruption	ZnS·Mn

2. In chemiluminescence, each molecule only reacts once to form an excited state, while the excited product (actual emitter) has a different chemical structure from the initial substrate.

See also **Bioluminescence**.

Light-Emitting Diode (LED)

Recombination of injection electroluminescence was first observed in 1923 by Lossew, who found that when point electrodes were placed on certain silicon carbide crystals and current passed through them, light was often emitted. Explanation of this emission has been possible only with the development of semiconductor theory. If minority charge carriers are injected into a semiconductor, i.e., electrons are injected into *p*-type material or "positive holes" into *n*-type material, they recombine spontaneously with the majority carriers existing in the material. If some of these recombinations result in the emission of radiation, electroluminescence results. Minority-carrier injection may occur not only at point contacts, but also at broad area rectifying junctions: in this case, the junction must be biased in the forward or "easy flow" direction, and the electric field in the junction is lower when the voltage is applied than in its absence. This type of emission has been observed in several materials, including SiC, diamond, Si, Ge, CdS, ZnS, ZnSe, ZnO, and some of the so-called III–V compounds, such as AlN, GaSb, GaAs, GaP, InP, and InSb. The emission of many of these materials lies in the infrared region of the spectrum. For radiation in the visible region (instead of the infrared), the energy difference between the holes and electrons (band gap of the semiconductor) must be more than 1.8 eV. Numerous materials satisfy this requirement, notably those used for cathode-ray tube phosphors, but the materials present difficulties in fabricating *p-n* junctions and thus are not candidates for light-emitting diodes.

The list of materials for LEDs includes GaP, GaAsP, GaAlAs, GaN, and SiC. The two materials of choice to date have been GaP and GaAsP. Early commercial LEDs were made from $GaAs_{0.6}P_{0.4}$ deposited epitaxially as a thin layer on a GaAs crystal substrate. With these, *p-n* junctions were made, using diffusion techniques similar to those used in making silicon diodes. The band gap is 1.92 eV. There is an emission band of red light with a peak at about 650 nm, resulting from direct recombination of electrons and holes.

GaAsP has a high index of refraction, and consequently only light emitted toward the surface (4%) is usable—the remainder is reflected back. A diode can be encapsulated in epoxy material to take on the shape and form of a lens. These diodes are particularly effective where a number are fabricated in close proximity on a single-crystal chip.

Diodes that emit light in shorter wavelengths (green, yellow, etc.) can be made by increasing the phosphorus content, but only up to about 40% because of rapid decrease in efficiency. Efficiency can be increased by incorporating nitrogen atoms into crystals. The N atoms act as isoelectronic centers, trapping electron-hole pairs in an excited state. Three types of nitrogen-doped diodes have gained some importance: $GaAs_{0.65}P_{0.35}$ (orange light); $GaAs_{0.85}P_{0.15}$ (yellow light); and GaP (green light). Zinc and oxygen doping are also used. Diodes operate more efficiently if driven with periodic pulses of high current rather than with constant current. The short response time of junction diodes to current pulses (a fraction of a microsecond) and their rectifying property (they block current flow in the reverse, nonemitting direction) combine to make the diodes a good choice for *X-Y* addressing arrangements.

LUTETIUM. [CAS: 7439-94-3]. Chemical element symbol Lu, at. no. 71, at. wt. 174.97, fourteenth and last element in the Lanthanide Series in the periodic table, mp. 1,663°C, bp 3,402°C, density 9.841 g/cm³ (20°C). Elemental lutetium has a close-packed hexagonal crystal structure at 25°C. The pure metallic lutetium is silver-gray in color and retains its luster at room temperature indefinitely. Although not as extensively studied as most of the other lanthanides, most of the basic properties of lutetium are known, and it behaves as a normal trivalent metal with no magnetic transitions because its 4*f* levels are completely filled. There are two natural isotopes ^{175}Lu and ^{176}Lu. The latter isotope is radioactive with a half-life of 2.2×10^{10} years. Fourteen artificial isotopes are known. The element was first identified by G. Urban in 1907 and independently by C.A. von Welsbach in 1908. Although not investigated fully, lutetium is classified with a low acute-toxicity rating. Lutetium is the least abundant of the Lanthanide elements, estimated as present on the average of 0.5 ppm in the earth's crust. Potentially, however, it is more plentiful than mercury, cadmium, or any of the precious metals. Electronic configuration

$$1s^2 2s^2 2p^6 3s^2 3p^6 3d^{10} 4s^2 4p^6 4d^{10} 4f^{14} 5s^2 5p^6 5d^1 6s^2$$

Ionic radius Lu^{3+} 0.848 Å. Metallic radius 1.735 Å. Other important physical properties of lutetium are given under **Rare-Earth Elements and Metals**.

The source of lutetium to date has been the processing of the other heavy rare-earth metals. Because of very limited availability, little research was conducted on lutetium until the mid-1960s. Most of these studies now are concentrating on prospective uses in phosphors, semiconductor, and other electronic circuitry components. A lutetium dithalocyanine complex has received much consideration recently for application in large, thin screens for television projection.

LUTIDINES. See **Coal Tar and Derivatives**; **Pyridine and Derivatives**.

LYOPHILIC. Characterizing a material that readily goes into colloidal suspension in a liquid; if into water, it is called *hydrophilic*. The colloid is stabilized by the formation of an adsorbed layer of molecules of the dispersing medium about the suspended particles. Systems of this type are said to be lyocratic. Examples include glue, gelatin, and milk-fat particles.

LYOPHOBIC. Characterizing a material that exists in the colloidal state but with a tendency to repel liquids; if the liquid is water, the material is called *hydrophobic*. Such colloids are generally stabilized by the adsorption of ions and coagulate when the charge is neutralized. Examples include colloidal gold, and colloidal arsenic sulfide.

LYSINE. See **Amino Acids**.

M

MACERATE. (1) To soften or break up a fibrous substance by long soaking in water at or near room temperature, often accompanied by mechanical action, as in the preparation of paper stock in the beater. (2) In the plastics industry, to comminute a fabric so that it can be used as a filler in a plastics composition. (3) The term is also used in pharmacy to describe a method of preparing medicinal compositions.

MACROMOLECULAR SCIENCE. Macromolecules or polymers are now such a common feature of modern life that it is sometimes forgotten that the rapid development of such materials in industry has taken place in the last 60 years. In fact, the idea that such molecules exist was proposed by Staudingser, Mark, and coworkers in the 1920s and it was some time before these concepts were accepted by the scientific community.

Polymers are long-chain molecules synthesized by the linking together of a large number of identical or similar small units termed *monomers*. The large size of macromolecules leads to their many useful properties. Macromolecular science is the study of these properties in relation to their chemical and physical structure. Naturally occurring or biological macromolecules, such as proteins, carbohydrates, nucleic acid, and natural rubber, are studied by the same methods as synthetic polymers, resulting in a number of industrial and biomedical applications.

In response to the needs of industry, a number of centers for graduate study in macromolecular science have developed. The first such center was at Brooklyn Polytechnic Institute (now Polytechnic University) and large centers now exist at Case Western Reserve University in Cleveland Ohio (Fig. 1), University of Massachusetts (Amherst) and University of Akron (Ohio). The first accredited engineering undergraduate degree program in polymer science was developed in the Department of Macromolecular Science at Case Western Reserve University.

In the past, research emphasis has centered on the synthesis of new macromolecules. This is still a major emphasis, especially as applied to the production of new polymers or composite systems having unique electrical and/or mechanical properties and to the synthesis and fabrication of unique transport and barrier membranes. Such research areas relate directly to the current emphasis on high tech, high price products rather than on bulk commodity polymers.

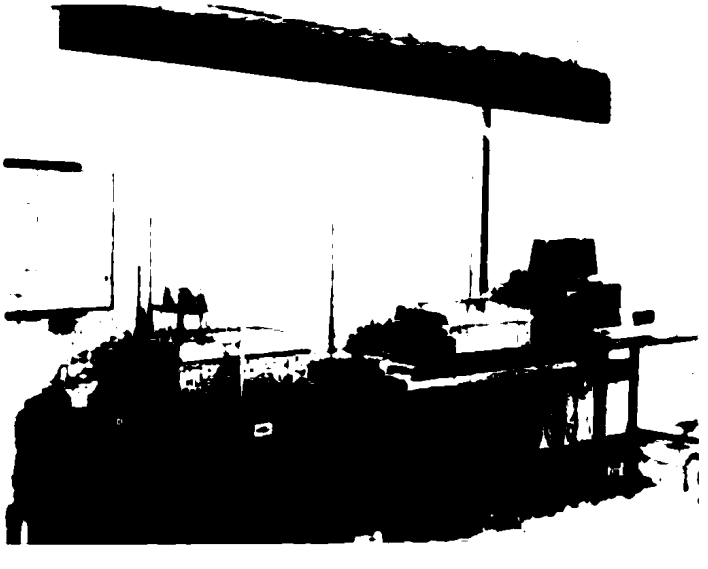

Fig. 1. Automated Langmuir-Blodgett deposition station used for production of ultrathin films and located in a clean room at the Polymer Microdevice Laboratory, Case Western Reserve University, Cleveland, Ohio

At least equally important in aiding in the solution of current problems of society has been the development, primarily over the past ten years, of the fields of polymer physics and engineering. The general thrust of this development has been to gain an understanding of the physical structure and morphology of macromolecules and to develop methods to modify these parameters to produce useful properties in both polymer and composite systems. See accompanying illustration. See also **Macromolecule**; **Molecular and Supermolecular Electronics**; and **Colloid Systems**.

MACROMOLECULE. A molecule, usually organic comprised of an aggregation of hundreds or thousands of atoms. Such giant molecules are in general of two types: (1) Individual entities (compounds) that cannot be subdivided without losing their chemical identity. Typical of these are proteins, many of which have a molecular weights running into the millions. (2) Combinations of repeating chemical units (monomers) linked together into chain or network structures called polymers. Each monomer has the same chemical constitution as the polymer, e.g., isoprene (C_5H_8) and polyisoprene $(C_5H_8)_x$. Synthetic elastomers (plastics) are typical of this kind of macromolecule. Cellulose is the most common example found in nature. Most macromolecules are in the colloidal size range.

MAGNESITE. The mineral magnesite is carbonate of magnesium, $MgCO_3$. It is a hexagonal mineral, but usually found massive. It has a rhombohedral cleavage; conchoidal fracture; brittle; hardness, 3.5–4.5; specific gravity, 3.75–4.25; luster, vitreous to dull; color, white, gray, yellow, or brown; transparent to opaque. Most magnesite is believed to have been derived from the action of carbonated waters upon rocks rich in magnesium. Magnesium-bearing waters, on the other hand, may have in some cases acted upon calcite or dolomite. Magnesite deposits are known in Greece, Austria, Norway, India, Australia, and the Republic of South Africa. In the United States, magnesite is found in California and Nevada, some of which deposits seem to be of original sedimentary character. Magnesite is in demand for the manufacture of refractories and various compounds of magnesium.

MAGNESIUM. [CAS: 7439-95-4]. Chemical element, symbol Mg, at. no. 12, at. wt. 24.305, periodic table group 2, mp 649°C, bp 1,090°C, critical temperature (calculated) 1,867°C, density 1.74 g/cm³ (20°C), 1.64 g/cm³ (solid at 650°C), 1.57 g/cm³ (liquid at 650°C). Elemental magnesium has a close-packed hexagonal crystal structure, as do the common alloys of magnesium except those that contain lithium in excess of 11%.

Magnesium is a silver-white metal, malleable and ductile when heated; unattacked by dry oxygen, by H_2O or alkalis at room temperature; when heated to about 800°C reacts in air or steam and emits a brilliant white light of high actinic power; reactive with acids including carbonic at room temperature; reactive upon heating with nitrogen, phosphorus, arsenic, sulfur, in some cases with such vigor as to constitute a hazard.

Magnesium occurs extensively in the earth's crust, ranking 8th among the chemical elements in terrestrial abundance. An average composition of igneous rocks contains 2.09% magnesium. Of the elements present in seawater, magnesium ranks 5th with an estimated 6,125,000 tons of magnesium per cubic mile (1,323,000 metric tons per cubic kilometer) of seawater, its content exceeded only by hydrogen, oxygen, sodium, and chlorine. Magnesium is a constituent of over 150 minerals and also is found in bitterns and subterranean brines and salt beds. Only a few magnesium minerals are important commercially, notably dolomite, $CaO \cdot MgO \cdot 2CO_2$, as a source of magnesium. See also **Dolomite**. More than half of metallic magnesium produced is extracted from seawater. There are three naturally occurring isotopes, ^{24}Mg through ^{26}Mg; and three radioactive isotopes have been identified, ^{23}Mg, ^{27}Mg, and ^{28}Mg, all with comparatively short half-lives measured in seconds, minutes, or hours. The first known magnesium compound to be isolated was Epsom salt, $MgSO_4$, which Nehemiah Grew obtained in 1695 by evaporating the mineral waters at Epsom, England. In 1754, Joseph Black demonstrated that magnesia and lime were two different substances, but the exact identify of magnesia was not reported until 1808 by Sir Humphrey Davy who demonstrated that magnesia was an oxide of a heretofore unknown element. He first termed the element magnium. Metallic magnesium was first isolated by A. Bussy in 1828 when he fused magnesium chloride with potassium. Michael Faraday produced the first magnesium metal electrolytically in 1883. First ionization potential 7.64 eV; second, 14.97 eV. Oxidation potential $Mg \longrightarrow Mg^{2+} + 2e^-$, 2.375 V; $Mg + 2OH^- \longrightarrow Mg(OH)_2 + 2e^-$, 2.67 V. Other important physical properties of magnesium are given under **Chemical Elements**.

Production

There are two principal magnesium production processes: (1) electrolytic, and (2) metallothermic reduction. Electrolytic processes account for 80% of commercial production. In this process, seawater is pumped into large settling tanks where it is treated with lime. Roasted oyster shells sometimes are used if a convenient source is nearby. The lime precipitates the magnesium as the insoluble hydroxide. The hydroxide is filtered and then converted into a slurry with fresh H_2O. Subsequent treatment with HCl converts the $Mg(OH)_2$ into $MgCl_2$. The latter compound is dried and then electrolyzed in the fused state to produce molten magnesium and chlorine gas. The latter is recycled. The magnesium is cast into ingots. In the thermal or ferrosilicon process, used in some European countries, a mixture of magnesium oxide and powdered ferrosilicon (an iron-silicon alloy) is fed into a retort and heated under vacuum to about 1,200°C. The magnesium is freed in the form of vapor and condenses into crystals at the cool end of the retort. The crystals then are remelted and cast into pigs.

Uses of Magnesium

Magnesium finds principal uses as a primary metal to which other metals are added in various alloying amounts to enhance the properties of magnesium. Magnesium is the lightest of all structural metals and consequently the metal has enjoyed much attention over the years in connection with the transportation industry, notably for applications in the aircraft, aerospace, and automotive industries. Vehicle designers constantly are aware of the additional power requirements for simply moving "dead weight" that wastes fuel and contributes to air pollution.

In addition to its use as a structural metal, magnesium is an important metallurgical chemical in the form of a deoxidizer and desulfurizer and as the constituent of numerous industrial and laboratory chemical compounds.

Magnesium Alloys. Even prior to the use of magnesium as a structural metal in the aerospace field, in 1921, Louis Chevrolet put a set of magnesium-alloy pistons in the Ford racing car that won the Indy 500 for him that year. The magnesium pistons gave racing and sports cars faster acceleration and deceleration. This application of magnesium was not intended so much as a dead-weight savings feature for the car, but rather more in terms of inertia (obviously also relative to weight). Although the magnesium pistons provided better acceleration/deceleration because of smaller inertia, the early designers encountered what is known as piston slap, which results when the piston material has a considerably higher coefficient of thermal expansion than the cylinder material does.

The use of magnesium castings for auto wheels was introduced a few years later and also serves the principal purpose of reducing inertia. With wheels, it is not just faster acceleration/deceleration that can be achieved, but also minimizing the amount of unsprung weight for a smoother and easier-to-control ride and minimizing the problem of gyroscopic action of the rapidly spinning wheels. Designers of racing cars switched from wire-spoke wheels to magnesium-alloy wheels in the early 1950s. The use of magnesium has increased not only in racing cars, but some passenger cars, both for the purpose of reducing inertia and weight. Today, magnesium is used for transmission and differential housings and a variety of other racing car parts. Serious attention continues to be given to major engine components, such as the cylinder block, head, and oil sump, all of which are candidates for reducing dead weight and increasing fuel economy.

The most extensive use of magnesium castings in automobiles commenced in 1936, with the introduction of the Volkswagen Beetle. Each Beetle used from 40 to 50 pounds (18 to 23 kg) of primary magnesium ingot plus scrap metal.

Magnesium has a density only $\frac{2}{3}$ that of aluminum, $\frac{1}{4}$ that of zinc, and about $\frac{1}{5}$ that of irons and steels. In addition to the obvious aerospace and automotive applications, other applications include hand trucks, containers, materials-handling equipment, portable electric and pneumatic tools (such as chain saws), hand tools, luggage, sporting goods, dockboards, and tooling jigs and fixtures. It has been found that lighter-weight equipment significantly reduces accidents and lost time due to injuries. On an arbitrary scale, where the power required to machine magnesium alloys is 1.0, the figures for other metals are: aluminum alloys, 1.8; brass, 2.3; cast iron, 3.5; mild steel, 6.3; and nickel alloys, 10.0.

Some magnesium alloys are listed in Tables 1 and 2.

Magnesium in Other Metal Alloys. Magnesium is an important alloying ingredient in the production of other base metal alloys. When added during metallurgical processing, magnesium in small amounts has a marked effect on final properties of the metals:

Aluminum—Magnesium increases resistance to corrosion, facilitates heat treatment, and increases most mechanical properties. If magnesium-containing aluminum is remelted, the magnesium may be lost and should be replaced by adding pure magnesium to the casting ladle or pot.

Copper—Magnesium improves tensile strength and allows age hardening. Magnesium is used mainly as a deoxidizer, notably in copper-nickel-zinc alloys and in leaded brasses and bronzes. The magnesium is added during melting.

Lead—Magnesium increases hardness, strength, and resistance to creep. Magnesium also is used as a debismuthizer in refining primary lead.

Nickel—Magnesium, in combination with carbon, forms an age-hardenable alloy. The main use of magnesium is to deoxidize and desulfurize the melts, including pure nickel, nickel-chrome, and nickel-copper alloys.

Tin—Magnesium increases hardness and tensile strength. The effect of magnesium on tin can be dramatic. However, too much magnesium will reduce corrosion resistance and ductility.

Zinc—Magnesium improves dimensional stability and reduces the intergranular corrosion of zinc die castings. Magnesium refines the grain and increases hardness and creep strength of zinc sheet. Magnesium also is used in zinc-base bearing metals and in zinc alloy metalworking dies.

Magnesium alloy extrusions have become very popular for numerous items in recent years. Extrusion is particularly attractive as a parts making method—when extruded parts and sheet can be easily joined to form an assembly, where the desired shapes are too costly to machine from castings, and where pieces cut from extrusions can replace individually cast or forged parts. Final products with outstanding performance qualities coupled with light weight include concrete hand finishing tools, tennis racquets, portable shelters for the military, snowshoes, and improved luggage, among others.

The use of magnesium composites has become popular for rotary engine parts. Rotary engines remain attractive for business aircraft, boats, industrial equipment and compressors, and well over a million rotary-engine-powered cars have been built. In a research program (NASA

TABLE 1. REPRESENTATIVE MAGNESIUM ALLOYS

Alloy designation	Elements added	Tensile strength 1,000 psi	Brinell hardness	Melting point°C	Forms available	Features
AZ31B	3% Al 1% Zn	29	49	627	Sheet, plate, extrusions, forgings.	Moderate strength, good formability, general-purpose alloy. Dent resistant, weldable.
AZ91B	9% Al 0.6% Zn	33	67	596	Die casting alloy.	Good strength and castability. Popular for portable tools, business machines, vehicles.
AZ91C	8.7% Al 0.7% Zn	40	53	596	General-purpose sand and permanent-mold casting alloy.	Good castability, pressure tightness, and weldability. Moderate strength.
HK31A	3% Th 0.7% Zn 0.7% Zr	38	57	649	Sheet and plate for aerospace uses. (200–370°C). Sand and permanent-mold castings.	Good short-time, elevated temperature characteristics. Weldable without stress relief. Low microporosity in cast form.
HM21A	0.6% Mn 2% Th	35	56	650	Sheet, plate, forgings for aerospace uses. (200–425°C)	Very stable at elevated temperatures. Good creep strength and formability. Weldable without stress relief.
HM31A	1.2% Mn (min) 3% Th	44	63	605	Extrusions for aerospace uses. (200–425°C)	Excellent elevated temperature properties. Weldable without stress relief.
QE22A	2% Pr 0.7% Zr 2.5% Ag	40	78	549	Castings for aerospace uses. (up to 260°C)	Superior tensile strength plus excellent creep and fatigue strength.
ZK60A	5.7% Zn 0.5% Zr	47	—	635	Highly stressed parts of aerospace and military uses. Used as a forging alloy.	High strength, good toughness, good spot-weldability. Limited arc-weldability.

Note: 1 psi(pounds/square inch) = 0.0069 megapascal (MPa). *Designation of Magnesium Alloys (an ASTM system now accepted by the SAE)*. A four-part system is used:

1. Letters indicate the two principal alloying elements: A, Aluminum; E, Rare-Earth; H, Thorium; K, Zirconium; M, Manganese; Q, Silver, S, Silicon; T, Tin; Z, Zinc. Thus HK signifies a thorium-zirconium magnesium alloy.
2. The approximate amounts (percent, wt) of the two principal alloying materials follow to the immediate right of the alloying element letters. Thus HK31 indicates approximately 3% thorium, and 1% zirconium.
3. The next two letter symbols to the right are used to distinguish two different alloys of the same chemical composition. Any letter may be used except I and O.
4. A fourth part of the designation (not indicated in this table) is separated by a dash from the foregoing parts and is used to indicate temper and other characteristics, such as F (as fabricated), 0 (annealed), H10 and H11 (slightly strain hardened), H23, H24, and H26 (strain hardened and partially annealed), T4 (solution heat treated), T5 (artificially aged only), T6 (solution heat treated and artificially aged), and T8 (solution heat treated, cold worked, and artificially aged). Thus, the complete designation may appear as: AZ91C-T6 for an aluminum-zinc-magnesium alloy containing 9% Al, 1% zinc, C indicating that this is the third alloy standardized with the same percentages of Al and Zn and T6 indicating that the alloy is solution treated and artificially aged.

TABLE 2. MAGNESIUM CASTING ALLOYS FOR AUTOMOTIVE APPLICATIONS

AM60B[2]	Die-casting alloy for uses needing toughness and ductility.		
	5.5–6.5% Al	0.25% Mn (min)	0.002% Ni (max)
	0.010% Cu max	0.22% Zn (max)	0.10% Si (max)
		0.005% Fe (max)	
AZ91D[2]	Provides an optimum combination of properties with die castability.		
	8.3–9.7% Al	0.15% Mn (min)	0.02% Ni (max)
	0.030% Cu (max)	0.35–1.0% Zn	0.10% Si (max)
		0.005% Fe (max)	
AZ91E[2]	A sand and permanent-mold casting alloy with properties and castability similar to AZ91B.		
	8.1–9.3% Al	0.17–0.5% Mn	0.0010% Ni (max)
	0.015% Cu (max)	0.40–1.0% Zn	0.20% Si (max)
		0.005% Fe (max)	
ZE41A	A sand and permanent mold casting alloy for applications to 175°C (350°F). Low microporosity and good pressure tightness.		
	0.0% Al	0.15% Mn (max)	0.40–1.0% Zr
	0.010% Cu (max)	0.75–1.75% Re	0.01% Ni (max)
		3.5–5.0% Zn	
ZC63	A proprietary sand and permanent-mold casting with properties Similar to ZE41A, but less expensive.		
	0.0% Al	0.25–0.75% Mn	
	2.4–3.0% Cu	5.5–6.5% Zn	

Lewis Research Center) rotary engine parts are made from graphite-fiber-reinforced magnesium. An AZ91C magnesium alloy is reinforced by 30% (vol) graphite fibers.

Progress has been in the early 1990s toward the development of metal-matrix composites (MMCs) that blend liquid magnesium alloys with ceramic particles, such as silicon carbide (SiC) and alumina (Al_2O_3). The method is similar to methods that have been developed for aluminum composites in that blending is accomplished by way of a high-shear process. Major differences of the new process result from increased general reactivity of magnesium and the difference in surface chemistry between the Al-SiC and Mg-SiC systems.

The particulate-reinforced MMCs are lightweight and demonstrate a significant increase in modulus and tensile strength at both ambient and elevated temperatures of the unreinforced material. The process was announced in late 1992 by Magnesium Elektron Ltd., Manchester, U.K.

Chemistry and Compounds

The behavior of magnesium is intermediate between that of beryllium and the higher alkaline earths. While it reacts readily with halogens, oxygen, and sulfur to form halides, oxide, and sulfide, it reacts with cold water only when the formation of protective oxide is prevented by amalgamation. All its compounds are divalent. Its oxide does not react with water to form the hydroxide, and it does not normally form a peroxide. Its major difference from the higher elements of the group is its much greater number of complexes. Anhydrous magnesium halides, especially, combine easily with many oxygen-functional organic compounds to form addition compounds. These reactions usually suggest covalent or dative bonding (both electrons from the oxygen) of the magnesium. Magnesium salts often form amines and amine complexes, though these are less stable than beryllium complexes. Magnesium also forms some basic salts, and many more of its salts are hydrated than are those of the higher alkaline earths. The metal reacts with alkyl and aryl halides to form the Grignard reagents, through which many organic reactions are conducted. The Grignard reagents themselves form complexes with ethers, tertiary amines, tertiary phosphines and many other type compounds. See also **Grignard Reactions**.

Important compounds of magnesium include the following:

Magnesium Acetate. [CAS: 142-72-3]. (1) $Mg(C_2H_3O_2)_2$ or (2) $Mg(C_2H_3O_2)_2 \cdot 4H_2O$, colorless, crystalline aggregate or nonoclinic crystals; acetic acid odor. (1) Mp 323°C, d 1.42 (2) mp 80°C, d 1.45, soluble in water and dilute alcohol, formed by reaction of magnesium carbonate and acetic acid. Uses: The largest use of magnesium acetate is in the production of rayon fiber, a dye fixative in textile printing, as a deodorant, a disinfectant, and antiseptic in medicine, and as a reagent chemical.

Magnesium Acetylacetonate. $Mg(C_5H_7O_2)_2$, crystalline powder, slightly soluble in water, resistant to hydrolysis, a chelating nonionizing compound.

Magnesium amide, $Mg(NH_2)_2$, whitish to gray crystals, d1.40, decomposes when heated, formed by reaction of magnesium and ammonia under elevated pressure. Use: Catalyst for polymerization.

Magnesium Arsenate. (arsenic acid, magnesium salt), [CAS: 10103-50-1]. $Mg_3(AsO_4)_2 \cdot xH_2O$, white powder, when pure it is insoluble in water.

Magnesium Ammonium Arsenate. $MgNH_4AsO_4$, white precipitate, solubility 0.0013 molar, formed by reaction of soluble magnesium salt solution and sodium arsenate in the presence of excess ammonium hydroxide, and upon igniting yields magnesium pyroarsenate, $Mg_2As_2O_7$, white solid.

Magnesium Benzoate. [CAS: 553-70-8]. $Mg(C_7H_5O_2)_2 \cdot 3H_2O$, white crystalline powder, loses $3H_2O$ at 110°C, mp approximately 200°C, soluble in water and alcohol.

Magnesium Borate. $3MgO \cdot B_2O_3$ (orthoborate) or $Mg(BO_2)_2 \cdot 8H_2O$ (metaborate) transparent, colorless crystals or white powder, soluble in alcohol, acetic acid and inorganic acids, slightly soluble in water, formed by heating magnesium oxide and boric anhydride. Uses: Magnesium borate is used as a preservative, antiseptic in medicine, and fungicide. Magnesium boride, Mg_3B_2, brown solid, by reaction of boron oxide and magnesium powder ignited.

Magnesium Bromide. [CAS: 7789-48-2]. $MgBr_2 \cdot 6H_2O$, white solid, soluble, formed by reaction of magnesium carbonate and hydrobromic acid. Magnesium bromide is found in seawater, some mineral springs, natural brines, inland seas and lakes such as the Dead Sea and the Great Salt Lake, and salt deposits such as the Stassfurt deposits. The solubility of magnesium bromide is 101 g/100 mL of water at 29°C; soluble in alcohols and forms addition compounds with numerous organic substances such as alcohols. Uses: Magnesium bromide is used in medicine as a sedative in treatment of nervous disorders, in electrolyte paste for magnesium dry cells, and as a reagent in organic synthesis reactions. Magnesium carbonate, $MgCO_3$, white solid, K_{sp} 4.0×10^{-5}, formed by reaction of soluble magnesium salt solution and sodium carbonate or bicarbonate solution. Present in carbonate minerals and rocks, magnesite (more or less pure magnesium carbonate), dolomite (magnesium-calcium carbonate mixtures), dolomitic limestone. When ignited yields magnesium oxide and CO_2; when treated with acids yields the corresponding magnesium salt and CO_2, but with carbonic acid yields soluble magnesium bicarbonate. Magnesium bicarbonate, $Mg(HCO_3)_2$, colorless solution, by reaction of magnesium carbonate and carbonic acid, yields, upon boiling, magnesium carbonate and CO_2; magnesium ammonium carbonate, $(MgCO_3 \cdot NH_4)_2CO_3 \cdot 4H_2O$, white precipitate (soluble in ammonium chloride solution) by reaction of soluble magnesium salt solution and excess ammonium carbonate. Uses: Magnesium salts, heat insulation and refractory, rubber reinforcing agent, inks, glass, pharmaceuticals, dentrifice and cosmetics, free-running table salts, antacid, making magnesium citrate, filtering medium.

Magnesium Chlorate. [CAS: 10326-21-3]. $Mg(ClO_3)_2 \cdot 6H_2O$, white powder; very hygroscopic. D 1.8, mp 35°C (decomposes at 120°C), soluble in water; slightly soluble in alcohol. Uses: Defoliant, desiccant.

Magnesium Chloride. [CAS 7786-30-3]. (1) $MgCl_2$ (2) $MgCl_2 \cdot 6H_2O$, white solid, soluble, formed by reaction of magnesium carbonate (or hydroxide, oxide, or metal) and HCl, loses hydrogen chloride when heated, yielding magnesium oxychloride; anhydrous magnesium chloride, $MgCl_2$, white solid, soluble, formed: (1) by heating hydrated magnesium chloride crystals in a current of dry hydrogen chloride, and (2) by heating magnesium ammonium chloride, mp 712°C. Magnesium ammonium chloride, $MgCl_2 \cdot NH_4Cl \cdot 6H_2O$, white solid, soluble, when heated yields anhydrous magnesium chloride; magnesium potassium chloride, $MgCl_2 \cdot KCl \cdot 6H_2O$, white solid, soluble, when heated fuses to anhydrous magnesium potassium chloride; magnesium oxychloride, white solid, insoluble, formed (1) by heating hydrated magnesium chloride crystals, and (2) by mixing magnesium chloride solution and magnesium oxide. Uses: Source of magnesium metal, disinfectants, fire extinguishers, fireproofing wood, magnesium oxychloride cement, refrigerating brines, ceramics, cooling drilling tools, textiles (size, dressing and filling of cotton and woolen fabrics, thread lubricant, carbonization of wool), paper manufacture, road dust-laying compounds, floor-sweeping compounds, flocculating agent, catalyst.

Magnesium Chromate. [CAS: 13423-61-5]. $MgCrO_4 \cdot 5H_2O$, small readily soluble, yellow crystals, formed by reaction of magnesium carbonate and chromic acid solution. Use: Since it does not produce a fusible alkaline residue when thermally decomposed, it is used as a corrosion inhibitor in the water coolant of gas turbine engines. Insoluble basic magnesium chromates also are available. Their potential applications are in the treatment of light metal surfaces.

Magnesium Citrate. $Mg_3(C_6H_5O_7)_2 \cdot 4H_2O$, white solid, soluble, formed by reaction of magnesium carbonate and citric acid.

Magnesium Fluoride. [CAS: 7783-40-6]. MgF_2, white precipitate, K_{sp} 6.5×10^{-9}, formed by adding sodium fluoride or hydrofluoric acid to a solution of magnesium salt. Uses: Ceramics, glass, single crystals for polarizing prisms, lenses and windows. Magnesium formate, $Mg(CHO_2)_2 \cdot 2H_2O$, colorless crystals, soluble in water; insoluble in alcohol and ether; combustible. Used in Analytical chemistry.

Magnesium Gluconate. [CAS: 3632-91-5]. $Mg(C_6H_{11}O_7)_2 \cdot 2H_2O$, white powder or fine needles, odorless, almost tasteless, soluble in water, combustible, formed by reaction of magnesia or magnesium carbonate dissolved in gluconic acid. Uses: Medicine, and vitamin tablets.

Magnesium Hydroxide. [CAS: 1309-42-8]. $Mg(OH)_2$, occurs naturally as the mineral brucite, white precipitate, K_{sp} 9.0×10^{-12}, formed by reaction of soluble magnesium salt solution and NaOH solution. Use: The principal use of magnesium hydroxide is in the pulp (qv) and paper (qv) industries. The main captive use is in the production of magnesium oxide, chloride, and sulfate. Other uses include, ceramics, sugar refining, pharmaceuticals (antacid, laxative), plastics, flame retardants/smoke supressants, residual fuel oil additive, sulfate pulp, uranium processing, dentrifrices, in foods as frying agent, color retention agent, frozen desserts, and the expanding environmental markets for wastewater treatment and SO_x removal from waste gases.

Magnesium Hypophosphite. [CAS: 10377-57-8]. $Mg(H_2PO_2)_2 \cdot 6H_2O$, white solid, soluble, formed by reaction of magnesium carbonate and hypophosphorous acid.

Magnesium Iodide. $MgI_2 \cdot 8H_2O$, white solid, soluble, formed (1) by reaction of magnesium carbonate and hydriodic acid, (2) anhydrous, by heating magnesium metal and iodine.

Magnesium Lactate. [CAS: 18917-93-6]. $Mg(C_3H_5O_3)_2 \cdot 3H_2O$, white solid, soluble, formed by reaction of magnesium carbonate and lactic acid.

Magnesium Iodide. MgI_2 can exist as two deliquescent and heat-sensitive compounds: the octahydrate, $MgI_2 \cdot 8H_2O$, and the hexahydrate, $MgI_2 \cdot 6H_2O$, soluble in alcohols and many other organic solvents, and forms numerous addition compounds with alcohols, esters, aldehydes, esters, and amines. Uses: Used in the deoxygenation of oxiranes into olefins and iodine. Anhydrous MgI2 is used in a process for producing organometallic and organobimetallic compositions, which are important in the preparation of pharmaceutical and special chemicals.

Magnesium Methoxide. (magnesium methylate), $(CH_3O)_2$ Mg, colorless, crystalline solid, decomposes on warming, formed by reaction of magnesium and methanol. Uses: Dielectric coatings, a cross-linking agent to form stable gels, and catalyst.

Magnesium Molybdate. $MgMoO_4$, crystalline powder, soluble in water. Use: Electronic and optical applications.

Magnesium Nitrate. [CAS: 10377-60-3]. $Mg(NO_3)_2 \cdot 2H_2O$, white crystals, D1.45, mp 95–100°C, decomposes at 330°C, soluble in water and alcohol, deliquescent. Uses: A soluble form of magnesium nitrate is used as a fertilizer in states such as Florida, where drainage through the porous, sandy soil depletes the magnesium. Used as a prilling aid in the manufacture of ammonium nitrate and in Pyrotechnics. Another use is as an alternative to sulfuric acid in the purification of nitric acid.

Magnesium Nitride. [CAS: 12057-71-5]. Mg_3N_2, yellow solid, with moist air or water yields ammonia and magnesium hydroxide, formed by heating magnesium to a high temperature in nitrogen or NH_3 (hydrogen gas evolved).

Magnesium Oleate. [CAS: 1555-53-9]. $Mg(C_{18}H_{33}O_2)_2$, yellowish mass, soluble in linseed oil, hydrocarbons, alcohol, and ether, insoluble in water, combustible, formed by reaction of soluble magnesium salt solution

and sodium oleate. Uses: Varnish driers, in dry-cleaning solvents (to prevent spontaneous ignition), emulsifying agent, and lubricant for plasticizers.

Magnesium Oxalate. $MgC_2O_4 \cdot 2H_2O$, white solid, insoluble. K_{sp} 8.6×10^{-5}, formed by reaction of soluble magnesium salt solution and ammonium oxalate solution.

Magnesium Oxide. [CAS: 1309-48-4]. MgO, white solid, reacts slowly with H_2O to form magnesium hydroxide, has cubic structure, absorbs CO_2 from the air to form magnesium carbonate, is readily soluble in acids, insoluble in alkalies; formed (1) by heating magnesium carbonate to high temperature (CO_2 gas evolved), (2) by heating magnesium hydroxide, nitrate, sulfate, or oxalate, (3) by burning magnesium metal in air or oxygen. Uses: Refactories, especially for steel furnace linings, polycrystalline ceramic for aircraft windshields, electrical insulation, pharmaceuticals and cosmetics, inorganic rubber accelerator, oxychloride and oxysulfate cements, paper manufacture, fertilizers, removal of sulfur dioxide from stack gases, adsorption and catalysis, semiconductors, and food and feed additive.

Magnesium Peroxide. [CAS: 14452-57-4]. MgO_2, white solid, insoluble in water, soluble in dilute acids with formation of hydrogen peroxide, formed by reaction of soluble magnesium salt solution and sodium or barium peroxide. Uses: Bleaching and oxidizing agent, in medicine for treating hyperacidity in the gastric intestinal tract and in the treatment of metabolic diseases such as diabetes and ketonuria.

Magnesium Ammonium Phosphate. $MgNH_4PO_4$, white precipitate, K_{sp} 2.5×10^{-12}, by reaction of soluble salt solution and sodium phosphate in the presence of excess ammonium hydroxide, upon igniting yields magnesium pyrophosphate, $Mg_2P_2O_7$, white solid.

Magnesium Phosphate, Dibasic. (Dimagnesium orthophosphate; dimagnesium phosphate; magnesium phosphate, secondary; magnesium hydrogen phosphate), [CAS: 7782-75-4]. $MgHPO_4 \cdot 3H_2O$, white, crystalline powder, D 2.13, loses water at 205°C, decomposes at 550–650°C, decomposes to pyrophosphate on heating, soluble in dilute acids, slightly soluble in water. Uses: Stabilizer for plastics, food additive, and medicine (laxative).

Magnesium Phosphate, Monobasic. (Magnesium biphosphate; acid magnesium phosphate; magnesium tetrahydrogen phosphate), $MgH_4(PO_4)_2 \cdot 2H_2O$, white, hygroscopic, crystalline powder, decomposes to metaphosphate on heating, soluble in water and acids, insoluble in alcohol. Uses: Fireproofing wood, and as a stabilizer for plastics.

Magnesium Phosphate, Tribasic. (Magnesium phosphate, neutral; trimagnesium phosphate), $Mg_3(PO_4)_2 \cdot 8H_2O$ or $4H_2O$, soft, bulky, white powder, odorless, tasteless, loses all water at 400°C, soluble in acids, insoluble in water, formed by reaction of magnesium oxide and phosphoric acid at high temperatures. Uses: Dentifrice polishing agent, pharmaceutical antacid, adsorbent, stabilizer for plastics, food additive and dietary supplement. Magnesium salicylate, $Mg(C_7H_5O_3)_2 \cdot 4H_2O$, white solid, soluble in water and alcohol, formed by action of salicylic acid on magnesium hydroxide. Use: Medicine (antiinfective).

Magnesium Silicide. [CAS: 22831-39-6]. Mg_2Si, bluish crystals, mp 1085°C, d 1.9, decomposes on heating above 500°C, also by water and hydrochloric acid, formed by heating magnesium powder with silicon in ratio of 20:6. Uses: Semiconductor technology, and electrical equipment.

Magnesium Stannate. [CAS: 12032-29-0]. $MgSnO_3 \cdot 3H_2O$, white crystalline powder, decomposes at 340°C, soluble in water. Use: Additive in ceramic capacitors.

Magnesium Stannide. Mg_2Sn, blue-white crystals, Mp 775°C, soluble in water and dilute hydrochloric acid, has electrical and magnetic properties. Use: Semiconductor technology, magnetochemistry, thermoelectric research.

Magnesium Stearate. [CAS: 557-04-0]. $Mg(C_{18}H_{35}O_2)_2$ or with one H_2O, soft, white, light powder, tasteless, odorless, insoluble in water and alcohol. Uses: Dusting powder, lubricant in making tablets, drier in paints and varnishes, flatting agent, in medicines, stabilizer and lubricant for plastics, emulsifying agent in cosmetics, and dietary supplement.

Magnesium Sulfate. [CAS: 7587-88-9]. (1) $MgSO_4$, (epsom salts) $MgSO_4 \cdot 7H_2O$, colorless crystals, very soluble in water, soluble in glycerol, sparingly soluble in alcohol, (1) formed by action of sulfuric acid on magnesium oxide, hydroxide, or carbonate, (2) mined in a high degree of purity. Uses: Primarily in the chemical and pharmaceutical industries, fireproofing, textiles (warp-sizing and loading cotton goods, weighting silk, dyeing and calico printing), mineral waters, catalyst carrier, ceramics, fertilizers, paper (sizing), cosmetic lotions, and as a dietary supplement.

Magnesium Sulfide. [CAS 1032-36-9]. MgS, red-brown, crystalline solid, decomposes above 2000°C, decomposes in water. Use: Source of hydrogen sulfide, laboratory reagent.

Magnesium Sulfite. $MgSO_3 \cdot 6H_2O$, white, crystalline powder, D 1.725, mp loses $6H_2O$ at 200°C, bp (decomposes), slightly soluble in water, insoluble in alcohol, formed by action of sulfurous acid on magnesium hydroxide. Use: Manufacture of paper pulp (as bisulfite).

Magnesium Tungstate. [CAS: 13573-11-0], (magnesium wolframate) $MgWO_4$, white crystals, D 5.66, soluble in acids, insoluble in water and alcohol, formed by interaction of solutions of magnesium sulfate and ammonium tungstate. Use: Fluorescent screens for X-rays, luminescent paint.

Magnesium Zirconium Silicate. $MgZrSiO_5$, or $MgO \cdot ZrO_2 \cdot SiO_2$, white solid, mp 1760°C, d 80 lb/ft^3, insoluble in water and alkalies, slightly soluble in acids. Use: Electrical resistor, ceramics, glaze opacifier.

MAGNESIUM (In Biological Systems). Magnesium is an integral part of the molecule of chlorophyll, the green pigment in plants that absorbs solar energy. See also **Chlorophylls**. Magnesium deficiency is a fairly common cause of poor crop yields, especially among crops produced on sandy soils. Magnesium is a prosthetic ion in enzymes that hydrolyze and transfer phosphate groups. Hence it is essential for energy-requiring biological functions, such as membrane transport, generation and transmission of nerve impulses, contraction of muscles, and oxidative phosphorylation. See also **Phosphorylation (Oxidative)**. Magnesium is essential for the maintenance of ribosomal structure and thus protein synthesis. Magnesium may be related to the incidence of ischemic heart disease among Western populations.

The accumulation of magnesium from the soil by plants is strongly affected by the species of plant. The leguminous plants, such as clovers, beans, and peas, usually contain more magnesium than grasses, tomatoes, corn (maize), and other nonleguminous plants, regardless of the level of available magnesium in the soil where they grow.

A very high level of available potassium in the soil interferes with the uptake of magnesium by plants, and magnesium deficiency in plants is often found in soils that are very high in available potassium. High levels of available potassium may occur naturally, especially in soils of subhumid and semiarid regions; or they may be caused by heavy applications of certain commercial fertilizers or animal manure. On sandy and loamy soils, applications of magnesium fertilizers are often effective in increasing crop yields and the concentration of magnesium in the crop, but on fine-textured, clay-containing soils, especially those with substantial reserves of potassium, the application of a magnesium fertilizer may not cause higher magnesium concentration in crops. Since magnesium is not a highly toxic element in either plants or animals, precautions against its overuse are rarely necessary. When animals are fed diets primarily of grains, a proper balance among magnesium, calcium, and phosphorus should be maintained to minimize danger from urinary calculi.

The biological functions of magnesium, such as its essential role as a nutrier, its activation of enzyme systems, and its pharmacological properties, have been widely investigated. Nevertheless, some aspects of its critical physiological role remain obscure.

Distribution in System

Magnesium, primarily an intracellular ion, is distributed among all tissues. It constitutes about 0.05% of the animal body and, of this, 60% occurs in the skeleton and only 1% in extracellular fluids.

Reported serum magnesium values for most species range from 1.0 to 3.5 meg/liter, with a mean value of about 2. Between 65% and 80% of the plasma magnesium is ultrafilterable, and most of this exists as the free ion. The nonfilterable portion is reversibly bound to plasma protein. Cerebrospinal fluid contains slightly more than plasma. Interstitial fluid is similar to plasma ultrafiltrate.

The magnesium content of soft tissues varies from 0.06 to 0.13% of dry weight and remains remarkably constant regardless of the magnesium status of the animal. Normally, the intracellular concentration is more than 20 times that of the interstitial fluid, and the highest concentration occurs in the cell nucleus. Maintenance of such a large concentration gradient across the cell membrane suggests an active transport mechanism.

In late 1990's, R.R. Preston (University of Wisconsin-Madison) reported that recent reappraisals of the rôle of ionized magnesium in cell function suggests that many cells maintain intracellular free Mg^{2+} at low concentrations and that external agents can influence cell functions via changes in intracellular Mg^{2+} concentration. There is considerable evidence to suggest that intracellular free magnesium ions may be a key physiological regulator of cell activity.

The relatively large proportion of magnesium found in the skeleton, which amounts to about 0.6% of dry, fat-free bone, serves in part as a body reserve. It occurs largely as Mg^{2+} and $MgOH^{+}$ ions held by electrostatic attraction to the apatite crystal surface. During deficiency in young animals, 30% or more of bone magnesium can be mobilized for metabolic functions. Calcium ions appear to replace the magnesium that occupied the original adsorption sites.

Metabolism

The rate of absorption from the intestine exerts an important role in magnesium metabolism. Whereas *in vitro* studies show that magnesium absorption is positively correlated with the concentration of magnesium, it does not appear to be a purely passive process. Magnesium absorbed in excess of body needs is excreted primarily by way of the kidney. Urinary excretion is controlled primarily by a filtration-reabsorption mechanism so that magnesium appears in the urine only when glomerular filtration exceeds tubular reabsorption. Acute renal failure is accompanied by hypermagnesemia. In some species, considerable endogenous magnesium is lost by way of the feces, the amount depending upon the magnesium status of the animal and upon other dietary factors, such as the digestibility of the diet. The endogenous fecal magnesium in calves has been estimated at 3.5 milligrams/kilogram of body weight.

In contrast with the metabolism of calcium, no one endocrine gland exerts a primary regulatory function on magnesium. Thyroparathyroidectomy in dogs causes only a temporary lowering of plasma magnesium. Adrenalectomy causes a rise, whereas hyper-aldosteronism produces a fall in the plasma level. Administrative of deoxycorticosterone or aldosterone to sheep lowers the magnesium concentration in plasma. Magnesium-deficient animals exhibit a higher metabolic rate than normal, and the toxic effect of excess thyroxine is partially overcome by increasing the dietary level of magnesium.

Function

Although magnesium activates isolated enzymes, in most cases an absolute requirement is difficult to establish because the enzymes are partially active without added magnesium. The stimulating effect is not always specific for magnesium. In some cases, manganese or calcium will also activate the system.

Magnesium is particularly concerned with enzyme-catalyzed reactions involving the cleavage of phosphate esters and the transfer of phosphate groups. Magnesium ions activate phosphatases and the phosphorylation reactions involving adenosine triphosphate (ATP). Among the latter group may be mentioned glucokinase, phosphoglucokinase, phosphofructokinase, myokinase, creatine transphosphorylase, arginine transphosphorylase, and flavokinase. It has been suggested that an ATP-Mg complex is the active substrate inasmuch as ATP forms a 1:1 complex with magnesium and maximal activation occurs when the ATP: Magnesium ration is 1. Alkaline phosphatases, pyrophosphatases, and ATPase are activated by magnesium, as are enolase, certain peptidases, and pyruvic oxidase. Since magnesium is tied to ATP utilization, it follows that magnesium plays a role in important metabolic processes, including the synthesis of protein, fat, and nucleic acids, and in the trapping and utilization of energy derived from catabolism of carbohydrate and fat.

There is little change in magnesium concentration of soft tissues from deficient animals even at the point of expiration. This does not preclude the possibility that a small component of the cell, such as the nucleus or a cell particulate, is deprived of its critical level, but the dramatic drop in extracellular magnesium suggests that a function outside the cell is of greatest significance. It appears that tetany and convulsions in deficient animals result from a derangement of neuromuscular transmission. Magnesium ion possesses strong pharmacological properties, depressing both the central and peripheral nervous systems. These effects are counteracted by calcium. In the presence of normal calcium levels, a reduction of extracellular magnesium is believed to increase the release of acetylcholine and to decrease the rate of its hydrolysis. Such effects would increase the irritability of the neuromuscular system.

Magnesium generally has not been considered a major factor in bone formation and strength, but recent studies suggest closer attention be given to dietary levels of magnesium in this regard. Because of the close interrelationship with calcium, it is not surprising to see research findings of magnesium interfering with calcium entry into cells of the islets of the pancreas in studies of diabetes. The recognized presence of magnesium as part of numerous enzyme systems has led to observations of the reduction in carbohydrate metabolism associated with a deficiency and to beneficial effects in reducing blood cholesterol and lipids associated with other dietary agents when supplemental magnesium is added to the diet. The relationship to calcium also shows up in a study showing that adding magnesium to the rations of laying hens causes an increase in shell thickness, with a consequent reduction in the number of broken eggs.

Magnesium-Induced Diarrhea

It is well established that an excessive intake of magnesium causes diarrhea. This source of diarrhea is difficult to differentiate from other causes of diarrhea. Consequently, the diagnosis may be long and costly unless the physician questions a patient on possible excessive magnesium intake, which may result from large dosages of antacids or off-the-shelf food supplements.

Pathology of Magnesium Deficiency

Although there are numerous clinical symptoms, two cardinal aspects of pathology have been observed in all species of higher animals. These are hyperirritability and soft tissue calcification. While there are species differences as to the dominating syndrome, this is determined in part by the severity of the deficiency. Metastatic calcification is more likely to occur in a chronic deficiency in which the animal does not succumb at an early age. Hyperirritability, terminating in convulsions and death, has been observed in rat, rabbit, pig, calf, chick, and duck. Magnesium deficiency in humans is characterized by muscle tremors and twitching, often accompanied by delirium and occasionally by convulsions. The guinea pig, calf, dog, and cotton rat are prone to metastatic calcification and develop grossly visible deposits in and around joints, along the muscles of the rib cage, and also in the heart, great vessels, and other critical organs. Most soft tissues show an elevated ash content and marked histopathology. Some researchers have hypothesized that long-term intakes of marginal dietary levels of magnesium may be related to the incidence of ischemic heart disease.

The first clinical symptom of magnesium deficiency is a hypomagnesemia which occurs in cattle and less frequently in sheep and is described by such names as grass tetany, grass staggers, lactination tetany, and wheat pasture poisoning. It is observed most frequently when animals are first grazed on lush grass or wheat pastures. The disease is characterized by irritability, tetany, and convulsions, and all animals have subnormal plasma magnesium. Symptoms can be relieved by administration of magnesium salts and cam be prevented by providing extra magnesium in the diet.

Hypomagnesemia, often associated with hypocalcemia, is frequently encountered in heavy users of alcohol. Alcoholism sometimes is ascribed to impaired intestinal calcium absorption.

Nutritional Requirements and Dietary Supplementation

As is true of many mineral nutrients, the requirement for magnesium is affected by other dietary constituents, by the age and species of the animal, and by the criterion of adequacy applied. An allowance for magnesium

TABLE 1. DISTRIBUTION OF MAGNESIUM IN VARIOUS FOOD GROUPS

Group (types of samples tested)	Magnesium concentration (milligrams/100 grams (wet))	Magnesium-calorie ratio (Micrograms/kilocalorie)
Milk products (cheeses, ice cream, milk, puddings)	6.8–25.7	18–198
Meat and meat alternates (chicken, dried beef, eggs, fish, sausage)	9.8–37.6	20–353
Vegetables (cabbage, carrot, onion, turnip)	6.7–20.6	196–1000
Breads and cereals (buns, cereals, cornbread, crackers, croutons, English muffins, pasta, taco shells)	10.6–126.0	27–325
Baked desserts (cakes, cookies, doughnuts, pastries, sweet rolls)	4.6–53.2	18–307
Candies	21.8–89.9	63–225

has been included in the Recommended Dietary Allowance since 1968. Calcium and magnesium have an important effect upon magnesium availability. Either of these ions in excess increases the requirements for magnesium, and their effects are additive. Since calcium is known to compete with magnesium pharmacologically, it is reasonable to believe that it also competes with magnesium for absorption sites in the intestine. It is believed that phosphate decreases magnesium absorption by formation of insoluble magnesium phosphates, and excess of calcium aggravates the effect of creating a more alkaline intestinal medium. Excess magnesium can be considered toxic, but this effect is largely due to the induction of a calcium deficiency. Magnesium deficiency in humans generally has not been fully documented except in cases of predisposing and complicating disease states.

Distribution of magnesium in food classes is summarized in Table 1.

MAGNETIC MATERIALS.

BULK

All materials that are magnetized by, i.e., exhibit a response in magnetic field are magnetic materials and are classified according to the nature of the response, e.g., as ferromagnetic or ferrimagnetic, the latter typified by the ferrites. Most commercially important magnetic materials are ferromagnets and ferrimagnets (see also **Ferrites**).

Soft Magnetic Materials

Soft magnetic materials are characterized by high permeability and low coercivity. There are six principal groups of commercially important soft magnetic materials: iron and low carbon steels, iron–silicon alloys, iron–aluminum and iron–aluminum–silicon alloys, nickel–iron alloys, iron–cobalt alloys, and ferrites. In addition, iron–boron-based amorphous soft magnetic alloys are commercially available. Table 1 summarizes the properties of some of these materials. Table 2 summarizes properties of some ferrites. Properties of amorphous soft magnetic alloys are listed in Table 3.

Uses of Soft Magnetic Materials. Because of low coercivity and high magnetic permeability, iron and low carbon steels tend to be used in static applications. Low carbon steels and the lower grade Fe–Si alloys are used in small motors and generators. The higher grade Fe–Si alloys have traditionally been used in power distribution transformers and large rotating machinery, but certain economical amorphous iron–metalloid alloys, because of their lower resistivity, are increasingly being used in the manufacture of distribution transformers by General Electric, Westinghouse, and Osaka. Ni–Fe alloys, used widely in high quality relays, electronic transformers, converters, and inverters in the electronics industry, have much higher permeability and much lower resistivity than Fe–Si alloys. Soft ferrites (oxides) are suitable for high frequency applications. The Co–Fe alloys are used because of their higher saturation polarization (flux density) electrical resistivity and Curie temperature compared to the iron–nickel alloys, but have the disadvantage of poorer workability and higher cost. Thus, they are used in special applications.

Soft magnetic ferrites are oxides and they are electrical insulators. Because of their exceptionally higher resistivities, ferrites are particularly suitable for high frequency applications, of about 100,000 cycles (10 kHz).

Hard Magnetic Materials

Hard or permanent magnetic materials are characterized by high coercivity and high energy product. The important commercial hard magnetic materials are hard ferrites such as ferroxdure (Table 4), rare-earth (R)-cobalt alloys, and the ternary alloys based on $Nd_2Fe_{14}B$. The last exhibits the highest coercivities and energy products. The use of Alnico and the

binary R–Co alloys has continually decreased because of the high cost of cobalt. These are being replaced by the ternary NdFeB materials, including $Nd_2Fe_{14}B$. The progress in energy products for hard magnetic materials is shown in Figure 1.

Uses. Hard ferrites are used widely in electromechanical devices, e.g., generators, relays, motors, and magnetos; electronic applications, e.g., loudspeakers, traveling-wave tubes, and telephone ringers and receivers; antitheft tags, holding devices such as door closers, seals, and latches;

and are perennial favorites in various toy designs. Loudspeakers are the largest use of permanent magnets (ca 50%). Strontum ferrites exhibit higher coercivities and are increasingly being produced.

The commercial development of magnets based on $Nd_2Fe_{14}B$ boride proceeded rapidly, and they are now being used in many diverse applications, for example, servo devices for machine tools, for over 30 dc motors for fully equipped automobiles (windshield wipers, cooling fans, window and antenna lift motors, etc), magnetic resonance imaging (mri), computer disk drives, and medical device applications. Their largest use is in positioning motors for computer hard disk drives. New designs of electrical machines are now taking place.

Economic Aspects

The manufacturers of permanent magnets include Hitachi which produces Alnico Grades 5–9, in cast form in various shapes, of Grades 2 and 5 in sintered form as well as the rare-earth–cobalt (Hicorex); IG Technologies Inc., which produces Alnico, cast grades (Hyflux) 5, 8, 9 in various shapes, sintered, grades 2, 5, 8, cunife magnets, ceramic magnets (Indox) grades 1 and 5, and the rare-earth–cobalt Incor; Crucible Magnetics, which produces Alnico, cast grades 5, 7, and 8, ceramic magnets (Ferrimag), and the rare-earth–cobalt Crucore; Arnold Engineering, which produces Alnico, cast grades 5 and 8, sintered grades 2, 5, 8; GM, Delco Remy Division which produces Nd–Fe–B, limited to several shapes only (Magnaquench), isotropic and anisotropic, many grades, under the name of Permag, in the form of disks, rectangles, and squares, supplied by the Magnetic Materials Division of the Dexter Corp.; Sumitomo, which produces Nd–Fe–B and sintered magnets; 3M Co., which produces magnetic oxides, ferrites rubber bonded to form flexible permanent magnet tape with or without adhesive (Plastiform); and AlliedSignal, which produces the amphorous magnetic alloys known as Metglas.

THIN FILMS AND PARTICLES

The largest use of magnetic films and particles, in the form of tapes and disks for recording and retention of audio, visual, and digital information, is in memory and storage technologies. Price per bit of information, including the cost of the peripheral electronics, and performance, as denoted by access time, generally are used to characterize the various memory technologies. Power, modular capacity, reliability, nonvolatility, etc. are also factors describing the efficacy of memories.

Magnetic Properties and Structure

The static or low frequency magnetic properties pertinent to thin-film materials generally are utilized to characterize magnetic materials. As a first approximation, these properties serve to suggest utility for device applications. Saturation magnetization M_s and Curie temperature T_C are intrinsic (structure insensitive) properties and are equal to the bulk values when thick films are made properly. For very thin highly paramagnetic films, such as those of platinum, sandwiched between ferromagnetic, e.g., Co, or antiferromagnetic, e.g., Cr, thin films, in the form of multilayered structures being developed for recording heads, a magnetization can be induced in the normally paramagnetic material. The surface area-to-volume ratio of the individual layers is so large that the atomic moments at the interfaces play an important role.

Fabrication

Fabrication methods include thermal evaporation, sputtering, magnetron sputtering, pulsed laser evaporation, molecular beam epitaxy, chemical vapor deposition, electrolytic and electroless deposition, and growth from solution.

Materials

Magnetic storage materials for storage of audio and video information as well as of digital data are in the form of tape and disks. There are two states of remanent magnetization for recording: longitudinal, in which the magnetization is in the plane of the recording medium; and perpendicular, in which the magnetization is normal to the plane. For particulate media in which the acicular submicronic particles are single domain and embedded in plastic, the magnetization is confined in the direction of the long dimension.

Multilayer materials exhibiting high magnetization and permeability are undergoing considerable research and development for advanced recording heads. The discovery of giant magnetoresistance in multilayered nano-thick magnetic materials is expected to become important for advanced read heads.

Particulate Materials. There are three principal classes of particulate magnetic materials: γ-ferric oxide, γ-Fe_2O_3, and its modifications; chromium dioxide, CrO_2; and iron. A comparison of the remanent magnetization, B_r, and coercivity, H_c, for several material systems is shown in Table 5.

Recording Heads. Materials that are suitable for read/write recording heads for tapes and disks are characterized by high saturation flux density, low remanent induction to avoid erasure of information when the writing current ceases, and low hysteresis and low eddy-current loss, particularly for high data rates or high frequency operation. In addition, because of the small air gap between the head and recording medium, the head material should be abrasion resistant. Dust particles and the magnetic attraction between head and tape can lead to abrasion.

For general-purpose audio recording, laminated Ni–Fe alloys exhibit the required high saturation and low remanence and eddy-current losses; moreover, abrasion is low. Head wear is improved by use of precipitation hardened material. The spinel structure oxides, manganese–zinc and nickel–zinc ferrites, exhibit good abrasion resistance and high frequency characteristics and in some cases are the preferred material despite their relatively low saturation.

For high quality audio and video recording where the recording medium is CrO_2 or Co impregnated γ-Fe_2O_3, sputtered Sendust alloy films (9.6 wt % Si, 5.4 wt % Al, balance Fe; see also Table 6) and ferrites are used as head materials.

Thin-Film Magnetic Metallic Media. Advanced magnetic recording media are in the form of thin films. The metallic media are typically sputtered films having carbon overcoats for protection. Cobalt-based alloys have been developed for use as longitudinal, i.e., *c*-axis of the crystalline Co-alloy parallel to the plane of the substrate, magnetic recording media (see **Cobalt** and **Cobalt alloys**). Magnetic disks are presently fabricated alloys on NiP coated aluminum alloy disk substrates.

Magnetooptic Materials. The application of magnetooptic effects to optical memory systems, such as for laser beam writing and magnetooptic read, has been the subject of much research.

Memory systems based on laser writing and reading through the interaction of electromagnetic radiation, either through reflection utilizing the Kerr effect or by transmission utilizing the Faraday effect, have begun to appear in the marketplace.

The magnetic storage media being employed are ternary amorphous alloys (Table 6) composed of the rare-earth elements gadolinium, Gd, and terbium, Tb, with Fe and Co for use in the near infrared. These materials are compatible with GaAs-based lasers. These alloys are ferrimagnetic.

The rare-earth (R) garnets, $R_3Fe_5O_{12}$, which are ferrimagnetic, are being investigated for magnetooptic recording.

Amorphous single-domain CoTaZr cores having Al_2O_3 interlayers where the CoTaZr thickness is from 0.23–0.9 μm, depending on the number of layers, and Al_2O_3 is 0.01-μm thick, were evaluated for use as thin-film heads. This material combination is attractive for low noise heads operating at frequencies up to 40 MHz.

Magnetic Superlattices. The discovery in the late 1980s of giant magnetoresistance (GMR) in antiferromagnetically coupled Fe/Cr superlattices stimulated great interest (see Table 7). Properties of metallic superlattices consisting of thin alternate single-crystal layers of different magnetic materials as well as alternate layers of magnetic and nonmagnetic materials were examined.

Co/Au multilayers	variable	PR
$Co_{1-x}Pt_x$ multilayers	$x = 0.45 - 0.9$	PA, MRM

[a] MR = magnetic recording; MD = magnetoresistive detectors; T = transducers; RH = recording heads; R = recording; TH = thermomagnetic or Curie-point writing; TS = tetrode sputtering; MRM = magnetooptic recording media or magnetooptical recording; SMB = soft magnetic behavior; PR = perpendicular recording; LR = longitudinal recording; HFRH = high frequency recording heads; RH/HDTV = recording heads for high definition television; and PA = perpendicular anisotropy.
[b] Where R = Gd or Tb.
[c] 8 A/m = 0.10 Oe.

Magnetoresistive recording heads offer much more sensitivity than inductive heads and there is strong evidence as of this writing that such heads will be used exclusively by the year 2000. The trend in the development of head materials is toward thin-film media. Although Permalloy films ($Ni_{18}Fe_{19}$) are used for magnetoresistive sensors, the change in resistance is only about 2.5%. Higher magnetoresistive materials are needed.

Magnetic Fluids. Magnetic fluids are stable colloidal suspensions of ferromagnetic particles, such as Fe_3O_4, and of subdomain size (ca 10 nm) in aqueous or organic bases. The fluid behaves as a homogeneous Newtonian liquid and reacts to a magnetic field. These materials are used in bearings, rotary-shaft seals, and feedthroughs.

TABLE 7. MAGNETIC SUPERLATTICES EXHIBITING GIANT MAGNETORESISTANCE

Material system	Multilayer information	Result[a,b]
Fe/Cr	var ((001) Fe/Cr(001))$_n$, 0.9–9.0-nm single-crystal layer thickness on single-crystal GaAs	resistivity lowered by factor of 2 at 4.2 K, switching fields on order of 1 T req'd
Co/Cu	var	strong antiparallel coupling through nonferromagnetic Cu; high (>800 kA/m) fields req'd to change antiferromagnetic spin structure into ferromagnetic
Co–Fe/Cu	1.0 nm Co_9Fe/1.0 nm Cu ion-beam sputtering on MgO(110) substrates	Co–Fe/Cu grew having inplane uniaxial anisotropy, easy axis parallel to cube direction in the MgO(110) plane; saturation field (240 kA/m) at RT for GMR = 45%
NiFe/Cu	$Ni_{81}Fe_{19}$/Cu/Co	GMR enhanced by presence of thin Cu layer; magneto-resistance of >17% for field changes of ±8 kA/m at RT
NiFe/Cu/Co	[$Ni_{80}Fe_{20}$/Cu/Co/Cu] r-f diode sputtering on Si(100) single-crystal wafers at RT	resistance changes ≤70% within a few amperes/m
NiFe/Cu/NiFe/FeMn		resistance changes of 3–4% in fields of 40–800 A/m
Co/Ag	Co(15 nm)/Ag(6.0 nm) electron-beam evaporation on top of a 5.0-nm Cr buffer layer on Si(111) substrates	interface roughness important in understanding connection between GMR and antiferromagnetic coupling

[a] To convert T to G, multiply by 10^4.
[b] To convert kA/m to Oe, divide by 7.958×10^{-2}.

MAGNETIC SEPARATION. Use of a magnetic field to remove unwanted magnetic particulates from solid or liquid mixtures of nonmagnetic materials, e.g., sands, and mineral processing. Low-gradient fields are suitable for separation of strongly magnetic materials, whereas high-gradient fields can separate particles of materials that are weakly magnetic, such as coliform bacteria from municipal wastes and sulfur from coal.

Removal of magnetic impurities from industrial wastewater is called magnetic filtration, e.g., reconditioning of boiler water and regeneration of condensate in power plants. See also **Electromagnetic Separation**; **Magnetic Materials**; and **Mass Spectrometry**.

MAGNETISM. A magnet is a body possessing the property of attracting magnetic substances. The so-called permanent magnet should be used where a constant magnetic field is to be produced, inasmuch as a well-made permanent magnet loses its magnetism very slowly, and then only up to a certain value, after which it is said to be aged. Therefore, it essentially maintains a constant degree of magnetism unless subjected to strong demagnetizing effects. Permanent magnets for precision apparatus are artificially aged during manufacture.

A bar that has been magnetized is found to have poles, which are centers where magnetic attraction is strongest. If the magnet is free to turn, the pole which points northerly is aptly termed the north pole; the other, the south pole. Like poles repel; unlike poles attract. Thus, because of the magnetic properties of the earth, a magnet can serve as a compass. The poles, of course, have no physical reality, but provide a convenient concept for describing certain magnetic phenomena.

Magnetic Field

The region surrounding a magnet (or an electric current) is endowed with specific properties. The most familiar is the torque experienced by a small magnet when placed in such a region. For any point of the field, there is only one direction in which the small magnet will reach stable equilibrium. The direction in which the north pole of the magnet points when in equilibrium is termed the direction of the field. By moving a small magnet in a magnetic field, it is found that the field direction will follow curved lines of force. If the field is due to the current flowing in a conductor, the lines form completely closed curves enclosing the conductor. If the field is due to a magnet, they appear to enter the iron at the south pole and emerge at the north pole, inferring that they complete themselves through the iron as they do through a coreless, current-carrying helix. A magnetic field may be defined as a vector function field described by the magnetic induction. The term magnetic field is used interchangeably to refer to magnetic induction and magnetizing force.

The difference in the magnetic potential at two points in a magnetic field is measured by the work necessary to move a unit magnetic pole against the field from one point to the other. This difference is sometimes called a magnetomotive force, in analogy to electromotive force.

The lines of magnetic intensity around a current-carrying wire are circular, having the plane of the circle perpendicular to the axis of the wire. The direction of the lines of force is determined by the "right-hand rule." When the wire is grasped by the right hand, the fingers encircling the wire, and the thumb pointing along the wire in the direction of the current, the fingers encircle the wire in the direction of the lines of force. This rule is used to determine in which direction the north pole would lie in a helix or solenoid of wire, for, instead of having a straight wire encircled by magnetic lines, the wire itself is bent into a circular form by being wound in a solenoid or helix. The lines of force will then produce an axial magnetic field, so that one end of the solenoid is equivalent to a north pole, the other to a south pole.

In the vicinity of magnets, electric currents, or time-varying electric fields, it is found that a small current-carrying wire loop, if free to turn, will come to an equilibrium orientation. This behavior is attributed to an auxiliary field vector **B** called the magnetic induction or the magnetic flux density. The magnetic moment of a current loop or a magnetized body is a measure of the magnetizing force **H**, produced by the current or magnetized body. The magnetic moment of a plane current loop is a vector (**m**), normal to the plane of the loop and directed so that the current has a clockwise rotation around **m**. The magnitude of **m** is the product of the current and loop area. The magnetic moment of a magnetized body is the vector summation of the magnetic moments of the internal current loops and spins of the body. The magnetizing force produced at a displacement **r** from a small source of moment **m**

$$\mathbf{H} = -\nabla \frac{\mathbf{m} \cdot \mathbf{r}}{r^3}$$

where ∇ is del, the vector differential operator.

The ratio of the magnetic moment of a magnetized body to its volume, expressed by the equation $\mathbf{B} = \mu_0(\mathbf{H} + 4\pi\mathbf{M})$, where μ_0 is the permeability of free space, **B** is magnetic induction, **H** is the external magnetizing force, and **M** is the magnetization. (The symbol **I** is sometimes used for intensity of magnetization.) The application of an increasing magnetizing force to a ferromagnetic substance yields a resulting intrinsic induction that asymptotically approaches a constant value known as the saturation magnetization. Spontaneous magnetism is the magnetic saturation of the domains of a ferromagnetic material, even in the absence of an applied magnetizing force. Each domain is magnetized to saturation at all temperatures below the Curie point, although the material as a whole may be unmagnetized because of the differing orientations of the various domains. See also **Ferromagnetism**.

The intensity of magnetization I induced at any point in a body is proportional to the strength of the applied field H:

$$I = \kappa H (\text{or } \kappa = I/H)$$

where κ is a constant of proportionality depending on the material of the body. It is called the magnetic susceptibility per unit volume, and may be defined qualitatively as the extent to which a material is susceptible to induced magnetism. For an isotropic body, the susceptibility is the same in all directions. However, for anisotropic crystals, the susceptibilities along the three principle magnetic axes are different, and measurements on their powder samples give the average of the three values.

Magnetic susceptibility is obviously related to magnetic permeability, and the following relationships may be derived:

$$B = \mu_H = 4\pi I + H$$

Therefore,

$$\mu = 4\pi I/H + 1 = 4\pi\kappa + 1$$

or

$$\kappa = (\mu - 1)/4\pi$$

Magnetic Flux. The magnetic flux through any closed figure, such as a circle, a rectangle, or a loop of wire, is the product of the area of the figure by the average component of magnetic induction normal to that area. Thus, if a rectangle 5 cm × 8 cm is placed in a region where there is a uniform magnetic induction of 2,500 gauss (other units defined shortly), and at an angle of 30° with the lines of induction, the magnetic flux through it is 2,500 gauss × 40 cm^2 × sin 30° = 50,000 gauss-cm^2 or "maxwells." The magnitude of this quantity is often conventionally represented by imagining the lines of induction to be so spaced that the number of them through a given area is equal to the number of gauss-cm^2 or maxwells of flux through that area. The flux in the above example would be commonly expressed as 50,000 "lines." When a coil has several (n) turns and each turn has approximately the same flux (ϕ) through it. This product, which is called the "linkage," is expressed in "maxwell-turns" or "line-turns."

The magnetic flux or the linkage through a loop or a coil may be measured by putting into the circuit a ballistic (undamped) galvanometer and then suddenly removing the flux (or the coil). If the resistance of the whole circuit and the constant of the galvanometer are known, the flux may be calculated from the "throw" of the galvanometer.

The *gauss* (G) is the electromagnetic CGS unit of magnetic flux density. The *tesla* (T) is the **SI** unit. The *maxwell* (**Mx**) is the electromagnetic CGS unit of magnetic flux. The weber (Wb) is the SI unit.

Magnetic Circuit. The flux from a bar magnet or from a straight electromagnet issues from one end of the magnet or coil, bends around, and reenters at the other end. As mentioned before, this can be exhibited by exploring the region with a small magnet or compass needle. If there is an iron frame or ring extending from one pole of the magnet or coil around to the other, and in the case of the coil, running clear through it, the magnetic flux is not only concentrated largely in the iron, but is much greater in total amount than if the induction is entirely in the air. Even a short gap in the iron reduces the flux considerably.

The analogy of such a magnetic path to an electric circuit is easily seen. The magnetic flux corresponds to a current. The magnet or coil corresponds to a battery, and provides magnetomotive force just as a battery supplies electromotive force. The amount of flux produced by a given magnetomotive force depends upon the dimensions and material of the "magnetic circuit," e.g., the length and cross section of the iron ring followed by the flux and the permeability of the iron; just as the dimensions and material of the electric conductor determine its resistance. The attribute of the magnetic circuit (corresponding to resistance) is called its reluctance.

It must be remembered that this analogy is purely mathematical, not physical. In magnetism, there is no flow of charge, as in electricity.

For a single magnetic circuit consisting of two parts, magnetic material having a permeability μ_1, length l_1, and A_1, and an air gap of permeability μ_0, length l_2 and area A_2. Ampere's circuital law gives $\int H \cos\theta dl = H_1 l_1 + H_2 l_2 = NI$. N is the number of turns and I the current through the coil producing the magnetic flux Φ_m. Now as

$$H_1 l_1 = B_1 l_1/\mu_1 = \Phi_m l_1/A_1\mu_1$$

and

$$H_2 l_2 = B_2 l_2/\mu_0 = \Phi_m l_2/A_2\mu_0$$

So

$$\Phi_m[l_1/A_1\mu_1 + l_2/A_2\mu_0] = NI$$

or

$$\Phi_m = \frac{NI}{[l_1 A_1 \mu_1 + l_2/A_2\mu_0]} = \frac{F}{R}$$

where F is the magnetomotive force in ampere-turns and R, the reluctance of the magnetic circuit. This relation is a magnetic analogy of Ohm's law known as Bosanquet's law.

The *gilbert* (Gb) is the electromagnetic CGS unit of magnetomotive force. The *ampere* (*or ampere turn*) (A) is the SI unit. The *oersted* (Oe) is the electromagnetic CGS unit of magnetic field strength. The *ampere per meter* (A/m) is the SI unit.

Magnetic Materials. The electrical industry is dependent upon four basic types of materials: (1) good conductors of electricity; (2) high-resistivity conductors capable of withstanding high temperatures; (3) insulators; and (4) magnetic materials. The development of better magnetic materials has contributed to marked improvements in motors, generators, transformers, and instruments of all kinds. See also **Magnetic Materials**.

The ferromagnetic elements are iron, nickel, and cobalt. Of these, iron is the only one that has important magnetic applications in pure, or commercially pure form. All three elements, and many others which themselves are nonmagnetic, are used in special alloys in which certain magnetic characteristics are developed to a high degree. It is even possible, by alloying, to develop magnetic material from certain nonmagnetic elements.

There are two distinct groups of ferromagnetic materials, those that are easily demagnetized, and those that are not. These are often designated as soft and hard magnetic materials. In many respects, iron is an excellent soft, magnetic material. It attains the highest saturation value of magnetic induction found in any material, with the exception of certain cobalt alloys. However, its maximum permeability (maximum ratio of magnetic induction to magnetizing force) is surpassed by other materials. When used as a core in a field induced by ac, the so-called "iron losses" are relatively high. Iron losses consist of energy losses related to the area of the hysteresis loop, and of eddy-current losses caused by induced current circuits within the metal. High values of residual induction (B_r on the typical hysteresis curve) and coercive force (H_c) are indications of high hysteresis loss. See also **Hysteresis**. A low value of electrical resistivity results in high eddy current losses. However, other factors such as the thickness of the sheets in laminated cores, and to a lesser degree grain size also affect eddy-current losses. By special heat treatments and by the use of specially purified iron, much higher values of permeability and lower hysteresis losses can be obtained.

With a good grade of silicon electrical steel, the hysteresis loss can be cut in half and the eddy-current loss reduced even more because of the high resistivity compared with iron. This results in much more efficient operation of alternating-current equipment.

Certain high-nickel alloys of the Permalloy type have very high permeabilities at low and moderate inductions and give low hysteresis losses. For many special applications in instruments and communications equipment, these higher cost alloys are economically justified. Power transformers, motors and generators, etc., are designed for silicon electrical steels.

In the use of any of these materials for ac applications, it is desirable to reduce the thickness of individual laminations to reduce eddy-current losses. For special applications at higher than usual power frequencies, extremely thin strips are used, approaching $\frac{1}{1000}$ of an inch (0.025 millimeter) in thickness. The most common thickness at 60-cycle power frequencies is about $\frac{14}{1000}$ inch (0.35 millimeter). In the communications field, where the use of very high frequency current greatly aggravates the problem of eddy-current losses, alloys of the Permalloy type are used. They are produced in powdered form, given a very thin insulating film, and compacted under high pressure into a suitable core shape.

In the production of magnetically soft materials, it is important that elements such as carbon and sulfur, which disturb the continuity of the base-metal crystal structure, be reduced to low residual amounts, and that the material be used in a strain-free condition. High annealing temperatures resulting in coarse grain structures are used. These conditions are, for the most part, reversed when magnetically hard materials are sought. These materials must be capable of reaching high inductions, but upon removal of the direct magnetizing force the magnetic flux remaining in the circuit should be high, therefore a hysteresis loop of large area is desired. A good overall measure of the quality of a permanent magnet is the "maximum external energy." This is the maximum value which can be obtained for the product of the coordinates of a point on the curve between B_r and H_c on the hysteresis curve.

Progress in Development of Magnetic Alloys. During the last 100 years of experience in producing and using permanent magnets, alloy magnets as of the early 1980s are the most powerful by a factor of 30. Until the late 1930s, magnets were produced from steel. Then considerable research was devoted to producing and testing various magnetic alloys. Alnico magnets became available in the mid-1940s, representative present-day Alnico magnets contain a number of other metals. For example, Alnico 5 contains 8% aluminum, 14% nickel, 24% cobalt, and 3% copper, the remainder being iron. Alnico 9 contains 7% aluminum, 15% nickel, 35% cobalt, 4% copper, 5% titanium, the remainder being iron. Work on the development or magnetic alloys containing various rare-earth elements commenced in the late 1950s. A number of magnetic alloys containing rare-earth elements and cobalt are available today. As pointed out by Chin (1986), the magnetism of the R-Co compounds is due to the interatomic exchange between the spins of the two sublattices plus the spin-orbit coupling within the rare-earth atoms. The spins of the lighter rare-earth elements, such as cerium, praseodymium, neodymium, and samarium, align parallel with the cobalt atoms, resulting in high saturation magnetization values at room temperature. Other rare-earth elements align antiparallel with the cobalt atoms and thus the values are lower. In the mid-1970s, the alloy $Sm_2(Co, Fe, Cu)_{17}$ was introduced. See also **Rare-Earth Elements and Metals**.

The importance of improved magnetic alloys is sometimes underestimated. Magnets are used widely in telecommunications and in scores of electrical and electronic instruments and appliances, and it has been estimated that the demand for permanent magnets has increased by a factor of three since 1970. Chromium-cobalt-iron alloys have increased markedly in application. It is interesting to note that these magnets have essentially about the same coercive force and maximum energy product as Alnico 5, but with only half the cobalt content.

See also **Magnetostriction**.

Molecular Magnets. Ordinary iron and alloy magnets are made of atomic constituents that are difficult to modify. By contrast, molecular magnets may be customized much more easily, and they account for the past decade of research into formulating superior molecular magnets. In mid-1991, A.I. Epstein (Ohio State University) and J.S. Miller (DuPont Central Research and Development Facility) appear to have synthesized an organic-based magnet that retains its magnetism at room temperature and up to and including an elevated temperature of 350°K. At the latter temperature, the polymeric material commences to break down chemically. M. Hoffman (Northwestern University) observes that, if this is a molecular magnet, it represents an enormous leap. No researcher in the field has come even close to 350°K.

This particular magnet, although of exceeding interest in the laboratory, is not considered for practical applications because the material deteriorates rapidly unless it is contained within an inert atmosphere. According to a paper released by J.M. Manriquez, et al., the magnet is the result of a reaction of bis (benzene) vanadium with tetrocyanoethylene (TCNE). The material is an amorphous black solid that exhibits field-dependent magnetism and hysteresis at room temperature.

Quantum Effects and Tiny Magnets. Since early computer designs of the 1950s, there has been tremendous pressure exerted to microminiaturize magnetic information systems. This marked trend continues as designers strive for increased information density. But is there a limit? Some scientists now are showing serious concern that, as magnetic devices

become smaller and smaller, the point may be reached where quantum effects could cause upheavals in the magnetic storage system. It is interesting to note that, in the computers of the 1950s, an estimated 100 billion atoms were needed to store one bit of information. In the early 1990s, this figure had dropped to an estimated 1 billion atoms. Experts then predicted that, by the year 2000, the storage of one bit of information would require only 100,000 or fewer atoms. Researchers at the IBM Thomas J. Watson Research Center and other researchers in the computer field have pioneered techniques for studying magnets composed of 100,000 atoms at temperatures approaching absolute zero. Some of these researchers, who have instrumentation that can measure a magnetic field with a million times the sensitivity of traditional instruments, have observed what they believe may be evidence of tunneling and other effects of quantum mechanics in experimental magnetic systems. One group claims that, when a tiny magnet is cooled to absolute zero, the north and south poles of this magnets can be reversed effortlessly, causing havoc to enter the magnetic storage system. Another group clings to the concept of classical mechanics and the idea that "spins" cannot occur without receiving energy—thus a so-called "energy barrier." By contrast, consistent with quantum mechanics, there is a "chance" that spins will be capable of breaking through the energy barrier. As pointed out by R. Ruthen, "This phenomenon is analogous to the ability of an electron to tunnel through an energy barrier."

Thus, a profound difference of opinion remains and will require continued research to find the truth.

An excellent description of the early investigations of electricity and magnetism is given by L. Pearce Williams (reference listed).

MAGNETITE. The mineral magnetite, ferroferric oxide, Fe_3O_4, is isometric, commonly occurring in octahedrons, dodecahedrons, and massive, granular, and laminated forms. It is brittle with an uneven fracture; cleavage is not distinct, but with pressure an octahedral parting may develop; hardness, 5.5–6.5; specific gravity, 5.18; luster, metallic to dull; color, iron black, streak, black. It is opaque and strongly magnetic; when possessing polarity it is known as lodestone. Important large ore bodies are products of magmatic segregations, with titanium a prominent constituent of such deposits. Magnetite is a common mineral in the igneous rocks, especially those of the ferromagnesian varieties, and is found in many metamorphic types. It is associated with corundum in emery.

In northern Sweden are located what may be the largest magnetic deposits in the world, believed to have been formed by segregation in the magma. Magnetite is also found in Norway, in the Urals, Italy, Switzerland, Australia, and Brazil. In the United States, the Precambrian rocks of the Adirondacks contain large beds of magnetite, as well as extensive deposits of titaniferous magnetite, and the mineral is found also in New Jersey, Arkansas, and Utah. In Canada it is found in Quebec and Ontario. The lodestone or natural magnet is found in Siberia, the Harz Mountains, Germany; the Island of Elba; and at Magnet Cove Arkansas. The name magnetite is said to be derived from the district of Magnesia, near Macedonia. There is, however, a fable that it was named for a shepherd, Magnes, whose iron-bound staff and shoes with iron nails struck to the ground in which magnetite was present.

This mineral is an important ore of iron, 72% being metallic iron. Magnetite sometimes is referred to as magnetic iron ore.

MAGNETOCHEMISTRY. A subdivision of chemistry concerned with the effect of magnetic fields on chemical compounds; analysis and measurement of these effects, (e.g., magnetic moment and magnetic susceptibility) are important tools in crystallographic research and determination of molecular structures. Substances that are repelled by a magnetic field are diamagnetic (water, benzene); those that are attracted are paramagnetic (oxygen, transition element compounds). Diamagnetic materials have only induced magnetic moment; paramagnetic materials have permanent magnetic moment. Magnetochemistry has been useful in detection of free radicals, elucidation of molecular configurations of highly complex compounds, and in its application to catalytic and chemisorption phenomena. See also **Nuclear Magnetic Resonance (NMR) and Magnetic Resonance Imaging (MRI)**, and **Magnetism**.

MAGNETOHYDRODYNAMICS (MHD). The behavior of high-temperature ionized gases passed through a magnetic field. A power-generating method using MHD involves an open cycle in which hot combustible gases from coal, seeded with cerium or potassium to increase electrical conductivity, constitute the working fluid. These are sent through a nozzle surrounded by a magnet; the electricity induced by movement of the ionized gas through the magnetic field is passed to electrodes and the gas sent to a steam generator. Efficiency is rated at 50–60% compared with 40% for conventional fossil fuel plants and 33% for plants using nuclear fuels. Two-phase liquid-metal systems are being studied as auxiliary units for a number of energy converters. MHD is an important field of expansion of research activity on new sources of energy; its high efficiency and low pollution factor indicate that it may have a significant future in electric power supply.

MAGNETOSTRICTION. When a polycrystalline nickel sample is placed in a magnetic field, it contracts along the field direction by about 30 parts per million and elongates in the transverse direction by about half that amount. There is also a small volume change. Such changes in dimension of magnetic materials with variation of magnetic field strength or direction are termed *magnetostriction*. See also **Magnetic Materials**. They are measured by strain gages, optical dilatometers, capacitance variation, and x-ray analysis. Below the Curie Temperature, magnetostriction in weak fields is caused by domain rotation, becoming appreciable at fields near the knee of the $B - H$ curve. See also **Hysteresis**. The saturation magnetostriction of a single crystal depends upon the direction of the (sublattice) magnetization and the direction of measurement with respect to the crystal axes. Magnetostriction coefficients vary greatly, depending upon the material, temperature, and the magnetization state. The source of magnetostriction is the dependence of magnetic energy on strain. Because the elastic energy is quadratic in strain while the magnetoelastic energy is linear in strain, the minimum free energy occurs at nonzero strain.

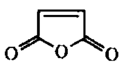
Magnetostriction has been put to practical use in the magnetostrictive resonator. This is essentially an iron rod maintained in longitudinal elastic vibration by a high-frequency current in a helix wound upon it, and used, through the joint operation of the Joule and Villari effects, to control the frequency of the current, somewhat after the manner of the familiar piezoelectric (crystal) resonator. It is also used in band-pass electrical wave filters.

MALACHITE. The mineral malachite is a basic carbonate of copper corresponding to the formula $Cu_2(CO_3)(OH)_2$. It is monoclinic, crystals

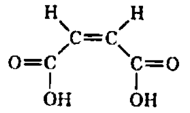
tending to be acicular, but usually found massive. It is a brittle mineral: hardness, 3.5–4; specific gravity, 4.05; luster, vitreous to silky or dull; color, green; streak, green; translucent to opaque. Malachite is an alternation product found associated with other copper-bearing minerals. It is a rather common mineral and is found quite widely distributed. Large quantities have been found in the Ural Mountains; it is also found in Germany, France, England, Zaire, Rhodesia, and Australia. In the United States, beautiful radiated masses of fibrous crystals have been found in Berks County, Pennsylvania, as well as in Tennessee at Ducktown, and in Arizona, Nevada, and Utah. Malachite, besides being an ore of copper, has been used for various ornamental purposes. The word malachite is derived from the Greek, meaning a *mallow*, because of its green color.

MALAPRADE REACTION. Compounds containing two hydroxyl groups or a hydroxyl and an amino group attached to adjacent carbon atoms undergo cleavage of the carbon-to-carbon bond when treated with periodic acid.

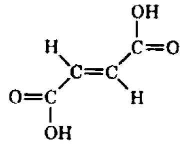
MALEIC ANHYDRIDE, MALEIC ACID, AND FUMARIC ACID. Maleic anhydride [CAS: 108-31-6], (**1**), maleic acid [CAS: 110-16-7], (**2**), and fumaric acid [CAS: 110-17-8], (**3**) are multifunctional chemical intermediates that find applications in nearly every field of industrial chemistry. Each molecule contains two acid carbonyl groups and a double bond in the α, β position. Maleic anhydride and maleic acid are important raw materials used in the manufacture of phthalic-type alkyd and polyester resins, surface coatings, lubricant additives, plasticizers, copolymers, and agricultural chemicals (see **Alkyd Resins**; **Polymers**, and **Lubricant**). Both chemicals derive their common names from naturally occurring malic acid.



(**1**)



(**2**)



(**3**)

Fumaric acid occurs naturally in many plants and is named after *Fumaria officinalis*, a climbing annual plant, from which it was first isolated. It is used as a food acidulant and as a raw material in the manufacture of unsaturated polyester resins, quick-setting inks, furniture lacquers, paper sizing chemicals, and aspartic acid.

Physical Properties

Physical constants for maleic anhydride, maleic acid, and fumaric acid are given in Table 1. From single crystal x-ray diffraction data, maleic anhydride is a nearly planar molecule with the ring oxygen atom lying 0.003 nm out of the molecular plane.

Maleic and fumaric acids have physical properties that differ due to the cis and trans configurations about the double bond.

Chemical Properties

Extensive descriptions of the chemistry of maleic anhydride and its derivatives are available in the literature. The broad industrial applications for this chemistry derive from the reactivity of the double bond in conjugation with the two carbonyl oxygens. Reactions include acid chloride formation, acylation, alkylation, amidation, concerted nonpolar reactions, decomposition and decarboxylation, electrophilic addition, esterification, free-radical reactions, grignard-type reactions, halogenation, hydration and dehydration, hydroformylation, isomerization, ligation to metal atoms, nucleophilic addition, oxidation, polymerization, reduction, and sulfonation.

Manufacture

Process Technology Evolution. Growth in the worldwide maleic anhydride industry is exclusively in the butane-to-maleic anhydride route, often at the expense of benzene-based production. Table 2 shows 1995 and estimated 1996, 1997, and 2000 worldwide maleic production capacity broken down in categories of benzene, butane and phthalic anhydride coproduct. As can be seen from this table butane routes are expected to grow at the expense of benzene-based processes.

Recovery and Purification. All processes for the recovery and fining of maleic anhydride must deal with the efficient separation maleic anhydride from the large amount of water produced in the reaction process. Recovery systems can be separated into two general categories: aqueous- and nonaqueous-based absorption systems. Solvent-based systems have a higher recovery of maleic anhydride and are more energy efficient than water-based systems.

Fumaric Acid. Fumaric acid for commerce is derived from maleic acid through catalytic isomerization. Purified maleic anhydride is the main source of maleic acid. High purity fumaric acid is produced through crystallization of the aqueous mixture, washing, and drying. Decolorizing and crystallization techniques are used to treat impure maleic solutions.

Shipment

Molten maleic anhydride is shipped in tank rail cars, tank trucks and isotanks (for overseas shipments). Solid form maleic anhydride is produced from molten maleic anhydride as briquettes or pastille weighing 0.5 to 20 g. Fumaric acid is shipped in solid form, the particles size varying based upon the specification.

Economic Aspects

The switch of feedstock from benzene to butane was completed in the U.S. in 1985, being driven by the lower unit cost and lower usage of butane in addition to the environmental pressures on the use of benzene. Worldwide, the switch to butane was continuing with 58% of the total world maleic anhydride capacity based on butane feedstock in 1992. This capacity percentage for butane increased from only 6% in 1978. In 1995, 31% of the total world maleic anhydride capacity was based on benzene feedstock and 2% was derived from other sources, primarily phthalic anhydride by-product streams.

Another characteristic of the maleic anhydride supply picture has been the emergence of newer capacity, predominantly in Asia, which has resulted in a significant oversupply to that area of the world. The historically largest and second largest maleic anhydride markets are North America and Western Europe, respectively. Although the names of the producers in both of these areas of the world have changed rather dramatically between the late 1970s and the early 1990s, the total capacity in these world areas has only declined a small amount. Beginning in the late 1980s, small commercial plants based on butane fluidized-bed technologies were built in Asia. As of the end of 1992, fixed-bed butane-based technology accounted for 74% of the butane-based maleic anhydride facilities worldwide with butane-based fluidized-bed technology accounting for the remainder. The butane-based transport-bed process announced by DuPont is scheduled to start up in Spain in 1996.

TABLE 1. PHYSICAL PROPERTIES OF MALEIC ANHYDRIDE, MALEIC ACID, AND FUMARIC ACID

Health and Safety Factors (Toxicology)

Maleic Anhydride. The ACGIH threshold limit value in air for maleic anhydride is 0.25 ppm and the OSHA permissible exposure level (PEL) is also 0.25 ppm. Maleic anhydride is a corrosive irritant to eyes, skin, and mucous membranes. Pulmonary edema (collection of fluid in the lungs) can result from airborne exposure. Maleic anhydride is combustible when exposed to heat or flame and can react vigorously on contact with oxidizers.

Maleic Acid. Maleic acid is produced by the hydration of maleic anhydride. The hazards of its use are analogous to those of maleic anhydride. It is a skin and severe eye irritant. It is combustible when exposed to heat or flame and can react vigorously with oxidizing agents.

Uses

Maleic anhydride itself has few, if any, consumer uses but its derivatives are of significant commercial interest. The majority of the maleic anhydride produced is used in unsaturated polyester resin (see **Polyesters, Unsaturated**). Unsaturated polyester resin is then used in both glass-reinforced applications and unreinforced applications.

Fumaric acid and malic acid are produced from maleic anhydride. The primary use for fumaric acid is in the manufacture of paper sizing products. Fumaric acid is also used to acidify food as is malic acid. Malic acid is a particularly desirable acidulant in certain beverage selections, specifically those sweetened with the artificial sweetener aspartame.

Lubrication oil additives represent another important market segment for maleic anhydride derivatives. Maleic anhydride is used in a multitude of applications in which a vinyl copolymer is produced by the copolymerization of maleic anhydride with other molecules having a vinyl functionality. The use of maleic anhydride in the manufacture of agricultural chemicals has declined in the U.S. since the early 1980s.

There are numerous further applications for which maleic anhydride serves as a raw material. These applications prove the versatility of this molecule. The popular artificial sweetener aspartame is a dipeptide with one aminoacid (L-aspartic acid) which is produced from maleic anhydride as the starting material. An important future use for maleic anhydride is believed to be the production of products in the 1,4-butanediol-γ-butyrolactone–tetrahydrofuran family. This technology can be used to produce the product mix of the three molecules as needed by the producer.

MALEIC HYDRAZIDE GROWTH INHIBITOR. This compound (1,2-dihydro-3,6-pyridazinedione) is used to inhibit the growth of certain food commodities when in storage, including onion and potato. Maleic hydrazide is also used to promote dormancy in citrus trees as well as increasing protection from frost.

MALONIC ACID AND DERIVATIVES

Malonic Acid

[CAS: 141-82-2]. Malonic acid, HOOC–CH_2–COOH, was discovered and isolated in 1858 as a product of malic acid oxidation. The physical properties of malonic acid are listed in Table 1.

Reactions. Malonic acid is a useful tool for synthesizing α-unsaturated carboxylic acids because of its ability to undergo decarboxylation and condensation with aldehydes or ketones at the methylene group. Cinnamic acids are formed from the reaction of malonic acid and benzaldehyde derivatives. If aliphatic aldehydes are used acrylic acids result. Similarly this facile decarboxylation combined with the condensation with an activated double bond yields α-substituted acetic acid derivatives. Reactions of the carboxylic acid groups include monoesterification, diesterification, or conversion with thiols.

TABLE 1. PROPERTIES OF MALONIC ACID[a]

Property	Value
mol wt	104.06
melting point, °C	135 dec
solubility	
in water at 20 C	139 g/100 mL
in pyridine at 15°C	15 g/100 g

[a] Also called propanedioic acid or methanedicarboxylic acid.

Preparation. The industrial production of malonic acid is much less important than that of the malonates. Malonic acid is usually produced by acid saponification of malonates. Further methods which have been recently investigated are the ozonolysis of cyclopentadiene, the air oxidation of 1,3-propanediol, or the use of microorganisms for converting nitriles into acids.

Economic Aspects. Malonic acid is produced by Juzen and Tateyama in Japan as well as Lonza Ltd. in Switzerland and Riedel-De Haen Ltd. in Germany.

Health and Safety Factors (Toxicology). Due to its acidity malonic acid is classified as a mild irritant (skin irritation, rabbits).

Meldrum's Acid. Meldrum's acid is commercially used for the production of monoesters of malonic acid and beta-keto acids.

Malonates

Physical Properties. Industrially, the most important esters are dimethyl malonate, [CAS: 108-59-8], CH_3OCO–CH_2–$COOCH_3$, and diethyl malonate, [CAS: 105-53-3], C_2H_5 – OCO–CH_2–$COOC_2H_5$, whose physical properties are summarized in Table 2. Both are sparingly soluble in water (1 g/50 mL for the diethyl ester) and miscible in all proportions with ether and alcohol.

Reactions. The chemical properties of malonates are highlighted by the acidity of the methylene group ($pK_a \sim 13$) to such an extent that a proton can be easily detached by a strong base, usually alkoxides.

Manufacture. The predominant manufacturing processes are the hydrogen cyanide process and carbon monoxide process.

Economic Aspects. Dimethyl and diethyl malonates are produced via the carbon monoxide process at Hüls (Germany), Juzen (Japan), and Korean Fertilizers (S. Korea); they are produced via the hydrogen cyanide process at Lonza (Switzerland) and Tateyama (Japan). Total capacity is estimated to be about 12,000 t/yr. Furthermore, producers are also reported in the People's Republic of China and in Romania.

Health and Safety Factors. Dimethyl malonate and diethyl malonate do not present any specific danger of health hazard if handled with the usual precautions. Nevertheless, inhalation and skin contact should be avoided.

Diisopropyl Malonate. This dialkyl malonate has gained industrial importance for the synthesis of the fungicide isoprothiolane through condensation with carbon disulfide and ethylene dichloride. Diisopropyl malonate is produced by Mitsubishi Chemical (Japan) using the carbon monoxide process.

TABLE 2. PHYSICAL PROPERTIES OF DIMETHYL AND DIETHYL MALONATE

mol wt	85.06	99.09	113.12
mp, °C	66	−22	−22
bp °C/kPa[a]	108°/1.5 kPa	203°/101 kPa	206°/101 kPa

[a] To convert kPa to mm Hg, multiply by 7.5.

Cyanoacetic Acid and Cyanoacetates

Physical Properties. The physical properties of cyanoacetic acid $N{\equiv}C{-}CH_2COOH$ are summarized in Table 3. The industrially most important esters are methyl cyanoacetate and ethyl cyanoacetate. Both esters are miscible with alcohol and ether and immiscible with water.

Reactions. The chemical properties of cyanoacetates are quite similar to those of the malonates.

Manufacture. Cyanoacetic acid and cyanoacetates are industrially produced by the same route as the malonates using a modified hydrogen cyanide process, starting from a sodium chloroacetate solution via a sodium cyanoacetate solution.

Economic Aspects. In order to avoid the extraction and evaporation steps, most of the cyanoacetic acid derivatives are made directly from solution; therefore, only a small portion of the acid produced is traded. Cyanoacetic acid is produced by Boehringer-Ingelheim and Knoll (Germany), Juzen (Japan), as well as Hüls (U.S.).

Methyl cyanoacetate and ethyl cyanoacetate are produced by Lonza (Switzerland) and Huls (U.S.), as well as Juzen and Tateyama (Japan). The total production capacity is estimated to be in the range of 10,000 metric tons per year.

Health and Safety Factors. Handling of cyanoacetic acid and cyanoacetates do not present any specific danger or health hazard if handled with the usual precautions.

Uses. In many cases cyanoacetic acid, cyanoacetates, or cyanocetamide can be used alternatively. The traded cyanoacetic acid is mainly intended for the synthesis of the cough remedy dextromethorphan and of the fungicide cymoxanil See also **Fungicides**. Otherwise cyanoacetic acid is directly converted as a solution with 1,3-dimethylurea into 2-cyano-*N*, *N'*-dimethylcarbamoyl acetamide which is further upgraded into the diuretics theophylline and caffeine.

The largest application of methyl and ethyl cyanoacetate is the production of the cyanoacrylate adhesives widely used within the car and electronic industries.

Malononitrile

Physical Properties. The physical properties of malononitrile $N{\equiv}C{-}CH_2C{\equiv}N$ are listed in Table 4.

Reactions. As in the case of malonates and cyanoacetates, the chemical properties of malononitrile are determined by two reactive centers, namely the methylene group and the two cyano functions. A peculiar reaction of malononitrile is the base-catalyzed dimerization leading to 2-amino-1,1,3-tricyanopropene.

Manufacture. Malononitrile can be produced batchwise by elimination of water from cyanoacetamide with phosphorous pentachloride. Most of it is now produced continuously starting from cyanogen chloride and acetonitrile in a high temperature gas phase reaction.

Removal of maleic and fumaric acids from the crude malononitrile by fractional distillation is impractical because the boiling points differ only slightly. The impurities are therefore converted into high boiling compounds in a conventional reactor by means of a Diels-Alder reaction with a 1,3-diene.

TABLE 4. PHYSICAL PROPERTIES OF MALONONITRILE[a]

Property	Value
mol wt	66.06
mp, °C	31
bp at 76 kPa[b], °C	218–219
d_4^{35}, g/mL	1.0494
solubility in water, g/mL	0.133

[a] Also called propanedinitrile and dicyanomethane.
[b] To convert kPa to mm Hg, multiply by 7.5.

Economic Aspects. Malononitrile is produced by Lonza Ltd. (Switzerland) using the cyanogen chloride process.

Health and Safety Factors. Malononitrile is usually available as a solidified melt in plastic-lined drums. Remelting has to be done carefully because spontaneous decomposition can occur at elevated temperatures, particularly above 100°C, in the presence of impurities such as alkalies, ammonium, and zinc salts. Occupational exposure to malononitrile mainly occurs by inhalation of vapors and absorption through the skin. Malononitrile has a recommended workplace exposure limit of 8 mg/m³.

Uses. Malononitrile is extensively used in the life sciences industry. The most important products are vitamin B_1 (thiamine) and bensulfuron-methyl, a sulfonyl urea herbicide. Most other product uses fall under the *N*-containing heterocycles.

MALT. Unless otherwise specified, malt usually connotes barley malt. Malt, however, can be prepared from other cereal grains. Between 75 and 80% of the malt produced in the United States goes into the manufacture of beer and associated beverages. Nearly 15% of the production goes to the manufacture of distilled alcohol products; and the remainder (about 5–6%) goes into the preparation of malt syrups, breakfast foods, malted milk concentrates, and coffee substitutes.

Barley malt is barley that has been germinated by moisture under controlled conditions and for a specified time, after which the germinated plants are carefully dried under controlled conditions. The drying or kilning operation and other operations in the total malting process are customized to the final product in which the malt will be used. The principal stages of the malting process are diagrammed in Fig. 1.

Upon receipt, the barley must be inspected carefully to make certain that it fully meets the minimum acceptable specifications established by the malt manufacturer. The qualities desired in grain for malting are described in the entry on Barley.

Prior to processing, the barley is stored for up to 6 weeks to permit any further ripening (after-ripening) to take place. This enhances later germination. The cleaning operation that follows removes impurities, unwanted foreign seeds, and damaged and broken kernels. Because the size of the kernels affects handling during the germinating operation, the barley is graded into 2 or 3 size ranges, each of which is malted separately.

The role served by malt in the later production of beer and distilled spirits is that of furnishing enzymes, which convert starches and other

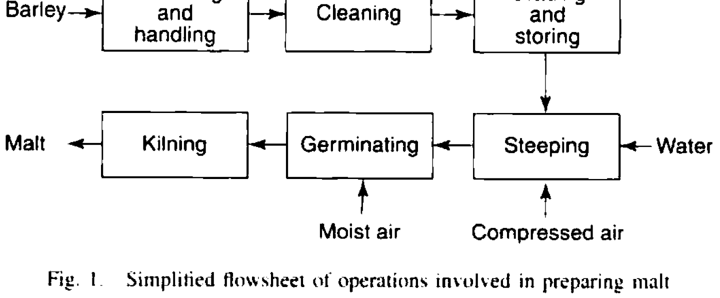

Fig. 1. Simplified flowsheet of operations involved in preparing malt

ingredients during the brewer's and distiller's mashing operations. J. de Clerck states: "Quantitatively the most significant chemical constituent of the grain is starch which constitutes some two-thirds of the dry weight of barley. Apart from a comparatively small contribution from other sugars in barley it is the starch which eventually furnishes some 85–90% of malt extracts, of which some 70% is fermented in brewing and sometimes nearly all in distilling. Starch, therefore, occupies a key position in relation to the brewing and distilling industries and its chemistry is, apart from its intrinsic biochemical interest as the final product of photosynthesis, of outstanding importance." The starch granules of barleys are first seen in the cells of the endosperm a few days after development of the seed begins as small spheres later developing into the bean-shaped and lenticular forms characteristic of mature starch. Luers observed that barley starch undergoes enzymic degradation during malting and that malt starch is different from barley starch. This was recognized as early as 1902. The loss in starch that occurs during malting has been estimated by various researchers. Luhder (1908) first established that the starch content of barley declined considerably during malting. For example, Moravian barley before malting contains 65.57% starch and after malting, 54.89%. Of the two starch constituents amylopectin and amylose, the former is more susceptible to enzymolysis during malting. Several theories have been proposed to explain this difference. The principal factors that influence the amount of starch in barley are environmental during growth and also relate to the variety planted.

Brewers' and Distillers' Malts

Barleys of large grain size are desired for preparing brewers' malt. The larger sizes usually have a greater percentage of starch and relatively little protein. The grains, however, do contain adequate amylolytic enzymes for solubilizing native starch and also some of the other ingredients of the mashing operation at the brewery.

In contrast, the primary objective of distillers' malt is to furnish enzymes in larger quantities for later use in converting grains and starch present in other substances. Barley best suited for this purpose is of a relatively high nitrogen content, a factor that relates to the ability to produce amylases. In the United States, certain barley varieties, such as *Kindred*, *Manchuria*, *Montcalm*, and *Odessa*, are specifically selected for making distillers' malt.

Steeping

Once size-graded, the barley is transferred to large steeping tanks equipped with conical or funnel-shaped bottoms. Cool, clean water is added to partially fill the tank. Air agitation assists in cleaning the barley. Any light-weight kernels present automatically rise to the surface of the water and are skimmed off. During a period of from 45 to 60 hours, the barley soaks up water (steeps). At the end of the steeping period, the moisture content of the barley will range between 45 and 48%, representing sufficient moisture to commence germination. Distillers' malt usually requires a somewhat longer period of steeping in order to bring the moisture content up to a minimum of 50%. The process that takes place during steeping is, not surprisingly, essentially the same as the changes that occur when the seed is planted in moist soil.

Germinating

During the next process step, germination, enzymes are produced or liberated in a structure situated between the germ and endosperm of the barley kernel. During germination, the cell wall is made more permeable by the action of the enzyme cytase. Mellowness and friability of the finished malt is determined by this enzymatic action. In barley malt, the amylase enzymes are the most important. These enzymes convert starch into maltose sugars and dextrins in later brewing processes. During germination, only a small part of the starch present should be converted to maltose or other sugars, recalling the prior mention of starch losses. The principal conversion of starch occurs later in mashing operations at the brewery or distillery. Other enzymes that transform proteins also are produced or activated during malting.

Over the years, three principal malting procedures have been developed. The oldest of these is the germinating floor or floor malting, still practiced in some European countries. The steeped barley, once removed from the steeping tanks, is spread in heaps about 1 foot (0.3 meter) in height. The first spreading occupies perhaps only 40% of the available floor area. The barley commences to dry out and sprout, producing small hairlike fibers (rootlets). It is necessary to aerate the early-sprouting barley (known as *green malt*), which is accomplished by turning the heap over and over with forks. The barley is spread over a larger floor area. These actions, plus the use of forced aeration, cool the green malt. This procedure is repeated at regular intervals over a period of 5 to 7 days. The process is confined to the cooler seasons of the year because germinating temperature should be maintained within a span between 60° and 70°F (15.6° and 21.1°C). Excessive temperature accelerates germination and generates waste, increasing starch losses and excessively large rootlets. Technically, the optimum cut-off time for germination is when the plumule or acrospire reaches the length of the kernel. An extension of the floor malting process to avoid any seasonal limitations on the process is pneumatic floor or compartment malting. Instead of placing the barley on the floor in heaps, it is placed in box-shaped compartments, which hold the grain during the entire germinating period. Purified air is circulated through these compartments. The air is both temperature and humidity controlled. The green malt is turned by mechanical screws within the compartments. Such compartments will contain up to 5000 bushels (108 metric tons) of green malt.

In *drum malting*, widely used in modern malting plants, there are two concentric hollow metal cylinders. Grain is placed in the spaces between the cylinders, which are perforated for introduction and circulation of humidity-and-temperature-controlled air. To permit maximum movement of the grain, the equipment is only partially filled. The revolving action of the cylinders keeps the grain tumbling, constantly exposing new surfaces of the grain to the air stream. Capacity of these drums is up to 650 bushels (about 13.5 metric tons).

Drying or Kilning

These are not high-temperature or rotary kilns as one may visualize in connection with a cement or ore plant, but they are usually 2-story buildings. Drying is commenced on the upper story by spreading the green malt in layers of 2 to 3 feet (0.6 to 0.9 meter) in depth. The primary purpose of the kilning operation is to halt further germination, although the conditions of kilning also affect the final end-use properties of the malt. Hot air is drawn through the malt at a relatively low temperature for the first 24 hours to accomplish a partial drying. The malt is then transferred to the lower story, where the air temperature is increased. In the case of brewers' malt, the final kilning temperature is in the range of 160° to 180°F (71° to 82°C), and the malt is retained in the kiln until the moisture has reached a content of about 4%. The entire process requires from 48 to 72 hours. In the case of distillers' malt, the final kilning temperature is lower—in the range of 120° to 140°F (49° to 60°C) and the final moisture content is from 5 to 7%. The lower temperature preserves higher enzymatic activities. The higher temperature for brewers' malt introduces a more intense malt flavor and aroma, usually desired for the brewing process. In the case of porter, bock beer, and stout, the kilning temperature is higher and a caramel malt is produced. This imparts a dark color and distinctive flavor during the brewing of these malted beverages.

After kilning, the malt is cleaned to remove rootlets and any broken kernels that may remain in the batch.

Malting Process Innovations

In recent years, several steps to modernize and improve the operations just described have been made. Sophisticated control and conveying systems have assisted in more exacting control of processing conditions and reducing hand labor costs. There is a growing trend toward continuous operations. Some consideration has been given to the use of gibberellic acid as part of the steepwater or in the form of a spray during the germinating process. The objective of these steps would be that of increasing yield. It also has been found that potassium bromate in the steepwater will depress respiration and rootlet formation.

A nutritional profile is given in Table 1.

Malt from Other Grains

Sometimes wheat malt is used as a flour supplement for bakery products. The malt provides a source of a-amylase, which degrades starch to sugars, the fermentation of which causes rising of the dough. Of course, barley malt is also used in some bakery product flours. Wheat malt imparts a characteristic flavor to beer. Most consumers find this undesirable. However, *Weissbier*, made with wheat malt, is quite popular in certain regions of Germany. In producing wheat malt, kilning temperatures are more moderate.

TABLE 1. NUTRITIONAL PROFILE OF MALT (100-GRAM SAMPLES)

	Dry malt	Dried malt extract
Water	18.7 g	11.5 g
Food energy	374	374 cal

MALTHA. A black, viscous, natural bitumen consisting of a complex mixture of hydrocarbons. Its viscosity and rheological properties lie between those of crude oil and semisolid asphalt. It is the chief component of Athabaska oil sands.

MALTITOL. See **Sweeteners**.

MALTOSE. See **Carbohydrates**.

MANGANESE. [CAS: 7439-96-5]. Chemical element, symbol Mn, at. no. 25, at. wt. 54.9380, periodic table group 7, mp 1,244 ± 3°C, bp 1,962°C, density 7.3 g/cm^3 (solid), 7.21 (single crystal) (20°C). Manganese has a cubic (complex) crystal structure.

Manganese is a little-known element other than to a small circle of technical specialists who are predominantly metallurgists and chemists. Yet it is the fourth most used metal in terms of tonnage, being ranked behind iron, aluminum and copper, with in the order of 20 million tons of ore being mined annually (2000).

Manganese has numerous applications which impact on our daily lives, whether it be as consumers of objects made of steel, of portable batteries, or of beverage cans based on aluminum. In each case, manganese plays a vital role in improving the properties of the alloys and compounds involved in each specific application.

In the mid-17th century, the German chemist Glauber obtained permanganate, the first usable manganese salt. Nearly a century later, manganese oxide became the basis for the manufacture of chlorine. Yet manganese was only recognized as an element in 1771, by the Swedish chemist Carl Wilhelm Scheele. It was isolated in 1774 by one of his collaborators, J.G. Gahn. At the beginning of the 19th century, both British and French scientists began considering the use of manganese in steelmaking, with patents granted in the U.K. in 1799 and 1808. In 1816, a German researcher observed that manganese increased the hardness of iron, without reducing its malleability or toughness.

In 1826 Prieger in Germany produced a ferromanganese containing 80% manganese in a crucible. J.M. Heath produced metallic manganese in England in about 1840. The following year, Pourcel began industrial-scale production of "spiegeleisen", a pig-iron containing a high percentage of manganese, and in 1875 he started the commercial production of ferromanganese with a 65% manganese content. The major breakthrough in the use of manganese occurred in 1860. At that time, Sir Henry Bessemer was trying to develop the steelmaking process which was to bear his name. But he experienced difficulty with an excess of residual oxygen and sulphur in the steel. The problems were overcome thanks to the beneficial effect of manganese, disclosed in a patent granted to Robert Mushet in 1856. Mushet suggested adding "spiegeleisen" after the blow to introduce both manganese and carbon and remove oxygen. This procedure made the Bessemer process possible, and thus paved the way for the modern steel industry. Ten years later, in 1866, Sir William Siemens patented the use of ferro-manganese in steelmaking so as to control the levels of phosphorus and sulphur.

Subsequently, and in contrast to all the early work involving manganese and steelmaking, Leclanché in 1868 developed the dry cell battery. This uses manganese dioxide as a depolariser in a simple yet effective dry cell and the battery market today is the second largest consumer of manganese. The history of manganese in the 20th century has been a stream of new processes and metallurgical/chemical applications developed with a significant impact on markets as diverse as beverage cans, agricultural pesticides and fungicides and electronic circuitry used in consumer products. Details of these applications are analysed later.

Manganese is a silver-white metal, not notably hard (becomes hard on alloying with carbon), brittle, capable of taking a brilliant polish but readily oxidized upon heating, reacts with water upon boiling, soluble in dilute acids. In terms of abundance, manganese is present in igneous rocks to an average extent of 0.10% (weight). In terms of cosmic abundance, in the estimate by Harold C. Urey (1952), using a base figure of 10,000 for silicon, the figure for manganese is 75. Manganese is estimated as 34th among the elements in its content in seawater, an estimated 9.5 tons per cubic mile of seawater. There are eight isotopes of manganese, ^{50}Mn through ^{57}Mn, all radioactive with exception of ^{55}Mn. Half-lives range from a fraction of a second for ^{50}Mn to approximately 140 years for ^{53}Mn. Electronic configuration $1s^2 2s^2 2p^6 3s^2 3p^6 3d^5 4s^2$. Ionic radius Mn^{2+} 0.83 Å. Metallic radius 1.365 Å. First ionization potential 7.32 eV; second, 15.7 eV. Oxidation potentials $Mn \longrightarrow Mn^{++} + 2e^-$, 1.18 V; $Mn^{2+} + 2H_2O \longrightarrow MnO_2 + 4H^+ + 2e^-$, −1.28 V; $Mn^{2+} \longrightarrow Mn^{3+} + e^-$, 1.51 V; $Mn^{2+} + 4H_2O \longrightarrow MnO_4^- + 8H^+ + 5e^-$, −1.52 V; $MnO_2 + 2H_2O \longrightarrow MnO_4^- + 4H^+ + 3e^-$, −0.168 V; $Mn(OH)_2 + OH^- \longrightarrow Mn(OH)_3 + e^-$, 0.40 V; $MnO_4^{=} \longrightarrow MnO_4^- + e^-$, −0.54 V; $MnO_2 + 4OH^- \longrightarrow MnO_4^- + 2H_2O + 3e^-$, −0.58 V. Other important physical properties are given under **Chemical Elements**.

Occurrence. The most common manganese ore is pyrolusite, MnO_2. Other commercial ores include braunite, Mn_2O_3; hausmannite, Mn_3O_4; and rhodochrosite, $MnCO_3$. Although not of industrial value, manganese also exists in nature as the silicate, sulfate, sulfite, and tungstate. See also **Pyrolusite**; and **Rhodochrosite**.

Manganese Nodules. These are rocks composed largely of ferromanganese oxides formed by precipitation at the bottom of lakes and the oceans. They range in size from micrometers to meters. Their morphology is highly variable. They contain up to 55% manganese, 35% iron, and 2% nickel, cobalt, and copper. Manganese nodules were first discovered in the open ocean by Thompson, Murray, and Renard during the *Challenger* expedition (1873–1876). Buchanan reported the occurrence of nodules in the Firth of Clyde, a shallow-water area, and by the end of the century at least five additional occurrences of manganese nodules in shallow marine environments had been discovered. Early workers chemically analyzed about a score of manganese nodules and hypothesized about their mechanism of growth. Two principal concepts emerged: (1) they grow by the slow precipitation of manganese from seawater; and (2) they are formed by the rapid precipitation of manganese released in submarine volcanism.

Until the 1950s, little additional work was done except for some early measurements of manganese nodule growth rates. During recent years, however, there has been a strong revival of interest in manganese nodules, stimulated both by the expansion of oceanographic facilities and the realization of the economic importance of the nodules as ores. It has been found that in large areas of the ocean floor, manganese nodules may be absent. In other areas, they may cover nearly 100% of the area. In all of the Pacific Ocean, nodules have been estimated to cover approximately 10% of the ocean floor. The estimated coverage in the Indian and Atlantic Oceans is less. The local variability in manganese nodule concentration is large. Two ocean bottom photographs only a few meters apart may show very different nodule concentrations. In some locations, the weight concentration of nodules ranges up to 5 g/cm^2.

Manganese nodules are composed of cryptocrystalline minerals. They are known to consist of three major manganese phases: (1) δMnO_2 (birnessite); (2) 10-Å manganite; and (3) 7-Å manganite. The first is the most highly oxidized form, and has a chemical composition of about

$Mn_{1.9}$. Barnes (1967) examined the depth dependence of the mineralogy in nodules taken from the Pacific. His data indicate that above 3,500 m in depth, the only important manganese phase is δ MnO_2, but, below the 3,500 m depth, both 10-Å manganite and 7-Å manganite coexist with the δ MnO_2. The observed phase changes may be pressure induced.

During recent years, the growth rates of manganese nodules have been determined by various methods. Results all indicate that the nodules measured grow at a rate of a few millimeters per million years. This does not exclude the possibility that nodules in certain areas evolve more rapidly, but it appears that most deep-sea nodules grow slowly. There is some belief that the nodules are primarily the result of bacterial fixation of manganese. Other investigators believe that the nodules are formed by inorganic precipitation of metals supersaturated in sea water. There is some experimental and theoretically tenable evidence to support both concepts.

Research gathered during the DeepSea Drilling Project (DSDP) and the International Decade of Ocean Exploration (IDOE) programs is described in the entry **Ocean Resources (Mineral)**.

Hypotheses continue to evolve concerning the manner in which manganese nodules develop. In the early 1980s, in an effort to sweep away some of the mysteries concerning the Mn nodules, a consortium of American researchers participated in the MANOP (Manganese Nodule Project) program. The program involved the creation of mathematical models, not a simple task because it has been estimated that nodule attrition is about one atomic layer of the Mn-O structure per year. As reported by J. Dymond and colleagues (Oregon State University), two different processes operate within sediments, the particular process depending on whether any oxygen remains below the sediment surface. The amount of oxygen present, of course, is a function of the biological productivity of the overlying surface waters. Where winds and currents mix the sea in the needed manner, microscopic plants and animals do well and part of their inorganic skeletons and probably about one percent of their organic tissues will sink to the bottom—along with clay washed from the land. Regardless of how deep the sea floor is, bacteria and animals dwelling on and in the sediment will oxidize organic matter. However, a small percentage of their organic matter does reach the bottom. If the falling organic matter is light, not all of the sediment oxygen will be consumed. It is proposed that toxic chemical alterations (oxic diagenesis) of the sediment can then supply metals to nodules. It is further reasoned that oxic sediments must be altered chemically to produce nodules because under such oxidizing conditions, Mn and Fe are tied up as insoluble oxides, which cannot move and thus cannot be incorporated in nodules. Several possible diagenetic reactions, such as those involving volcanic ash and skeletal opal, have been suggested. As reported by Kerr (1984), the Oregon State University team concluded that the nodule composition most typical of growth under oxic diagenesis is that of the nodule bottom most rich in trace metals from a siliceous sediment in the tropical North Pacific. In terms of the overall picture, some scientists have observed that manganese nodules should not be there, but are! Obviously Mn nodule research will require many more years in supplying answers. See also **Ocean Resources (Mineral)**.

Todorokites may be defined as calcium-bearing manganese oxides, which are found in terrestrial Mn ore deposits, in weathering products of Mn-bearing rocks, and in some Mn nodules. In some cases, todorokites are the principal constituents of Mn nodules. Knowledge collected concerning todorokites has contributed and will continue to contribute to a better understanding of Mn nodule formation in ocean waters. See also **Todorokites**.

Processing

Manganese metal can be obtained from oxide ores by reduction with carbon, aluminum, magnesium, or sodium in an electric furnace. The main form in which manganese is used is *ferromanganese*. This material contains approximately 80% manganese and 20% iron. Ferromanganese is generally made in a blast furnace or an electric-arc furnace. Usually a mixture of ores is used, proportioned to yield the final desired specifications of the alloy. To reduce slag volume, low-silica ores are preferred. It is also desirable to maintain a low phosphorus content in the alloy. The charge to the electric furnace process for making ferromanganese is the manganese ore, coke, and limestone. The loss of metal to the slag is determined by the silica present. Usually about 75% of the metal is recovered. Where high-purity manganese is produced, the ore is first roasted to MnO, then leached with H_2SO_4 to form the sulfate. The solution is then neutralized to precipitate iron and aluminum. Other impurities are removed as the sulfides. Electrolysis of the resulting solution yields a 99.94% pure manganese metal.

The high-purity (electrolytic) manganese is used as a deoxidizing agent and sometimes as a constituent of nonferrous metals where it improves strength, ductility, and hot-rolling properties. Because of their very high temperature thermal coefficient of expansion, manganese-base alloys with 72% manganese (balance is copper and nickel) are used in bimetals for switching applications. Manganese (60–80% Mn) and copper alloys find application because of their vibration-damping properties.

The standard ferromanganese (7% carbon; 74–78% Mn) is used both to produce a manganese alloy steel and as a deoxidant. As early as 1856, Robert Mushed used *spiegeleisen* (10–23% Mn; 4–5% C) in alloys. Where the carbon content of steel is critical, low-carbon ferromanganese is added. Silicomanganese is used as a blocking agent to stop the reaction of carbon and oxygen in steel. Developed in 1888, Hadfield steel contains about 13% manganese. It finds use where a very hard material is needed and it has the interesting property of increasing its hardness when subjected to repeated impacts. In the 200 series of stainless steels, manganese is replacing nickel in order to achieve more economical austenitic materials.

Manganese Inorganics. A number of chemical processes have been developed to upgrade Mn ore which produce an intermediate Mn compound. These intermediates usually are free of most siliceous matter. Although these processes were designed to convert the compound to an oxide for use in metallurgical applications, the purity of the compounds often renders them suitable for commercial use.

The ammonium carbonate process (developed by Manganese Chemicals Corp.) is the first such upgrading process that has reached commercial application. The high-grade manganese carbonate produced is sold to the chemical industry. The process involves reducing the ore to MnO by roasting with gases rich in CO as the initial step. The calcine is then ground and leached in an aqueous solution containing 18 moles of NH_3 and 3 moles of CO_2. The resulting product is decomposed to yield $MnCO_3$ and NH_3.

The manganese nitrate process is the second upgrading process that has reached commercial application. The high-purity manganese oxides produced are sold to the chemical and ferrite industries. The process involves the reaction between NO_2 and manganese ore to form manganese nitrate solution. The resulting aqueous solution is then thermally decomposed to produce MnO_2 and nitrogen oxides. The nitrogen oxides are recycled to the leaching step, while the MnO_2 is recovered and processed by reduction to Mn_2O_3, Mn_3O_4, or MnO. Processes of lesser importance include the chloride and sulfur oxide processes and bacterial leaching.

Chloride Process. In 1985, investigators at the Argonne National Laboratory reported on the success of a two-step process that extracts cobalt and manganese from low- and medium-grade ores that are mined mainly for other metals. Inasmuch as cobalt and manganese are strategically critical minerals for the United States and several other industrial nations, a viable process for secondary sources of Co and Mn is attractive. A molten salt is used to dissolve more than 90% of the Co and Mn found in common nickel- and copper-bearing ores. The salt mixture contains the chlorides of sodium, potassium, and magnesium (mp 750°C; 1382°F). Approximately one part (wt) of the ore requires four parts of the chloride mixture. The latter is recyclable. The desired metals are subsequently separated electrolytically.

Chemistry of Manganese

Manganese has a $3d^5 4s^2$ electron configuration, and compounds in all oxidation states from 0 to 7+ are known, although those of 1+ and 5+ are uncommon. The reducing power of the manganese atom ($Mn \longrightarrow Mn^{2+}$, 1.18 V) is less than that of magnesium, although the first and second ionization potentials are closely similar, due to the higher heat of sublimation of manganese. However, manganese is oxidized by the halogens, H+ or even H_2O to the dipositive state.

Like so many other metals manganese forms compounds with nitrogen, carbon and even oxygen that exhibit unusual valences, or are even of nonstoichiometric character. With nitrogen manganese combines with unusual valence of 5+ to form Mn_3N_5; with carbon it forms Mn_3C, while with free oxygen it forms first MnO, then Mn_3O_4, and finally Mn_2O_3. An exception to this rule is the MnO_2 produced by thermodecomposition of concentrated manganese nitrate solutions where the oxygen-to-manganese ratio is 1.99+.

Manganese (0) compounds are exemplified by the carbonyls discussed below.

Manganese(I) is found chiefly in the few complex ions, such as the hexacyanomanganate(I) ion $[Mn(CN)_6]^{5-}$, produced by vigorous reduction

(e.g., by aluminum in alkaline solution) of the corresponding manganese(II) ion $[Mn(CN)_6]^{4-}$, or in isocyanide complexes (formed by reduction of the diiodide with alkyl isocyanides) $[Mn(RNC)_6]^{+}$ where R is an alkyl radical.

Manganese(II) (manganous) compounds are obtained, as stated above, by action of water, halogens (except fluorine) or acids upon the metal, or by reduction of more highly oxidized compounds in acid solution. Many salts of Mn^{2+} are known, including all four of the common halides, the nitrate, the sulfate, the sulfite, various phosphates, the arsenate, and many salts of organic acids, e.g., the acetate, butyrate, citrate, lactate, oleate, and tartrate. The manganese(II) compounds are in general relatively resistant to oxidation, due to the stability of the half-filled $3d$ subshell. However, the oxide, MnO, and the hydroxide, $Mn(OH)_2$, are rather easily oxidized by air.

This stability of the Mn(II) state is also reflected in the relatively strong oxidation potential of Mn^{3+} (manganic) ion (the value for Mn^{3+}/Mn^{2+} being -1.51 V), and the readiness with which Mn(III) compounds disproportionate. Manganese(III) fluoride, produced by the action of fluorine on lower compounds, reacts with H_2O to produce the difluoride, hydrogen fluoride, and MnO_2. In general, however, the manganic compounds such as dimanganese trisulfate and manganese triacetate, decompose in H_2O to divalent manganese ions and Mn_2O_3, forming the MnO_2 only if the pH is definitely below 7. The phosphate, $MnPO_4$, is easily formed by action of nitric acid on manganese(II) phosphate in concentrated phosphoric acid. The fluoro salt K_3MnF_6 is formed by reduction of potassium permanganate, $KMnO_4$, in 40% hydrofluoric acid by an excess of diethyl ether or manganese(II) salt. Manganese(III) also forms a variety of complexes with chelating agents, e.g., oxalate, glycine, acetylacetone, and the like. Like other tripositive transition metal ions it forms alums. The cyanide $K_3Mn(CN)_6$ is stable. All Mn(III) compounds undergo hydrolysis except the complexes.

In addition to the dioxide and the manganites, formed by fusion of MnO_2 with alkali, manganese(IV) forms a number of complexes, such as K_2MnF_6 by reduction of potassium permanganate in 40% hydrofluoric acid with a limited amount of diethyl ether or manganese(II) salts; and Cs_2MnCl_6, by action of cold concentrated HCl containing cesium chloride on MnO_2. Complex iodates are known, e.g., $M_2^{I}[Mn(IO_3)_6]$, as are cyanides, formed by the action of potassium cyanide on potassium permanganate and said to be $K_4Mn(CN)_8$ (cf. $K_4Mo(CN)_8$ and $K_4Re(CN)_8$).

Manganese rarely occurs with an oxidation number of 5+. In addition to the nitride, there is another compound of interest, in that it can be formed in solution. It is an oxyanion of pentavalent manganese, MnO_4^{3-}, which occurs in the compound, $Na_3MnO_4 \cdot 7H_2O$, formed by reduction of the manganate in strongly alkaline formate or sulfite solutions or by heating MnO_2 in alkali hydroxide at very high temperature. Upon neutralization, it disproportionates to the manganate (and MnO_2).

The manganates, containing MnO_4^{2-}, and produced by alkaline oxidation of MnO_2, are the principal known compounds of hexavalent manganese. They are unstable in neutral or acidic solution, undergoing disproportionation to permanganate (MnO_4^-) and MnO_2. In basic solution, the reaction is reversible. The equilibrium is displaced toward the MnO_4^- by the action of strong oxidants.

The permanganates are strong oxidizing agents, and are usually reduced down to Mn^{2+} under acidic conditions, but to MnO_2, manganate, MnO_4^{2-}, or even hypomanganate, MnO_4^{3-}, under progressively more alkaline conditions. Permanganic acid, $HMnO_4$, and its anhydride, Mn_2O_7, can be obtained at lower temperatures, but they are unstable, decomposing above 0°C. Permanganyl fluoride, MnO_3F, formed by the action of liquid hydrogen fluoride on potassium permanganate, decomposes at about 0°C. In strongly acidic media, such as 100% H_2SO_4, manganese (VII) appears to exist as permanganyl ion, MnO_3^+. The sigma bond hybridization in MnO_4^-, MnO_4^{2-} and MnO_4^{3-} is best represented as d^3s.

The only compound of manganese with carbon monoxide alone is the decacarbonyl dimanganese, $(CO)_5MnMn(CO)_5$, but several hydrogen-containing carbonyls, such as $HMn(CO)_5$, halogen-containing carbonyls, such as $Mn(CO)_5Br$, alkyl carbonyls, such as $C_2H_5Mn(CO)_5$ and oxygen-function organometallic compounds, such as

$$[CH_3C(=O)O]_3Mn$$

are known. With the exception of the dicyclopentadienyl compounds, $C_5H_5MnC_5H_5$ manganese does not combine with unsubstituted hydrocarbons or their radicals.

It is interesting to note that some bacteria found near manganese ore plants have the ability to dissolve manganese oxides in solutions of pH 5–6 by the slow addition of H_2SO_4. The only requirement other than the organisms is a nutrient solution. The extraction of manganese as a sulfate is on the order of 71.7–99.9%, depending on the ore. The action of the bacteria is not fully understood.

See also **Manganese (In Biological Systems)**.

Health and Safety Factors

Health and Environment. Manganese in trace amounts is an essential element for both plants and animals and is among the trace elements least toxic to mammals, including humans. Exposure to abnormally high concentrations of manganese, particularly in the form of dust and fumes, is, however, known to have resulted in adverse effects to humans. Two kinds of disease owing to manganese are known in humans: manganic pneumonia and manganism.

Airborn manganese concentrations in the U.S. range from 0.02 to 0.57 μg/m³ in urban areas and 0.0017–0.047 μg/m³ in non-urban areas. The ACGIH (American Conference of Governmental Industrial Hygienists; http://www.acgih.org/) recommends a TLV (threshold limit values) of 5 mg/m³.

Plant Safety. Of the many ferroalloy products produced in electric furnaces, ferromanganese has the greatest potential for furnace eruptions or the more serious furnace explosions.

Most of the serious eruptions of manganese furnaces can be traced to a set of conditions that cause bridging or hang-up of the charge materials so that the normal downward movement through the furnace is disrupted or retarded. Safe operation of ferromanganese furnaces requires careful control of raw material particle size, oxygen content of the ore blend, and charge stoichiometry.

MANGANESE (In Biological Systems). Manganese is required by both plants and animals. Although its deficiency is normally a problem in small areas of fields, it has caused economic losses in the production of cereal small grains on some alkaline soils. In acid soils, manganese is more soluble and plants may be damaged by excessive uptake of the element. Reduced crop yields due to manganese toxicity on acid soils are probably responsible for greater economic losses in a number of regions of the world than are reduced crop yields as the result of manganese deficiency. Measurement of the total manganese concentration in any soil is of little value for predicting possible manganese deficiency or toxicity. The amounts of soluble manganese are more directly related to the level of manganese in plants, but soluble manganese in the soil may fluctuate over short periods because of flooding or drying of the soil or the addition of fresh organic matter. The concentration of manganese in food and in feed plants varies widely; it is more dependent upon the acidity or alkalinity of the soil than on the amount of manganese used in fertilizers.

Although established as an essential trace element, manganese is less well understood than many of the other trace elements. The evidence for its essentiality rests extensively on the consequences of limiting or curtailing the supply of the element of various organisms. Manganese deficiency has induced in most organisms studied a diminished life expectancy. The element is associated with reproductive processes.

Additional manifestations depend upon the kind of organism under observation, its age, the degree and duration of manganese deficiency, as well as the coexistence of still another deficiency. For example, in plants, a striking manifestation is chlorosis in which the leaves become pale or yellow, while the veins of the leaves remain green. Manganese plays a significant role in photosynthesis by plants, but it also participates in the regulation of several other enzymic processes.

In poultry, manganese deficiency causes a different clinical picture when it affects the egg than when it affects the hatched bird. In the case of the egg, the embryo become swollen and deformed, and their skeletons become defective and fragile ("chondrodystrophy"). Adult birds develop perosis (slipped tendon) which is an enlargement and malfunction of the tibial metatarsal joint, followed by slipping of the Achilles tendon from the condyles. The bone deformities seen in poultry also can be induced in mammals.

Manganese deficiency also results in the birth of "crooked calves" that are born with enlarged joints, stiffness, and twisted legs.

If the deficiency is induced prior to birth, there is a high intrauterine mortality and whatever young are born alive tend to suffer from an inability to coordinate their muscles (ataxia). These young also have convulsions, delayed growth, and defective bone formation. Adequate manganese intake after birth will correct many of these anomalies, but not the ataxia. If the deficiency is imposed on adult female mammals, ataxia develops infrequently. Instead there appear anemia, defective bone formation, infertility, a tendency to miscarry, and a tendency to absorb the embryo which die within the uterus. The sickly offspring are jeopardized after birth by a disinterest on the part of the manganese-deficient mothers. These avoid nursing their young even when they produce adequate milk. In males, in addition to poor growth, bone deformities and anemia, impotence and infertility develop. Adult animals also develop defects in metabolizing body fat, which are reflected in abnormal amounts and abnormal distribution of body fat. This liptropic effect of manganese extends also to the metabolism of cholesterol and, in this particular role, it can be antagonized by vanadium. The bone deformities are ascribed primarily to poor synthesis of the mucopolysaccharides that make up the matrix of the bones. The infertility is a consequence of death of the testicle's germ cells.

On the other hand, manganese in excessive amounts can cause manganese toxicity. In the past, this disease has mainly affected miners who work either in manganese mines or in ore crushing mills. The manganese ore enters the body by inhalation of the dust. Among the many miners exposed throughout the world, some develop brain symptoms. Involvement of the brain manifests itself first in mental aberrations. Later, neurological changes occur in the form of trembling, rigidity, salivation, mask-like face, and a general appearance of a person afflicted with Parkinson's disease. Chronic manganese poisoning has occurred in epidemics. The condition is incurable, but not necessarily life-limiting.

It is believed that high manganese diets in cattle will decrease fiber digestion. Manganese interferes with iron metabolism by antagonizing the enzyme system that oxidizes or reduces iron at the absorption site, thus affecting iron availability. It is also suggested that manganese may cause a condition in ruminant cattle (hypomagnesia). Most of the foregoing observations can be explained on the basis of manganese activating various cellular enzymes. Much importance has been given to the particular enzyme systems responsible for oxidative phosphorylation. These systems determine the generation and utilization of energy from foodstuffs by the cells. Additionally, manganese appears to activate many other enzymes (arginase, enolase, peroxidases). It also appears to participate in the structure of the nucleic acids responsible for the manufacture of enzymes and other proteins. Manganese probably plays a number of unique roles. No other metal replacement for the element in biological functions has been identified to date.

Manganese occurs in the liver of the animal body. Even though the amount of manganese present in mammalian tissues is very small, its concentration seems to be accurately controlled by elaborate mechanisms. These mechanisms function primarily by promoting the excretion of excesses of the element from the body rather than by regulating the amounts of manganese the body absorbs. The mechanisms are located in the liver and on the mucosa of the gut. In cases of manganese toxicity, it is assumed that these mechanisms become saturated.

One vital feature of manganese, which is not widely appreciated, is its role as an essential element in maintaining human health. Recommended daily dietary intake levels have been established by US regulatory authorities in an effort to ensure the maintenance of good health.

The exact role of manganese is not fully understood, but complex cellular reactions involving metallo-enzymes have been identified. Humans have well-developed homeostatic control mechanisms whereby manganese levels are regulated to keep them in the desired range. Medical research into conditions arising from an excess or deficit of body manganese is being carried out in a number of institutions.

Cereals and pulses (peas and beans) are the major sources of manganese in human diets, and diets containing these foods can be expected to provide adequate manganese. Dietary supplements for manganese (feeds and foodstuffs) include: manganese chloride, manganese gluconate, manganese glycophosphate, manganese hypophosphate, and manganese sulfate. The usual intake of this mineral is 2 to 5 mg/day, and absorption is 5 to 10%.

MANGANITE. The mineral manganite is a hydrous oxide of manganese corresponding to the formula MnO(OH). It occurs in prismatic monoclinic crystals, sometimes in massive columnar forms, granular, concretionary, and stalactitic. It is a brittle mineral, with perfect prismatic cleavage; hardness, 4; specific gravity, 4.33; luster, submetallic; color, steel gray to iron black; streak, red-brown to almost black; opaque. Manganite is of secondary origin and it may itself alter to pyrolusite. It is usually associated with other manganese minerals. It is found in the Harz Mountains, Germany; Sweden; Cornwall and Cumberland, England; and in the United States in Michigan. It is an ore of manganese. See also **Pyrolusite**.

MANNANS. See **Sweeteners**.

MANNICH REACTION. Reaction of active methylene compounds with formaldehyde and ammonia of primary or secondary amines to give β-aminocarbonyl compounds.

MANNITOL. See **Sweeteners**.

MANY-BODY FORCE. An interaction between two particles that becomes modified when a third particle is present, e.g., the forces between polarizable molecules. A large part of the experimental data of physics is concerned with natural objects that may be looked upon as being made up from smaller bodies. Thus, results the so-called many-body problem; there are several approaches to its solution. This highly theoretical topic is beyond the scope of this volume, but reference is suggested to the "Many-Body Problem," in *The Encyclopedia of Physics* (R.M. Besancon, editor), 3rd Edition, Van Nostrand Reinhold, New York, 1985.

MARATHON-HOWARD PROCESS. A treatment of waste sulfite liquor from sulfite pulp manufacture to recover chemicals and reduce steam pollution. The waste sulfite is treated with line and precipitates, (1) calcium sulfite for use in preparing fresh cooking acid for the sulfite pulp process, and (2) a basic calcium salt of lignin sulfonic acid (lignin sulfonates) that can be pressed and used as a fuel of used as raw material for vanillin, lignin plastics, and other chemicals. The remaining liquor with its BOD reduced 80% is the effiuent.

MARBLE. A metamorphic form of calcium carbonate, usually containing admixtures of iron and other minerals that impart variegated color

patterns. Marble chips are often used as source of carbon dioxide in laboratory experiments.

MARCASITE. The mineral marcasite, sometimes called white iron pyrites, is, like ordinary pyrites, disulfide of iron corresponding to the same formula, FeS_2. Marcasite, however, crystallizes in the orthorhombic system often yielding serrate, spear-shaped twins, hence the name "cock's comb pyrites." It is a brittle mineral; hardness, 6–6.5; specific gravity, 4.92; luster, metallic; color, light bronze-yellow; streak, greenish-black; opaque. Marcasite alters very easily and may disintegrate with the formation of sulfuric acid and iron sulfate. Fossils replaced by marcasite are therefore often destroyed after being placed in collections. Marcasite is found in numerous places in Europe, notably in Czechoslovakia, France, and England; in Mexico; and in the United States in the lead districts of Illinois, Wisconsin, and Missouri. The name marcasite is believed to be of Arabic origin and formerly was applied to common pyrite.

MARCUS, RUDOLPH A. (1923–). Professor Marcus from the California Institute of Technology, Pasadena, California, won the Nobel prize for chemistry in 1992 for his contributions to the theory of electron transfer reactions in chemical systems.

The processes Marcus has studied, the transfer of electrons between molecules in solution, underlie a number of exceptionally important chemical phenomena, and the practical consequences of his theory extend over all areas of chemistry. The Marcus theory describes, and makes predictions concerning, such widely differing phenomena as the fixation of light energy by green plants, photochemical production of fuel, chemiluminescence ("cold light"), the conductivity of electrically conducting polymers, corrosion, the methodology of electrochemical synthesis and analysis, and more.

From 1956 to 1965 Marcus published a series of papers on electron transfer reactions. His work led to the solution of the problem of greatly varying reaction rates.

MARK-HOUWINK EQUATION. Defines the relationship between the intrinsic viscosity and molecular weight for homogeneous linear polymers.

MARKOWNIKOFF RULE. When a halogen acid adds to an asymmetrical ethylenic compound, the halogen usually appears on the carbon atom carrying the smaller number of hydrogen atoms; this order of addition is frequently reversed with hydrogen bromide if peroxides are present (peroxide effect).

MARTENSITE. The chief constituent of hardened carbon tool steels. It is a solution of carbon or Fe_3C in β-iron, or and exceedingly fine-grained α-iron with carbon or Fe_3C in atomic or molecular dispersion. Carbon content up to 1%; easily obtained by quenching small bodies of hypereutectoid steel in cold water; more difficult to obtain in low-carbon steels.

MARTIN, ARCHER J. P. (1910–2002). An English chemist and engineer who won the Nobel prize for chemistry in 1952 along with Richard L.M. Synge. His work involved partition chromatography in analysis, which led to development of new antibiotics and amino acids. He received his doctorate from Cambridge University.

MASER. An acronym for microwave amplification by stimulated emission of radiation. The device is identical in theory of operation to the laser except that it operates at frequencies in the microwave region of the electromagnetic spectrum, rather than in the light range. See also **Lasers**.

Consider a stream of atoms in equilibrium for a given energy transition, that is, some are emitting radiation at the frequency of the transition and others are absorbing it. This process can be represented by the equation

$$h\nu_{21} = E_2 - E_1$$

where E_2 represents the energy of an atom in an excited state, E_1 represents its energy in a lower state, such as the ground state, h is Planck's constant, ν_{21} represents the frequency of a photon which would excite the atom from the state E_1 to state E_2, or conversely, the frequency of a photon that would be emitted in the reverse transition. Now consider a large number of atoms in thermal equilibrium in a closed box. The radiation inside the box will be black body radiation; in other words, the number of photons of given energy will be uniquely determined by the temperature. In addition, the temperature will fix the proportion of atoms in the excited state, which will be given by the Boltzmann distribution

$$\frac{N(E_2)}{N(E_1)} = \exp\left(\frac{-(E_2 - E_1)}{kT}\right)$$

where $N(E_2)$ and $N(E_2)$ are the populations of the states E_1, E_2, respectively. These two assertions, governing the number of excited atoms and the number of photons, respectively, are both fundamental thermodynamic principles and should fit together into a consistent picture. To bring about the energy balance necessary for equilibrium, an extra term is introduced, corresponding to a second process of radiation emission. The second term is quite different from the first in that it represents a process whose rate (or probability) is proportional to the intensity of radiation of frequency ν falling on the atom. The radiation field stimulates the excited atom to emit, and we can contrast this process of stimulated emission with the more familiar process of spontaneous (random) emission. The latter is more familiar because it is overwhelmingly dominant so long as $h\nu/kT$ is large, and this is so in the optical and infrared regions of the spectrum, where most of our accumulated experience lies. On the other hand, if $h\nu/kT$ is small (as it is the microwave region), stimulated emission is the more important; however, stimulated emission in the visible region may be significant under certain conditions.

In terms of photons, stimulated emission appears as the interaction of the photon with an excited atom, which leads to the emission by the atom of a second photon, identical with the primary. In other words the photon has multiplied.

To accomplish amplification it is only necessary to produce more photons by stimulated emission than are lost by absorption. The details of the balance at equilibrium show that the probability of an atom in the ground state absorbing a photon, and of one in the excited state emitting one by stimulation, are equal. Hence, if amplification is to be possible, the number of atoms in the excited state must be greater than the number in the ground state. A look at the Boltzmann equation shows that this cannot be attained at any (positive) value of temperature, which means that it cannot be attained in thermal equilibrium. The problem then is essentially one of disturbing equilibrium so as to bring about the population inversion required.

Although having a number of limitations, the ammonia maser can be used to describe the principles involved. What is involved is picking out the excited atoms from the unexcited ones, and segregating them. This implausible procedure is in certain cases possible, the most notable involving the ammonia molecule, NH_3. The structure of this molecule is pyramidal, with the nitrogen atom at the vertex and the three hydrogen atoms forming the base. It is possible for the molecule to execute vibrations in which the nitrogen atom vibrates back and forth through the plane of the hydrogen atoms. The energy difference between this excited state and the ground state (no vibration) corresponds to a wave-length in the microwave region, i.e., about 3 centimeters. Because of its lack of symmetry, the molecule in the ground state will have a dipole moment, but the average dipole moment of the molecule executing the vibrations is described as zero. If ammonia molecules are formed into a beam by allowing the gas to stream out of a collimating tube into a vacuum, and this beam is passed through a nonuniform electric field, the separation can be effected. The ground state molecules will be deflected by the nonuniform electric field, and lost to the beam; the excited molecules, however, by virtue of their zero dipole moment, experience no deflecting force, and are introduced into a resonant cavity resonating at the appropriate frequency. The cavity will then contain a preponderance of excited molecules, provided the lifetime of the excited state is long enough (as it will be at microwave frequencies). See Fig. 1.

If now an input signal of the resonant frequency is fed into the cavity, it can bring about spontaneous emission, and amplification will occur. The shortcoming of this arrangement is that the ammonia resonance cannot be tuned and it represents an impracticably narrow bandwidth. On the other hand, like any other amplifier, it can be made to oscillate, so that it can be used as a very stable frequency standard (ammonia clock).

The three-level maser provides a more versatile arrangement for achieving inversion. Three energy levels are associated with the same atomic or molecular system. See Fig. 2. A strong microwave signal of frequency ν_{31} corresponding to $E_3 - E_1$ raises some of the atoms to E_3. A limit is reached when the populations of E_3 and E_1 are the same, since then the radiation absorbed is just balanced by stimulated emission, a state of affairs known as "saturation." Not all the atoms in state E_3 will return

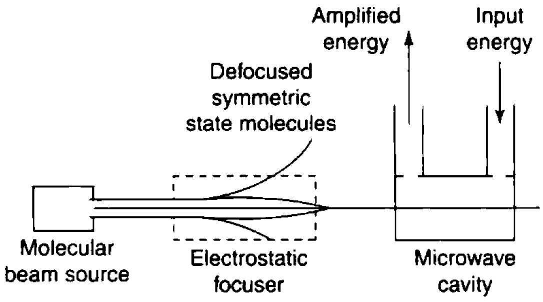

Fig. 1. Schematic representation of an ammonia beam maser. (*After Gordon, Zeiger, Townes*)

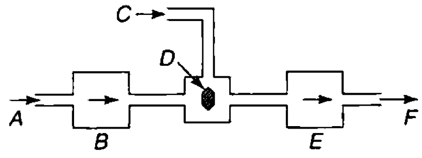

Fig. 2. Three-level maser amplifier, where A is signal input; B is the first isolator; C is the power input for pumping; D is the crystal; E is the second isolator, usually operated at low temperature as a noise reflector; and F is the signal output

directly to E_1—some will return via E_2. By the choice of states of suitable lifetimes ($\tau_2 > \tau_3$) it is possible to arrange that the number of atoms in E_2 exceeds that in E_1 because the "pump" frequency maintains a "head" of atoms in E_3. Thus E_2 and E_1 are inverted and amplification is possible.

Maser amplifiers are used where the requirement for a very low noise amplifier outweighs the technological problems of cooling to low temperatures. They have been used in passive and active radiostronomical work, in satellite communications, and as preamplifiers for microwave spectrometry. The ammonia and the atomic hydrogen masers have been studied as frequency standards and have been used in accurate tests of special relativity.

MASS. The physical measure of the principal inertial property of a body, i.e., its resistance to change of motion. At speeds small compared with the speed of light, the mass of a body is independent of its speed. Under these circumstances, the masses m_1 and m_2 of two bodies may be compared by allowing the two bodies to interact. Then

$$m_1/m_2 = |a_2|/|a_1|$$

where $|a_1|$ and $|a_2|$ are the magnitudes of the respective accelerations of the two bodies as a result of the interaction. This permits the measurement of the mass of any particle with respect to a standard particle (for example, the standard kilogram). At higher speeds, the mass of a body depends on its speed relative to the observer according to the relation:

$$m = m_0/\sqrt{1 - v^2/c^2}$$

where m_0 is the mass of the body as found by an observer at rest with respect to the body, v is the speed of the body relative to the observer who finds its mass to be m, and c is the speed of light in empty space as prescribed by the theory of relativity.

When relativistic mechanics is appropriate, e.g., when speeds comparable to the speed of light are involved, mass may be converted into energy and vice versa, hence the energy of the system must be converted into mass through the Einstein equation

$$E = mc^2$$

where c is the speed of light in empty space, before the conservation law may be applied.

MASS (Center of). The center of mass is that point in a collection of mass-particles which moves as if the total mass of the collection were concentrated there and the resultant of all the external forces were acting there. The position vector of such a point is given by

$$\mathbf{r} = \frac{\sum_{i=1}^{n} m_i \mathbf{r}_i}{\sum_{i=1}^{n} m_i}$$

where m_i is the mass of ith discrete particle. $\mathbf{r}_i$ is the position vector of ith discrete particle.

MASS DEFECT. The difference Δ between the atomic number A and the atomic mass M of a nuclide, $\Delta = A - M$. The negative of the mass defect, $-\Delta$, is known as the mass excess.

MASS NUMBER. The total number of nucleons in the nucleus of an atomic species is its mass number, which then is numerically equal to the sum of the atomic number and the neutron number of the species. See also **Chemical Elements**.

MASS SPECTROMETRY. A general quantitative and qualitative analyzer for most components in all types of samples—gas, liquid, or solid, but with some volatility limitations. A complete analysis is obtained from nanogram samples in a few seconds or minutes. The range is from parts per billion to 100% purity. Accuracy is ±1%; the specificity is good. Conventional methodology is first described after which recent trends are presented.

Operating Principle. With reference to Fig. 1, the sample to be studied is introduced into an evacuated area (ion source), where it is ionized, accelerated by an electrostatic field, and separated according to mass. The various masses are collected and measured.

Production of Ions. Several methods are used: (1) by bombardment with electrons from a heated filament; (2) by application of a strong electrostatic field (field ionization, field desorption); (3) by reaction with an ionized reagent gas (chemical ionization); (4) by direct emission of ions from a solid sample that is deposited on a heated filament (surface ionization); (5) by vaporization from a crucible and subsequent electron bombardment (e.g., Knudsen cell for high-temperature studies of solids; and (6) by radio-frequency spark bombardment of sample for parts-per-billion (ppb) elemental analysis of solids as encountered in metallurgical, semiconductor, ceramics, and geological studies. Ions also are produced by photoionization and laser ionization.

Fragmentation. Ionization usually is accompanied by partial fragmentation of the molecule. The fragmentation pattern is constant for a specific molecule and operating conditions. Fragmentation complicates computation, but permits distinguishing between isomers and gives molecular-structure information.

Ion Separation. After acceleration, the ions are focused and separated according to mass. The most common separating means is a magnetic field,

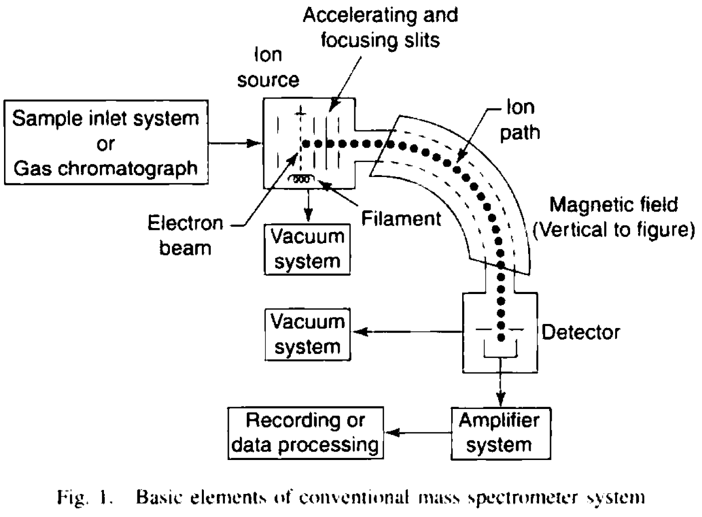

Fig. 1. Basic elements of conventional mass spectrometer system

which causes the ions to follow curved paths of radii proportional to their masses. Many different geometrics are used. The masses may be scanned by varying the accelerating voltage or magnetic field. Other separation means include: (1) combinations of electrostatic fields (double focusing cycloidal focusing); (2) crossed alternating electrical fields (quadrupole mass filter); and (3) use of a filled-free drift tube combined with pulsed ion source and gated detection (time-of-flight). Still additional means are omegatron, radio frequency, and cyclotron resonance.

Detection. Commonly used detection means are: (1) *electrical*—ion beams are successively scanned across a collector where they pick up electrons. The resulting current is amplified with an electron multiplier and/or electrometer and recorded or computer-processed. (2) *photographic plate*—ions strike a photographic plate, activating the emulsion and thus giving a line for each mass, after development. Line intensity is proportional to ion abundance. All masses are recorded simultaneously.

Sample Introduction. A variety of inlet systems is available for gases, liquids, and solids: (1) *heated batch inlet.* The sample is expanded into a volume at about 50 micrometers pressure and bled into the ion source through a molecular or viscous leak. This method will handle gases, liquids, and solids with vapor pressures above approximately 1 torr at 350°C. (2) *Direct introduction system.* The sample is inserted directly into the ion source through a vacuum lock on a heatable probe. Liquids and solids with vapor pressures above approximately 10^{-7} torr at 350°C can be handled. (3) *Direct insertion by venting,* or through a vacuum lock (spark or surface ionization). This method is well suited for involatile samples. (4) *Gas chromatograph interface.* A continuous inlet which permits mass spectrometric analysis of the separated components as they emerge from the gas chromatograph.

The combination of gas chromatograph and mass spectrometer provides a separating and identifying capability not achievable by other means, particularly for very small samples.

Data Processing. The high data output rate of many mass spectrometer systems requires data processing to fully utilize the capability of the instrument. The present trend is toward systems using small dedicated computers with digital tape, core, or disk memory, and printer, plotter, and cathode-ray tube output. Typical outputs available are: (1) mass and abundance printouts; (2) mass versus abundance plots; (3) elemental composition printouts (high-resolution mass spectrometer); (4) "total ionization chromatogram" plot (summed ion plot, similar to gas chromatogram); (5) mass chromatogram (similar to total ionization chromatogram, but for a selected mass or masses only); and (6) quantitative analysis printout.

Outputs are available from raw data, data with background or other spectra subtracted, and normalized data. A number of other options of data selection, manipulation, and output are usually available from the instrument manufacturers.

Uses and Applications. Common uses for mass spectrometers include: (1) compound identification; (2) elemental formula determination; (3) molecular-structure determination; (4) quantitative mixture analysis; (5) ppb solids elemental analysis; (6) isotope ratio determination; (7) leak detection (helium tracer); (8) residual-gas analysis in vacuum systems; and (9) age dating.

Mass spectrometers are widely used for studies and determinations in: organic chemistry; petroleum and biological laboratories; nuclear investigations; geochemistry and cosmochemistry; metallurgical, semiconductor, and ceramics investigations; pollution control; space programs; agricultural and pesticide research and manufacture; flavors and fragrances chemistry; and as a basic research tool in studies of ion-molecule reactions, high-temperature chemistry kinetics, free radicals, and thin films. Broad classes of instruments are summarized in Table 1.

TABLE 1. TYPES AND CHARACTERISTICS OF MASS SPECTROMETERS

General class	Type	Major uses
Leak detector	Magnetic analyzer (helium only)	Detects small leaks, using helium gas tracer.
Residual-gas	Magnetic or quadrupole analyzer	Analysis of gases in vacuum systems
Low-resolution	Magnetic, cycloidal, or quadrupole analyzer	Analysis of gases or light liquids
Medium-resolution	Magnetic analyzer	Identification, molecular-structure studies, mixture analysis, isotope ratios.
High-resolution	Magnetic and electric (mass and energy) focusing	Molecular-structure determinations, ppb solids analysis, isotope ratios of solids, high temperature chemistry

Advancements in Mass Spectrometers

The great strides made by mass spectrometry since its inception several years ago are aptly put forth by Delgass and Cooks (see reference), who describe the status of mass spectrometry as of the late 1980s. The applications of mass spectrometry have penetrated into physical chemistry (bond dissociation energies, ion enthalpies, proton affinities); organic chemistry (structure studies, organic ion structure and fragmentation); biology (drug metabolism, stable isotope tracer work, modifications in biopolymers); the earth sciences (chronology/dating of geological and life extinction events); and environmental science (trace organic analysis).

Mass spectrometry is undergoing a rapid development that shows little indication of abating either in the areas of instrument refinement or of extended applications. Mass spectrometry is expected to play a major role in the revitalized science of materials and surface phenomena.

Tandem Mass Spectrometry. Coupling mass spectrometers in series has many advantages for the analysis of specific organic compounds in complex mixtures. Sensitivity to picograms of targeted compounds can be achieved with high specificity and almost instantaneous response. As reported by McLafferty (see reference), the targeted compound is selectively ionized, and its characteristic ions are separated from most others of the mixture in the *first* mass spectrometer. The selected primary ions then are decomposed by collision and, from the resulting products, the *final* (or second) mass analyzer selects secondary ions characteristic of the targeted compound. Tandem mass spectrometry (MS-MS) can achieve specificities and sensitivities equivalent to those of methods such as radioimmunoassay and gas chromatography/mass spectrometry, while performing analyses in much shorter times. Just a few of the materials and systems successfully studied by tandem mass spectrometry include: polynuclear aromatics, DNA pyrolysis, steroid mixtures, ion structures, stereoisomers, pyrolysis of bacteria, alkaloids in plants, penicillins, polychlorodibenzodioxins, petrochemicals, drug metabolites, enkephalins, peptide mixtures, diesel exhaust, odors in the air, concealed drugs, parathion in lettuce, and ion plasmas.

Tandem mass spectrometry has been particularly effective in molecular structure determinations. To increase the number and absolute abundance of peaks in the secondary mass spectrum, it is necessary to add energy to the separated primary ions. Collisionally activated dissociation (CAD) is frequently used.

Fourier Transform Mass Spectrometry (FTMS). This technique enables chemists to use mass spectrometry in expanding and new ways. The technique enables the measurement of high molecular masses and, by application of ion manipulation (MS-MS), molecules can be degraded into more manageable pieces for which accurate mass measurement is feasible. As observed by Gross and Rempel, the unique applications of FTMS result from its ability to store ions. Ions in the trap can be reacted in very specific ways (chemical ionization) or activated by using lasers to give photodissociation spectra. Instead of operation at 1 torr of pressure as in the case of conventional mass spectrometers, FTMS chemical ionization must be conducted at 10^{-6} torr of reagent gas and 10^{-8} torr of sample.

Coupling Lasers with Mass Spectrometers. The analysis of inorganic atomic species can be facilitated by using lasers with mass spectrometers. A tunable dye laser, by itself or in combination with a pump laser, ionizes atoms by resonant excitation processes. The ions are then analyzed in the mass spectrometer. This combination of techniques has much potential for overcoming traditional limits of sensitivity and selectivity and will lead to increasing applications in analytical chemistry. As observed by Fassett, et al. (see reference), a large potential exists for the application of *multiphoton resonance ionization mass spectrometry*, ranging from basic spectroscopic studies of atoms and molecules to the detection of solar neutrinos and quarks. Discovery of the optogalvanic effect (Green, et al.) and earlier work (Hurst, et al.) led to the development of *laser-enhanced ionization (LEI)*. It has been determined that elements suitable for resonance ionization by the one-photon-resonant, two-photon ionization scheme (wavelengths between 260 and 355 nm) include: Na, Ca, Ba, Cr, Mn, Sc, Cr, Mn, Ru, Rh, Pd, Pt, Au, Ga, Ge, Sn, Bi, Eu, Gd, Tb, Ho, Tm,

and Yb. Elements for which resonance ionization has been demonstrated in the laboratory include: Li, Mg, Sr, Y, Ti, Zr, Hf, V, Ta, Mo, W, Re, Fe, Os, Co, Ni, Al, In, Ge, Sn, Pb, Dy, Er, Lu, Th, and U. Some elements also have been ionized by the two-photon-resonant, three-photon ionization scheme, including: Be, C, and I.

It is reported by Fassett, et al. that the resonance ionization process has an inherently high elemental selectivity. Mass spectrometric detection provides an increased selectivity that is a practical necessity for analytical problems in which nonspecific background ionization must be characterized and differentiated. Resonance ionization is ideally suited to mass spectrometry; ionization is well defined in both time and space, and only a small excess of translational kinetic energy is added to the atom by the process.

Nuclear Accelerators and Mass Spectrometers. An interesting area is that of using nuclear accelerators as high-sensitivity mass spectrometers. As recently as a decade ago, the Grenoble cyclotron was used as a mass spectrometer to measure ratios of $^{10}Be/^{9}Be$ of 10^{-8}, 10^{-9}, and 10^{-10} in standardized beryllium oxide samples. Measurements of this type also can be used to determine cosmogenic ^{10}Be profiles in various geophysical reservoirs, such as sea sediments and polar ice. See also **Particles (Subatomic)**.

Mass Spectrometers as Process Analyzers. The use of mass spectrometers in process analysis has not been widespread because of its perceived complexity and high cost. Technological advancements over the past decade or two have reduced costs and simplified mass spectrometry to the point where it is suitable for a number of process analytical applications in place of infrared absorption or gas chromatography (GC) techniques. The *quadrupole mass spectrometer* is well accepted in such applications because of low cost, good reliability, and ease of computer-controlled interfaces.

Simply, a quadrupole mass spectrometer can be divided into three parts: (1) the ionizer, (2) the mass filter, and (3) the detector, all of which are contained in a vacuum chamber maintained at a low pressure. When a gaseous sample is introduced into the system's ionizer, it is bombarded with a stream of electrons, producing positively charged parent ions (ions with the same molecular weight as the neutral molecule), and fragment ions. The ionizer has a series of lenses that serve to collimate the cloud of sample molecules toward the mass filter.

A quadrupole mass filter is a set of four rods disposed parallel and symmetrically with one another; opposite rods are electrically connected. An rf and dc voltage of equal potential, but opposite charge, is applied to each set of rods (Fig. 2). By varying the absolute potential applied to the rods, it is possible to stop all ions except those of a given *m/e* (mass-to-charge) ratio.

Finally, the ions flowing down the quadrupole strike the Faraday plate detector. In some cases, the signal is amplified further by an electron multiplier. Thus, there is obtained a spectrum of signal intensity versus *m/e* value. Each molecule has a unique fragmentation pattern so that a spectrum can be used as a fingerprint for compound identification. In addition, it is possible to quantitate the amount of a particular compound by comparing sample signal intensity with the intensity produced by a known amount of the compound.

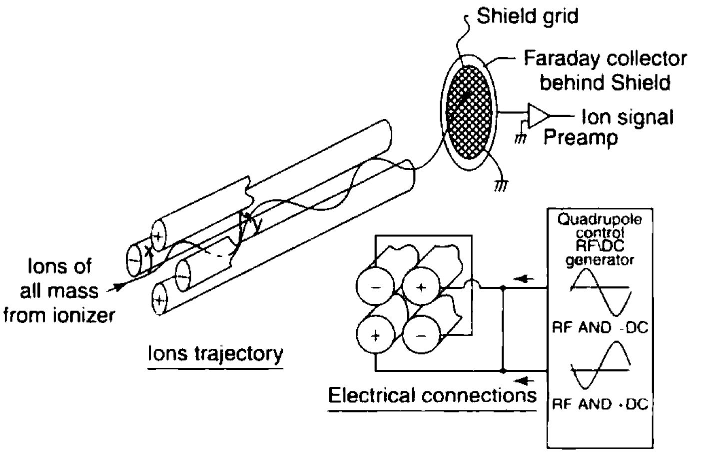

Fig. 2. Schematic diagram of quadrupole mass spectrometer of type used for process analysis. (*Extranuclear Laboratories*)

Many applications of the quadrupole mass spectrometer use a gas or liquid chromatograph to introduce the sample into the ionizer. When the spectrometer is used in this manner, it is most common to scan a wide mass range (50–1000 amu) at rates on the order of 1000 amu/second for compound identification. For process analyses, it is most common to introduce the sample directly into the ionizer and scan a shorter mass range. For both applications, computer systems are needed to collect the enormous amounts of data produced.

The computer is also used to control the potential applied to the quadrupole in order to scan the mass range of interest. Alternatively, the computer can command the appropriate potential required to focus a particular mass, a technique referred to as Selected Ion Monitoring (SIM). Process analysis is essentially continuous SIM to achieve online quantitation of the components in the process stream.

Once the stream components to be analyzed have been identified, the mass spectrum of each component must be compared to the spectra of all other components to find unique mass peaks. Not all constituents of the mixture will have unique peaks; some may have intense peaks that might be useful to measure that compound except that this mass peak also exists in another compound. Considering a stream containing N_2, CO, H_2O, and CO_2, Table 2 shows the mass peaks in each component's spectrum and their relative intensities using the largest peak from each compound as 100% in each case. Inspection of the table shows that *m/e* 18 and *m/e* 44 are unique peaks for H_2O and CO_2, respectively. However, the parent molecular ions of both N_2 and CO appear at *m/e* 28. Thus, some other method of measuring these components must be applied.

One might choose to measure CO at *m/e* 12 even though CO_2 has a fragment at this mass. Since the CO_2 intensity can be determined by measuring the peak at *m/e* 44, the CO_2 contribution to mass 12 is known and can be subtracted. The resultant at *m/e* 12 is then a measurement of the CO present in the mixture.

Two possibilities exist for the N_2 measurement: measure *m/e* 28 and subtract the CO contribution since CO intensity is known from the step above, or measure the intensity at *m/e* 14 and subtract the contribution from CO.

In practice, the spectral information used for calibration is obtained by actually introducing the compound of interest into the mass spectrometer and measuring the spectrum. This is usually done by using a known binary mixture of the particular compound in nitrogen or argon. The ratio of each mass peak compared to some standard ion, for example, *m/e* 28 of nitrogen, is measured. The fragmentation of the peaks of interest are then programmed into a fragmentation matrix. For each compound to be measured, only one mass peak is programmed.

For the analysis of N_2, CO, H_2O, and CO_2, the fragmentation matrix becomes:

	12	18	28	44
CO	4.00*	0.00	100.00	0.00
H_2O	0.00	100.00*	0.00	0.00
N_2	0.00	0.00	100.00*	0.00
CO_2	9.00	0.00	11.00	100.00*

TABLE 2. MASS PEAKS IN EACH COMPONENT'S SPECTRUM AND THEIR RELATIVE INTENSITIES. (LARGEST PEAK FROM EACH COMPOUND IS USED AS 100% IN EACH CASE)

Mass	H_2O	CO	N_2	CO_2
1	6.00			
12		4.00		9.00
14			5.00	
15			0.03	
16	4.00	1.00		10.00
17	28.00			
18	100.00			
28		100.00	100.00	11.00
29		1.00	0.73	0.09
30			0.02	
44				100.00
45				1.00
46				0.04

The peaks to be measured for each component are indicated by an asterisk. The subtraction of interfering mass peaks is accomplished by inverting the matrix to yield:

	12	18	28	44
CO	25	0	0	−2.25
H_2O	0	1	0	0
N_2	−25	0	1	2.14
CO_2	0	0	0	1

In the actual analysis, the amplitudes of peaks at masses 12, 18, 28 and 44 are measured and multiplied by the inverted matrix. For example:

	12	18	28	44	
CO	25	0	0	−2.25	I(12)
H_2O	0	1	0	0	I(18)
N_2	−25	0	1	2.14	I(29)
CO_2	0	0	0	1	I(44)

Therefore, CO intensity is determined by:

$$25[I(12)] + 0[I(18)] + 0[I(28)] - 2.25[I(44)]$$

H_2O, N_2, and CO_2 are similarly calculated. Intensities may be converted to percent concentration by dividing by the component's sensitivity and normalizing to 100%. The formulae for these calculations are therefore:

$$INT(J) = IBKG(J) - BKG(J)$$

$$CONC(J) = \text{Sum over } J[INVER(I,J) * INT(J)]/SENS(J)$$

$$\%CONC(J) = CONC(J) * 100/\text{Sum over } J[CONC(J)]$$

A modern mass spectrometric process analyzer should be designed for rapid response time, wide dynamic range, accuracy, and ease of computer operation. Because the instrument is a nonspecific detector, it is useful in detecting almost any gaseous compound that produces ions in the mass spectrometer's range (typically 200 amu). The instrument is adaptable to process analysis because it is easily and rapidly directed to monitor any mass ion peak within its range. One modern instrument is controlled by a computer system, which commands masses, gathers and reduces data, and presents useful information almost instantly to the operator. The instrument enables the operator to design analysis, calibration, and sampling sequence methods to optimize conditions for a particular application. An analysis method is designed by specifying the molecular weight and the mass to be monitored for each of the components to be analyzed. The data system then searches a library (electronically stored) for the spectra and sensitivity of the compounds of interest. The fragmentation matrix used for the analysis is thereby constructed. Changing the parameters for any or all compounds can be easily accomplished by the operator. Complex streams may require more than one calibration gas to properly calibrate all stream components.

The analyzer has three modes of operation: (1) *Sweep Mode*—the system can be commanded through the CRT keyboard to sweep the quadrupole over a specified range with the data displayed on the oscilloscope. This mode is useful for tuning or to determine the masses present in a particular stream. (2) *Manual Mode*—during real-time operation, the operator can display and change parameters in order to fine-tune a particular analysis. Data can be presented as intensity (raw signal voltages), percent concentration, or taken as a ratio to a specific component. Optionally, data can be printed or electronically stored. (3) *Automatic Analysis*?

MASTICATORY SUBSTANCES. The property of chewiness is one of several components that comprise so-called mouth feel experienced by the consumer of a food product. Whereas chewiness may be highly undesirable in a cut of roast beef, this property is the predominant rewarding factor of some food products, notably certain kinds of novelties, such as chewing gum. Biting and deformation resistance can be created or improved by the use of a number of essentially rubber-like substances. These are commonly termed *masticatory substances*. Chewiness is the main advantage contributed by such substances and thus other ingredients, such as sweeteners, flavorings, colorants, etc. are admixed with them to result in an overall attractive product for particular consumers.

Masticatory substances are of (1) vegetable origin, or (2) the products of organic synthesis. In the case of anhydrous lanolin, the source is fat from the wool of sheep.

Vegetable Substances

Masticatory substances derived from vegetables are gums from various plants and trees of the families *Apocynaceae* (dogbane family), *Euphorbiacea* (spurge family), *Moraceae* (mulberry family), and *Sapotaceae* (sapodilla family). Most of the naturally derived substances have unfamiliar names, usually known well only by persons in the trade. For example, from the *Apocynaceae* family are obtained jelutong, leche caspi or sorva, pendare, and perillo. From the *Euphorbiaceae* family, there are candelilla wax, chilte, and natural rubber (latex solids). From the *Moraceae* family, there are leche de vaca, Niger gutta, and tunu or tuno. From the *Sapotaceae* family, there are chicle, chiquibul, crown gum, gutta hang kang, gutta katiau, massaranduba balata, nispero, rosidinha, and Venezuelan chicle. Other naturally derived substances include lanolin, petroleum wax, rice bran wax, and natural terpene resin.

Synthetic Substances

During the last several decades, naturally derived masticatory substances have been displaced to a considerable degree by synthetic materials—for reasons of availability, economics, and, frequently, better control over purity. These developments essentially paralleled the development of the synthetic rubbers for industrial uses. Some of the synthetic substances now used and listed in the "Food Chemicals Codex," published by the National Academy of Sciences (Washington, DC) include: butadiene-styrene 75/25 rubber; butadiene-styrene 50/50 rubber; glycerol ester of partially dimerized rosin; glycerol ester of partially hydrogenated wood

rosin; glycerol ester of tall oil rosin; isobutylene-isoprene copolymer (butyl rubber); methyl ester of rosin (partially hydrogenated); paraffin (synthetic, by Fischer-Tropsch process); pentaerythritol ester of partially hydrogenated wood rosin; polyethylene; polyisobutylene, polyvinyl acetate; and terpene resin (synthetic).

MCLEOD GAGE. A liquid-level vacuum gage in which a known volume of gas, at the pressure to be measured, is compressed by the movement of a liquid column to a much smaller known volume, at which the resulting higher pressure is measured.

MCMILLAN, EDWIN M. (1907–1991). An American physicist who won the Nobel prize in chemistry in 1951 along with Glenn T. Seaborg for their discoveries in the chemistry of the transuranium elements. His work included research in nuclear physics and particle accelerator development as well as microwave radar and sonar. He and his colleagues discovered neptunium and plutonium. He was the recipient of the Atoms for Peace prize in 1963. His Ph.D. in Physics was awarded from Princeton University.

MEDICAL DIAGNOSTIC REAGENTS. Purified enzymes are widely used in medical diagnostic reagents in the measurement of analytes in urine, plasma, serum, or whole blood. Enzymes are very specific catalysts that can be derived from plants and animals, although microbial fermentation is the most popular production method. Enzymes are used extensively in diagnostics, immunodiagnostics, and biosensors to measure or amplify signals of many specific metabolites. Purified enzymes are expensive. This is the main reason for the increasing utilization of reusable immobilized enzymes in clinical analyses. See also **Enzyme**.

The main development in medical diagnostic reagents since the 1960s has been the steady growth of dry (solid-phase) chemistry systems. Dry chemistry systems have made substantial gains over wet clinical analysis in the number of tests performed in hospitals, laboratories, and homes because of ease, reliability, and accuracy.

Wet chemistry methods for analysis of body analytes, e.g., blood glucose or cholesterol, require equipment and trained analysts. In contrast, dry chemistry systems can be used at home.

Dry chemistry systems are useful not only to diabetics, but also to patients having other medical problems. These systems are also used in animal diagnosis, food, fermentation, agriculture, and environmental and industrial monitoring.

Enzyme-Catalyzed Reactions in Solution

Measurement Considerations. A prototype enzyme-catalyzed reaction where one substrate (S) produces only one product (P) may be described by

$$E + S \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} ES \xrightarrow{k_2} E + P$$

where E is enzyme, ES is the enzyme–substrate complex, and k_i represents the reaction rate constants. The reaction can be followed by monitoring the loss of substrate or the formation of product. A graph of the concentration of substrate, or product, vs time gives an exponential curve. In the equilibrium method (end point) used for S determination, data are collected when the concentration of S or P are time-independent. Methods where data are obtained from the early linear part of the curve are known as kinetic methods.

Glucose, urea (qv) and cholesterol are the substrates most frequently measured, although there are many more substrates or metabolites that are determined in clinical laboratories using enzymes. See also **Steroids**.

Indicators. There are certain compounds that are suitable as indicators for sensitive and specific clinical analysis. Nicotinamide adenine dinucleotide (NAD) occurs in oxidized (NAD^+) and reduced (NADH) forms. Nicotinamide adenine dinucleotide phosphate (NADP) also has two states, $NADP^+$ and NADPH. NADH has a very high uv–vis absorption at 339 nm, extinction coefficient = $6300(M \cdot cm)^{-1}$, but NAD^+ does not. Similarly, NADPH absorbs light very strongly whereas $NADP^+$ does not. In the enzymatic assays of cholesterol, glucose, and urea, oxygen is used and H_2O_2 is formed. The H_2O_2 generated reacts with a chromogen in the presence of the enzyme peroxidase to produce a color change.

Measurement of Analytes. Biochemical reactions used in the measurement of selected analytes are commercially available as prepackaged kits of reagents. Measurement of the reactions given plus many other analytes can be made. Kits are available for measurement of cholesterol, citrate, creatinine, galactose, glucose, lactate, triglycerides and blood urea nitrogen.

Assay of Enzymes. In body fluids, enzyme levels are measured to help in diagnosis and for monitoring treatment of disease. Enzyme levels are determined by the kinetic methods. The assays are set up so that the enzyme concentration is rate-limiting. The continuous flow analyzers, introduced in the early 1960s, solved the problem of the high workload of clinical laboratories. In this method, reaction velocity is measured rapidly; the change in absorbance may be very small, but within the capability of advanced kinetic analyzers.

Enzymes, measured in clinical laboratories, for which kits are available include γ-glutamyl transferase (GGT), alanine transferase (ALT), aldolase, α-amylase, aspartate aminotransferase, creatine kinase and its isoenzymes, galactose-1-phosphate uridyl transferase, lipase, malate dehydrogenase, 5′-nucleotidase, phosphohexose isomerase, and pyruvate kinase.

Immobilized Enzymes in Diagnostic Reagents. The use of immobilized, instead of soluble, enzymes for measurement of analytes has received considerable attention, especially for clinical analyses. Use of immobilized enzymes offers the advantages of greater accuracy, stability, and convenience. Only a few methods utilizing immobilized enzymes have become commercially available.

Dry Chemistry

Background. Enzymes are essential in user-friendly diagnostic dry chemistry systems. Dry chemistry test kits are available in thin strips that are usually disposable. They may be either film-coated or impregnated. The most basic diagnostic strip consists of a paper or plastic base, polymeric binder, and reactive chemistry components consisting of enzymes, surfactants, buffers, and indicators. Diagnostic coatings or impregnation must incorporate all reagents necessary for the reaction. The coating can be either single or multilayer in design. A list of analytes, enzymes, drugs, and electrolytes assayed by dry chemistry diagnostic test kits follows:

Analytes	*Enzymes*
glucose	alkaline phosphate (ALP)
urea	lactate dehydrogenase (LDH)
urate	creatine kinase
cholesterol (total)	MB isoenzyme (CK-MB)
triglycerides	lipase
bilirubin (total)	amylase (total)
ammonium ions	*Drugs*
creatinine	phenobarbitone
calcium	phenytoin
hemoglobin	theophylline
HDL cholesterol	carbamazepine
magnesium(II)	*Electrolytes*
phosphate (inorganic)	sodium ion
albumin	chloride
protein in cerebrospinal fluid	carbon dioxide

Dry chemistry systems are widely used in physician's offices and hospital laboratories, and by millions of patients in their own homes worldwide. These systems are used for routine urinalysis, blood chemistry determinations, and immunological and microbiological testing. The main advantage of this technology is elimination of the need for reagent preparation and many other manual steps common to liquid reagent systems. This yields greater consistency and reliability of test results. Furthermore, dry chemistry systems have longer shelf stability and hence there is a reduced waste of reagents. Each test unit contains all the reagents and reactants necessary to perform assays.

Molded Dry Chemistry. In general, most enzymes are very fragile and sensitive to pH, solvent, and elevated temperatures. The catalytic activity of most enzymes is reduced dramatically as the temperature is increased. Typical properties of diagnostic enzymes are given in Table 1. The presence of ionic salts and other chemicals can considerably influence enzyme stability. To keep or sustain enzymatic activity, the redox centers must remain intact. The bulk of the enzyme, polymeric in composition, is an insulator; thus, altering it does not reduce the enzyme's catalytic activity. It

TABLE 1. PROPERTIES OF DIAGNOSTIC ENZYMES

[b] At 40°C for 1 h.

has been suggested that molding of strips using reaction injection molding (RIM) may lead to useful chemistries, including biosensors, in the future.

Application of Diagnostic Technology in Monitoring Diabetes. Very frequent measurements of blood glucose to manage diabetes are one of the most important applications of diagnostic reagents. The blood glucose monitoring market (ca 1995) totaled about $7.5 × 10^8$ in the United States and was expected to grow at a rate of 10% annually.

In the early 1960s, a promising approach to glucose monitoring was developed in the form of an enzyme electrode that used oxidation of glucose by the enzyme GOD. This approach has been incorporated into a few clinical analyzers for blood glucose determination.

Much work has been done on exploration and development of redox polymers that can rapidly and efficiently shuttle electrons. Extensive work has been done on osmium-containing polymers. The most stable and reproducible redox polymer of this kind is a poly(4-vinyl pyridine) (PVP) to which $Os(bpy)_2Cl_2$, where bpy = 2, 2′ – bipyridine, has been attached to 1/16th of the pendant pyridine groups. The resultant redox polymer is water insoluble and biologically compatible by partial quaternization of the remaining pyridine groups using 2-bromoethyl amine. The newly introduced quaternized amine groups can react with a water-soluble epoxy, e.g., polyethylene glycol diglycidyl ether, and GOD to produce a cross-linked biosensor coating film.

Flexible polymer chains have also been used for relays to provide communication between GOD's redox centers and the electrode. These ferrocene-modified siloxane polymers are stable and nondiffusing. Biosensors based on these redox polymers gave good response and superior stability. Commercial electrochemical microbiosensors, e.g., Exactech (Medisense) and a silicon-based 6+ system (*i*-Stat) have appeared in the marketplace. These newer technologies should certainly impact rapid blood chemistry determinations by the year 2000.

The next generation of amperometric enzyme electrodes may well be based on immobilization techniques that are compatible with microelectronic mass-production processes and are easy to miniaturize. Integration of enzymes and mediators simultaneously should improve the electron-transfer pathway from the active site of the enzyme to the electrode.

Functionalized conducting monomers can be deposited on electrode surfaces aiming for covalent attachment or entrapment of sensor components. There is a pressing need for an implantable glucose sensor for optimal control of blood glucose concentration in diabetics. Two novel technologies have been used in the fabrication of a miniature electroenzyme glucose sensor for implantation in the subcutaneous tissues of humans with diabetes. An electrode-position technique has been developed to electrically attract GOD and albumin onto the surface of the working electrode. The resultant enzyme–albumin layer was cross-linked by glutaraldehyde. A biocompatible polyethylene glycol–polyurethane copolymer has also been developed to serve as the outer membrane of the sensor to provide differential permeability of oxygen relative to glucose, in order to avoid oxygen deficit encountered in physiologic tissues.

MELAMINE. [CAS: 108-78-1]. $(N{\equiv}C{-}NH_2)_3$, formula weight 126.12, white solid, mp 355°C, sp gr 1.56. The compound may be considered the trimer of cyanamide, or as the triamide of cyanuric acid. Melamine resembles an amide more than an amine. Liebig first prepared melamine in 1834. In early production methods, melamine was prepared from calcium cyanamide through conversion to the cyanodiamide and then to the trimer, melamine. The compound now is synthesized from urea. The production of melamine exceeded 450 metric tons annually in the early 1970s and has been growing at a rate of about 5% annually. Most of the melamine made is condensed with formaldehyde or other aldehydes to form resins. These resins possess particularly outstanding resistance to heat, water, and many chemicals. The electrical properties and surface hardness also are rated high. The consumption of melamine for these resins is: (1) protective and decorative laminates, 45%; (2) molding compounds, 30%; (3) textile resins, 9%; (4) coatings, 7%; (5) paper-treating resins and various adhesives, 9%. Typically, in a modern synthesis process, (1) urea is thermally decomposed into a gas mixture of cyanic acid and NH_3: $H_2N \cdot CO \cdot NH_2 \longrightarrow HCNO + NH_3$; (2) cyanic gas is thermally decomposed into a melamine-CO_2 vapor:

$$6\,HCNO \longrightarrow (N{\equiv}C{-}NH_2)_3 + 3\,CO_2.$$

Step 1 is endothermic; step 2 is exothermic; the overall reaction is endothermic. Because of the large quantities of CO_2 and HN_3 generated, the process often is undertaken in connection with urea manufacture, which permits the off-gases to be recycled usefully. The melamine synthesis may be carried out at low or medium pressures with the assistance of a catalyst; or at higher pressures without a catalyst.

MELTING POINTS (Chemical Elements). See **Chemical Elements**.

MEMBRANE (Semipermeable). See **Semipermeable Membrane (or Semipermeable Diaphragm)**.

MEMBRANE SEPARATIONS TECHNOLOGY. The separation of materials (solids from liquids; liquids from other liquids; solids of one size from solids of another size; gases from liquids; etc.) is one of the fundamental unit operations needed by the chemical, food, and related fluid processing industries. Such operations include adsorption, absorption, distillation, evaporation, extraction, filtration, ion exchange, settling, and preparative chromatography, among others. In recent years, membrane technology has made important inroads into several of these more traditional unit operations, and on adsorption, distillation, and filtration in particular. Either membrane technology has replaced traditional separation operations or is used in connection with them—with resulting improvement of the separation (in terms of product quality) and in operating efficiency as well. The membranes used are synthetic polymers, the pores of which are made in a number of interesting ways. Membrane separations are not a single technology, but rather they differ in the methodology used and in the degree of separation that can be effected. Membrane-using subtechnologies include electrodialysis, electrolysis, microfiltration, ultrafiltration, and reverse osmosis.

The general design of the equipment in which membranes are used is commonly (1) *perpendicular flow*, i.e., where the flow of unprocessed material approaches the "filtering" medium in an effrontal manner, passing through the medium, the processed material exiting the medium on the opposite side, and the material removed remaining on the surface of the medium. This is the common figuration that applies to traditional filters, such as cartridge, bag, diatomaceous-earth precoated, backwashable sand, and backwashable mixed-media filters. Some of these configurations allow regeneration by way of backflushing; some do not—the used media must

be discarded. See also **Filtration.** (2) In *crossflow*, the influent unprocessed stream is separated into two effluent streams, known as the *permeate* and *concentrate*, respectively. The permeate is that fraction which has passed through a semipermeable membrane; the concentrate is that stream which has been enriched with the solutes or suspended solids, i.e., those materials which have not passed through the membrane. This design permits the membrane medium to operate continuously in a self-cleaning mode, with solutes and solids swept away by the concentrate stream which is running parallel to the membrane (hence the term "crossflow"). As with conventional filtration, sometimes the trapped material (filter cake) is the principal desired end product; in other cases, the desired product is clarified effluent. However, in contrast with conventional filtering, membrane, methodologies not only separate solids (or gases) from liquids (or gases), but proper selection of the membrane will allow separation of solids (particles) by size range. Thus, the permeate (what passes through the membrane) will contain much smaller particle sizes (in the molecular range) than will the concentrate. Again, depending upon the objective of the process, the permeate or the concentrate will be the principal product of interest. In some instances, both products may be of vital interest. See Fig. 1.

Membranes may be *isotropic*, i.e., their pore structure and material are the same throughout the membrane; or they may be *anisotropic*, i.e., they have a dense skin layer on top which defines the degree of separation effected, with a spongy support layer underneath. The dimensions of the pores range widely as detailed later in this article. Membranes are made by a number of processes, including solvent casting and mechanical stretching to form pores in an otherwise impervious film. Irradiation, followed by acid etching, has been used to create pores. The cellulose acetate membrane (Fig. 2) is made by casting thin sheets of polymer dissolved in a water-miscible solvent on a flat plate, usually glass. Shortly after casting, the cast solution is immersed in water. The water diffuses into the solution and causes the polymer to coagulate at a rate that is a complex function of the polymer and solvent properties. These membranes are porous throughout, possessing a thin, relatively dense skin near one surface.

The range of small particles, molecules, and ions dealt with by membrane separation technology, particularly as encountered in the biochemical field are as follows.

Microfiltration

This process effects separations in the 0.02–2.0 micron range and historically has been run in the perpendicular flow mode, requiring disposal of the membrane medium as a result of binding by the retained material.

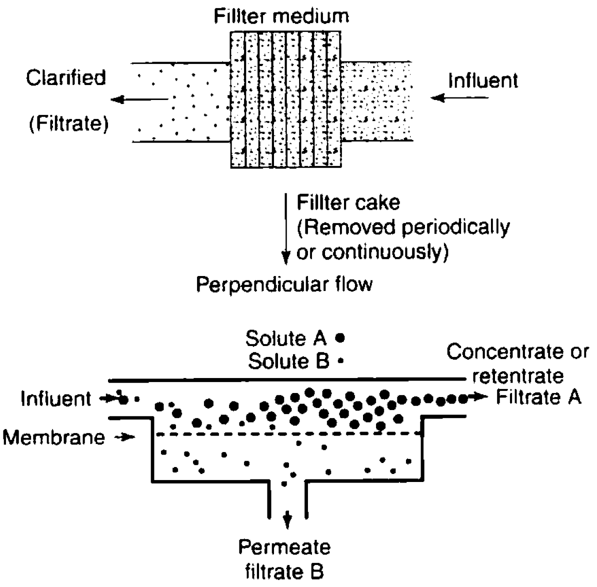

Fig. 1. Perpendicular flow contrasted with crossflow. Perpendicular flow is shown here in the familiar terms of conventional filtering, but the principle is the same if a membrane is used. There is one influent and a single effluent. In crossflow, there are two effluents, a concentrate (or retentate) and a permeate, usually both liquids of different concentrations in terms of particle size. However, membranes are also used for separating acid gases and hydrocarbons

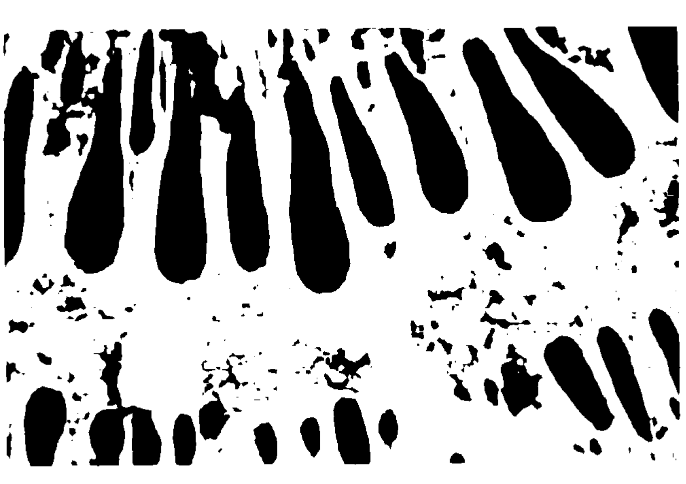

Fig. 2. Facsimile of photomicrograph of cellulose acetate membrane, prepared by solvent casting process, clearly showing pore structure

Crossflow technology is increasing, as it proves practical. Microfiltration membranes are of an isotropic and homogeneous morphology, i.e., the pore structure is consistent throughout. There is some movement, however, toward the use of "skinned" anisotropic membranes. Microfiltration membranes are available in a wide variety of polymers, including some that are quite chemically inert. They also are available as tubular, hollow fiber, or capillary fiber elements.

Ultrafiltration

This process effects separations in the 0.002 to 0.2 micron range—more specifically described as the 500–300,000 molecular-weight cutoff range, requiring pore sizes of from 15 to 1000 angstroms. For practical reasons, ultrafiltration almost always requires a crossflow configuration. Because of the size and the gelatinous nature of many of the solutions and particles handled by this process and that the membrane retains, an ultrafiltration membrane would have a very short life if used in the perpendicular flow mode. Nearly all membranes used in ultrafiltration are anisotropic, as previously defined. Membranes usually are of a homogeneous material, in that they consist of the same polymer or copolymer throughout their structure. Membranes must be made of tough, relatively inert materials, such as polysulfone polymer, or cellulose acetate polymer, the latter used more extensively in the earlier days of ultrafiltration.

Reverse Osmosis

Sometimes called *hyperfiltration*, this is the most technically complex class of membrane technology. Reverse osmosis effects separations both at the micromolecular and ionic size ranges. Pore sizes range from 5 to 15 angstroms. These membranes can effect separation of solutions down to a molecular weight of 150 and sometimes lower. Reverse osmosis membranes are anisotropic. Cellulose acetate has long been the favorite, especially for many industrial and medical applications. However, homogeneous polyamide-type membranes are finding a large share of the market and are increasingly favored for seawater desalting purposes.

Applications of Membrane Separations Technology

The food, biochemical, and petrochemical industries are the largest users. In the food processing industry, there are three main categories of use—processing, waste treatment, and pure water make-up. Processing applications include milk concentration and fractionation, numerous fermentation operations, and the production of colorants, among many others. Waste handling operations include corn processing byproducts, soybean protein reclamation, and handling meat processing oils and fish processing proteins and oils.

Membrane separations technology is also widely used in the pharmaceutical industry in connection with recovering antibiotic products. The list of references given at the end of this article is rather long. There the reader will find a wealth of information on applications, including the growing recognition by the petroleum and petrochemical industries of the viability of membrane technology as a replacement or companion for the more traditional separation processes.

Membranes Configurations for Use in Separation Equipment

For insertion into separation equipment, frequently with large throughputs, membranes are available in several configurations: (1) the tubular form ($\frac{1}{2}$ in; 12.5 mm) is common; (2) hollow-fiber; (3) plate-and-frame; and (4) spiral wound. The Paulson reference covers membrane formats in considerable detail.

MENDELEVIUM. [CAS 7440-11-1]. Chemical element, symbol Md, at. no. 101, at. wt. 256 (mass number of known isotope), radioactive metal of the Actinide series, also one of the Transuranium elements. The element was produced synthetically and first identified by A. Ghiorso, B.G. Harvey, G.R. Choppin, S.G. Thompson, and G.T. Seaborg at the University of California at Berkeley in 1955. ^{256}Md was produced by the bombardment of ^{253}Es on gold foil with 48-MeV alpha particles in the 60-inch cyclotron at Berkeley. By ion exchange treatment of the dissolved gold foil, only one or two atoms of ^{256}Md were obtained, which decayed (half-life 1.3 hours) by K-electron capture to ^{256}Fm, which underwent its characteristic spontaneous fission.

Probable electronic configuration $1s^2 2s^2 2p^6 3s^2 3p^6 3d^{10} 4s^2 4p^6 4d^{10} 4f^{14} 5s^2 5p^6 5d^{10} 5f^{13} 6s^2 6p^6 7s^2$. Ionic radius Md^{3+} 0.96 Å.

Another isotope, ^{255}Md, is also formed during the bombardment of ^{253}Es by alpha particles. It also decays by electron capture, and has a half-life of 30 minutes.

Regarding the first identification, scientists considered it notable in that only in the order of 1 to 3 atoms per experiment were produced, thus making Md the first element to be discovered on an atom-at-a-time basis. The techniques developed in the search for Md served as a prototype for the discovery of subsequent elements in the Transuranium series.

MENDELEYEV, DIMITRI (1834–1907). Born in Siberia, Mendeleyev made a fundamental contribution to chemistry in 1869 by establishing the principle of periodicity of the elements. His first periodic table recognized the regular variation in the chemical and physical properties of the elements and classified the 63 elements known at the time into groups placing the elements in ascending order of atomic weight and grouping them by similarity of properties. So accurate was Mendeleyev's thinking that he predicted the existence and atomic weights of several elements that were not actually discovered until years later. The original table has been modified and corrected several times, notably by Moseley, but it has accommodated the discovery of isotopes, rare gases, etc. Its importance in the development of chemical theory can hardly be overestimated. See also **Becquerel, Antoine Henri (1852–1908)**; **Mosley, Henry (1887–1915)**; and **Periodic Table of the Elements**.

MENISCUS. The curved surface of a liquid, particularly noticeable in vessels of tubes of small diameter and due to the surface tension of the liquid. If the liquid wets the containing vessel, the meniscus is concave; otherwise it is convex. The meniscus of mercury in glass is convex.

MERCAPTANS. Hydrogen sulfide yields two classes of organic compounds: (1) hydrosulfides, and (2) sulfides. The hydrosulfides are termed mercaptans, a name derived from *mercurium captans*, because of their ability to react with mercuric oxide to form crystalline compounds. Mercaptans also are termed thioalcohols and sulfur-alcohols. A more general term *thiols* also is used. This term not only embraces mercaptans, but also covers thioethers, sulfhydrates, and thiophenols.

Ethyl mercaptan C_2H_5SH, (legal label name for ethanethiol) one of the better known mercaptans, is an odorous liquid, mp −121°C, bp 36–37°C, sp gr 0.839. The compound is very slightly soluble in H_2O; soluble in alcohol and ether. It is prepared by distilling ethyl potassium sulfate with potassium hydrogen sulfide. Additional mercaptans can be prepared in a similar manner with the corresponding proper ingredients. All mercaptans have unpleasant garlic-type odors; when oxidized with HNO_3 they yield sulfonic acids.

Some formulations for styrene-butadiene rubber (GR-S) contain dodecyl mercaptan which plays the role of a chain-transfer agent used to control the molecular weight of the final synthetic product.

MERCURY. [CAS: 7439-97-6]. Chemical element, symbol Hg, at. no. 80, at. wt. 200.59, periodic table group 12, mp −38.84°C, bp 356.58°C, density 13.546 g/cm^3 (liquid), 14.193 g/cm^3 (solid). Solid mercury has a rhombohedral crystal structure. The element, sometimes referred to as quicksilver, is a silver-white liquid metal at standard conditions. There are seven stable isotopes of mercury, ^{196}Hg, ^{198}Hg through ^{202}Hg, and ^{204}Hg, and seven radioactive isotopes, ^{192}Hg through ^{195}Hg, ^{197}Hg, ^{203}Hg, and ^{205}Hg. With exception of ^{194}Hg (half-life of approximately 130 days) and ^{203}Hg (half-life of approximately 46 days), the half-lives of the radioactive isotopes are short, measured in terms of minutes or hours.

First ionization potential 10.434 eV; second, 18.65 eV; third, 34.3 eV. Oxidation potentials $Hg \longrightarrow \frac{1}{2}Hg_2^{2+} + e^-$, −0.7986 V; $Hg \longrightarrow Hg^{2+} + 2e^-$, −0.852 V; $Hg_2^{2+} \longrightarrow 2Hg^{2+} + 2e^-$, −0.905 V. $Hg + 2OH^- \longrightarrow HgO + 2H_2O + 2e^-$, −0.098 V; $2Hg + 2OH^- \longrightarrow Hg_2O + H_2O + 2e^-$, −0.123 V. Other important physical properties of mercury are given under **Chemical Elements**.

Mercury forms alloys, called amalgams, with most metals, but not with iron or platinum; does not wet glass but forms a convex surface when in a glass container; is slightly volatile at ordinary temperatures and a health hazard due to its poisonous effect; slowly tarnishes in moist air; upon heating in air or oxygen, somewhat below its boiling temperature of 357°C, forms mercuric oxide slowly, as in the classical experiment by Lavoisier on the composition of air; may be purified by distillation and condensation (health hazard); unattacked by dilute HCl or H_2SO_4, but dissolved by dilute or concentrated HNO_3 with the formation of mercurous and mercuric nitrates, respectively, and by hot concentrated H_2SO_4 with the

formation of both mercurous and mercuric sulfates; unattacked by alkalis. Discovery ancient.

When cooled to sufficiently low temperatures, mercury becomes *superconducting*, virtually conducting electricity with no resistance. See also **Superconductivity**.

Mercury was mined as early as 500 B.C. and currently ranks tenth in worldwide production of nonferrous metals. The unusual combination of physical properties possessed by the element give it an importance exceeding its production rating. The chief source of mercury is cinnabar, HgS, the red sulfide that contains 86.2% mercury. See also **Cinnabar**. Although the mineral occurs widely throughout the world, relatively few deposits are of commercial importance, notably those in China, Italy, Mexico, the Philippines, Peru, Spain, the former Soviet Union, the former Yugoslavia, and the United States. World reserves of mercury currently are estimated at 4 million flasks, of which sources in the United States account for about 300,000 flasks. A flask contains 76 pounds (34.5 kilograms) of the liquid metal.

The ore is concentrated to about 25–50% mercury by flotation. Beneficiation of mercury ores is not commonly practiced. The concentrate is roasted: $HgS + O_2 \longrightarrow Hg + SO_2$. The process is essentially one of distillation because the freed mercury quickly volatilizes, after which it is condensed with a resulting purity of 95% (furnace plants) to 98% (retort plants). The mercury is further refined, through filtering, oxidation, acid leaching of the impurities, or by distillation, to yield prime or virgin mercury with an average purity of 99.9%. This purity is satisfactory for all but the most exacting requirements. Some special mercury chemicals may require that the virgin mercury be triple distilled. Significant quantities of secondary mercury are recovered from waste products, such as dental amalgams, sludges, used batteries, used instruments, and other mercury-bearing materials. Secondary recovery accounts for close to 20% of the total domestic production of mercury in the United States.

Uses of Mercury

Because of the poisonous nature of Hg, wherever possible the industrial uses of the element have been reduced and research to find suitable substitutes for Hg for many applications has accelerated during recent years. Traditionally, mercury's largest usage has been in connection with electrical apparatus (switching, etc.), the electrolytic preparation of chlorine and caustic soda (mercury cells), in antifouling and mildew-proofing agents and paints, in industrial and clinical thermometers, in pharmaceutical preparations, in agricultural herbicides and pesticides, in dental preparations, in the preparation of amalgams, and in use of Hg as a catalyst for certain chemical reactions.

The consumption of mercury by the chlor-alkali industry may range from 15% to as high as 35% of the total in any given year, depending upon new construction. Large amounts of mercury are required for the start-up of mercury cell operations, whereas replacement requirements are quite low. Several areas of mercury use are declining gradually, particularly in the pharmaceutical field where sulfa drugs, iodine, and various antiseptics and disinfectants have made inroads on mercury chemicals. Mercury compounds, used for many years in the treatment of syphilis, for example, largely have been displaced by antibiotics and other treatments. Because of the fundamentally toxic nature of mercury and its compounds, the agricultural uses of mercury formulations are being deemphasized, with constant research for substitute materials. In the dental field, a number of metal powders, porcelain, and plastic materials have displaced mercury amalgams in many dental applications. In the explosives field, several compounds, such as lead azide, diazodinitrophenol, and other organic initiators, are serving the same function as mercury fulminate. The use of mercury as a heat-transfer medium in boilers was essentially abandoned a number of years ago. On the other hand, mercury-base catalysts are increasing in application and, to date, suitable substitutes for mercury in the antifouling and mildew-proofing formulations area have not been found. The essential properties of mercury that will be difficult to replace are its high specific gravity, fluidity at room temperatures, and excellent electrical conductivity.

In addition to some diminishment of mercury usage for various products because of increasing awareness of its toxicity potential, conservation-minded technologists also have pointed to the relatively limited world resources of the metal. Considerable ingenuity has been used to replace mercury. For example, diaphragm cells can be used in caustic-chlorine production, organic biocides are replacing mercury-containing compounds, gold recovery is accomplished by the cyanide process rather than by the amalgamation process, and plastic paints and copper oxide paints can be used in place of mercuric biocidal paints. The use of the diaphragm cell for chlorine-alkali production possibly is the most dramatic substitution in terms of mercury conservation. Diaphragm cells require no mercury, whereas the traditional mercury cells once accounted for as much as 35% of the mercury use in some years.

Chemistry and Compounds

The apparent anomaly between mercury and the lighter elements of transition group 2, in that mercury regularly forms both univalent and divalent compounds, while zinc and cadmium do so very rarely, is partly understood from the observation that mercury(I) salts ionize even in the gaseous state to Hg_2^{2+}, rather than Hg^+. Evidence for this double ion is provided by its Raman spectral line, by the lineal Cl–Hg–Hg–Cl units in crystals of mercury(I) chloride, and by the emf of mercury(I) nitrate concentration cells. The anomaly is further removed by the observation that cadmium also forms a (much less stable) diatomic ion Cd_2^{2+}, e.g., in $Cd_2(AlCl_4)_2$.

Oxides. Heating of mercury in air yields the (divalent) oxide HgO, which at higher temperatures decomposes into its elements. Mercury(II) oxide is also precipitated from solutions of mercury(II) salts by alkaline solutions. Alkalies precipitate a yellow form, while alkali carbonates give a red one. The yellow is apparently a finely divided form of the red, since they are crystallographically identical, but differ slightly in certain chemical and physical properties, including solubility. Mercury(II) oxide exhibits solubility in solutions of alkali salts, which is attributed to formation of complex ions such as $[Hg(OH)_2NO_3]^-$ and $[Hg(OH)_2SO_4]^{2-}$.

Halogen Compounds. All eight compounds of univalent and divalent mercury with the single halogens are known, as well as several compounds of mercury(II) with two halogens, such as HgBrI and HgClI. The mercury(I) halides are insoluble in water, with the exception of the fluoride which, like mercury(II) fluoride, is hydrolyzed by water. Like the zinc and cadmium halides, mercury(II) halides behave anomalously in aqueous solution, and for similar reasons, i.e., the presence of complex ions and un-ionized molecules. In the case of mercury(II) halides, with their more covalent character than zinc or cadmium halides, the ionization is somewhat less, and the concentration of Hg^{2+} relatively low. Thus, in aqueous solution, mercury(II) chloride, $HgCl_2$, is present largely as un-ionized molecules, but also ionizes $HgCl^+$ and Cl^-, and only secondarily and to a slight extent to give Hg^{2+}. In the presence of added Cl^-, an $HgCl_2$ solution is a complex system involving equilibria between $HgCl_2$, $HgCl^+$, Cl^-, Hg^{2+}, and the complex ions $HgCl^{3-}$ and $HgCl_4^{2-}$. Similarly, the hydrolysis of $HgCl_2$, though slight, involves several equilibria whose relative importance varies with the concentration of the solution. In more concentrated solutions the hydrolysis of $HgCl_2$ to HgOHCl, Cl^- and H^+ is prominent, while in more dilute solutions the most important equilibria involve the ionization $HgCl_2$ to $HgCl^+$ and Cl^-, and the hydrolysis of $HgCl_2$ to $[HgOHCl_2]_2^{2-}$ and H^+, and that of $HgCl^-$ to HgOHCl or $[HgOHCl]_2$ and H^+. Finally, oxyhalides, such as $HgBr_2 \cdot 3HgO$, $HgCl_2 \cdot 2HgO$, $HgCl_2 \cdot 3HgO$ and $HgCl_2 \cdot 4HgO$ are also obtainable, usually by action of alkali hydroxides upon mercury halides. Mercury(II) iodide, like the oxide, is polymorphic. It has three forms, yellow, red, and white, the second being the most stable up to 127°C, where it undergoes a definite transition to the yellow. The colorless HgI_4^{2-} is very stable, especially to alkalies, and is used in Nessler's reagent.

Salts. Mercury forms many salts, both of mercury(I) and mercury(II). In general, action of oxidizing acids upon the metal yields the latter, while the former requires either a limited amount of the oxidant or indirect methods. Mercury(I) salts are made by treating a solution of a soluble mercury(II) salt with metallic mercury. Thus, heating mercury with H_2SO_4 or HNO_3 yields mercury(II) sulfate or nitrate, $HgSO_4$ or $Hg(NO_3)_2$, respectively, crystallizing as hydrates, while mercuric(I) nitrate results from the use of cold acid in limited amount, and mercuric(I) sulfate is produced by the last method as well as from mercury(I) nitrate and sulfuric acid. The other salts of both univalent and divalent mercury include the acetates, antimonates, arsenates, bromates, carbonates, chlorates, chromates, fluorosilicates, iodates, oxalates, perchlorates, periodates, phosphates, tartrates,

thiocyanates, tungstates, uranates, and vanadates. Also known in both valences are the arsenides (from arsine and the mercury solutions), azides (from hydrozoic acid and the mercury solutions), nitrides and phosphides. Only mercury(II) selenide and telluride exist. Hg_2S_2 has been reported to be obtained as a black powder, but is believed to be a mixture of Hg and HgS. The latter exists in two forms, the black form that is usually precipitated by hydrogen sulfide, and the red, cinnabar, precipitated by H_2S from a solution of mercury(II) acetate and ammonium thiocyanate. The black changes to the red in liquid H_2S, and the red to the black on heating to 386°C. Cinnabar is the thermodynamically stable form at room temperature.

Compounds with Nitrogen and Sulfur. The reactions of mercury(I) compounds and NH_3 are complex, and published results vary. Recent (x-ray) studies show that this reaction, modified by the presence of ammonium chloride, NH_4Cl, yields three aminobasic compounds containing divalent mercury: $Hg_2NCl \cdot H_2O$, $HgNH_2Cl$, and $Hg(NH_3)_2Cl_2$. The first of these is the chloride of Millon's base, $Hg_2NOH \cdot 2H_2O$, which is produced by warming HgO with aqueous ammonia.

Mercury is the least active of the elements of its group as an electron acceptor from oxygen; however, with sulfur it is more active, the mercury halides forming dialkyl sulfide addition products, $R_2S \cdot 2HgX_2$, and HgS dissolves in alkali sulfides forming $[HgS_2]^{2-}$ or $Hg(SH)_4^{2-}$. Like zinc and cadmium, mercury forms a series of ammines, which with the mercury halides are principally the diammines, $[Hg(NH_3)_2]X_2$, where X is a covalently bonded halogen atom, and with more ionic mercury compounds, e.g., the nitrate and sulfate, especially in the presence of high concentrations of ammonium salts, the tetrammines, e.g., $[Hg(NH_3)_4](NO_3)_2$. These complexes also form with amines and diamines, e.g., ethylenediamine, which contributes three molecules per Hg^{2+} ion. Besides forming univalent and divalent cyanides, mercury forms complex cyanide ions, $[Hg(CN)_3]^-$ and $[Hg(CN)_4]^{2-}$, as well as additional compounds with the mercury(II) halides of the structure HgCNX. Mercury forms insoluble thiocyanates and complex ions, e.g., $Hg(SCN)_3^-$, $Hg(SCN)_4^{2-}$. Mercury cyanates and fulminates are insoluble. Mercury(II) mercaptides, $Hg(SR)_2$, decompose on heating to give HgS and R_2S. Mercury(II) hydrogen sulfite, $Hg(HSO_3)_2$, is actually mercuridisulfonic acid, $Hg(SO_3H)_2$, with Hg–S bonds. Like the halides, compounds such as $Hg[C(NO_2)_3]_2$, $Hg[C(CN)_3]_2$, $Hg(NO_2)_2$ (dinitromercury), $Hg(CF_3)_2$ are noteworthy for their lack of ionic dissociation.

Organometallic Compounds. Mercury also forms a large number of organometallic compounds of the type HgR_2, where R may be not only an alkyl radical, but an alkoxy radical, an acyl radical, a halogenated alkyl radical, an alkylthio radical, an aryl radical or a perfluoroalkyl radical. In addition, mercury also forms numerous organometallic compounds of structure RHgX, where X is a halogen atom, and R one of the foregoing organic radicals.

The organic compounds containing mercury that are used as disinfectants, germicides, and antiseptics are known as mercurials. Among these are Merthiolate, Mercurochrome, and Metaphen. Merthiolate is the sodium salt of ethylmercurithiosalicylic acid, $C_2H_5HgS \cdot C_6H_4 \cdot COONa$. It contains 49.5% of mercury. It is a crystalline, cream-colored powder which is very soluble in water, for about 1 gram dissolves in 1 milliliter of water. It is much less soluble in alcohol, 1 gram in 8 milliliters. It is insoluble in organic solvents like benzene and ether. It is used as an antiseptic for tissues in concentrations of the order of 1:1,000 to 1:30,000. It is commonly used as an antiseptic in biologics.

Mercurochrome, also known by the name of *Merbromin* and by many other trade names, is the disodium salt of 2,7-dibromo-4-hydroxymercurifluorescein, $C_{20}H_8Br_2HgNa_2O_6$. It forms green, iridescent scales or granules, which are freely soluble in water, yielding a bright red solution with dilute solutions having a yellow-green fluorescence. It is generally used in a 2% aqueous solution as a mild antiseptic. It is nearly insoluble in alcohol and is insoluble in organic solvents like acetone and ether. Most other common mercurials and iodine solution are considered to be better antiseptics. See also **Organometallic Compounds**.

Health and Safety Factors

One of the early examples of mercury poisoning may have involved the so-called "dark year" (1693) in the life of Sir Isaac Newton, when it was reported that Newton broke away from friends and associates, accusing them of plotting against him, when he slept very little, and when he reported conversations that actually did not occur. Initial explanations of Newton's erratic behavior included his failure to obtain certain appointive government positions, overwork, and the traumatic fire that destroyed a number of his valuable manuscripts. This evidence was not convincing, however, to investigators P.E. Spargo and C.A. Pounds. Through contacts with Newton's descendants, this team obtained four hairs taken from the head of the master and subjected them to laboratory tests. In the very interesting account by Broad (1981), the investigators concluded that Newton's madness was "due principally to poisoning by the metals which he used so frequently and with such cavalier disregard for his own safety." Locks of hair were located at Trinity College, Cambridge. One hair was found to contain 197 ppm Hg (even quite high in terms of modern-day Hg poison cases). Broad concludes his article, "Perhaps poisoning by mercury was not only the cause of Newton's brief lunacy, but was also the pivotal event that nudged the superstitious genius away from his researches in the laboratory to the seemingly less dangerous ways of the world." There are several doubters of the Spargo-Pounds hypothesis and the controversy is likely to persist.

Exposure. The exposure of humans and animals to mercury from the general environment occurs mainly by inhalation and ingestion of terrestrial and aquatic food chain items. Fish generally rank the highest (10–300 ng/g) in food chain concentrations of mercury.

In occupational settings mercury exposure results predominantly from direct dermal contact or inhalation of mercury vapors. Chloralkali plants are one of the principal sources for occupational exposure to mercury. Mining and refining of mercury contribute to exposure, and the processing of cinnabar can result in high exposures to the skin and lungs, producing poisoning in a relatively short time.

Toxicity. The toxic effects of mercury and mercury compounds are well known, and several detailed discussions on mercury toxicity are available. Toxicity to the central nervous system is more prominent after exposure to mercury vapor than to divalent mercury.

Short-term exposure to mercury vapor may produce symptoms within several hours. These symptoms include weakness, chills, metallic taste, nausea, vomiting, diarrhea, labored breathing, cough, and a feeling of tightness in the chest. Pulmonary toxicity may progress to an interstitial inflammation of the lung with severe compromise of respiratory function. Recovery, although usually complete, may be complicated by residual interstitial growth of excess fibrous tissue.

Chronic exposure to mercury vapor produces an insidious form of toxicity that is manifested by neurological effects and is referred to as the asthenic vegetative syndrome.

The biochemical basis for the toxicity of mercury and mercury compounds results from its ability to form covalent bonds with sulfur. Even in low concentrations divalent mercury is capable of inactivating enzymes containing sulfhydryl (–SH) groups, causing interference with cellular metabolism and function.

The affinity of mercury for sulfhydryl groups provides the basis for treatment of mercury poisoning using chelating agents (qv) such as dimercaprol (for high level exposures or symptomatic patients), or penicillamine (for low level exposure or asymptomatic patients).

MERESBURG REACTION. See **Fertilizer**.

MERRIFIELD, R. BRUCE (1921–). An American chemist who won the Nobel prize for chemistry in 1984. Merrifield was cited for work on the use of solid matrix as an aid to chemical synthesis of complex peptides and proteins. His synthesis techniques have been used in the development of solid matrix-bound inorganic and organic agents. Awarded doctorate from U.C.L.A.

MESITYL OXIDE (MSO). See **Ketones**.

MESODESMIC STRUCTURE. A type of ionic crystal in which one of the cation-anion bonds is equal in strength to all the bonds from the cation to the other anions. The silicates are important members of this class.

MESONS. The *mesons* are subatomic particles of the hadron family. See also **Hadrons**. Fermionic hadrons are called *baryons*; the others are called *mesons*. The meson family consists of eight members which fall into a triplet of *pions*, a singlet *eta*, a doublet of *kaons*, and a doublet of *antikaons*. (They are all pseudoscalar (spin zero and odd parity) and exhibit strong interactions.) The charged particles are coupled to the photon, but even the neutral members can participate in electromagnetic interaction by virtue of the large probability for virtual dissociation into charged particles. They participate in a variety of weak interactions including the nuclear beta decay interaction.

It is found that the kaons, the hyperons (baryons other than the neutron and proton) and their antiparticles, collectively known as *strange particles*, can decay by weak interactions not involving leptons or photons, with a lifetime which is large compared to the natural periods appropriate to strong interactions. On the other hand, these particles are produced copiously in high-energy nuclear collisions. These two circumstances can be understood in terms of the existence of another additive quantum number (*hypercharge*) which is conserved in strong and electromagnetic interactions, but violated in weak interactions.

The meson-baryon system exhibits further regularities as far as strong interactions are concerned. The neutron and the proton have very nearly the same mass and similar nuclear interactions although their electromagnetic properties are quite different. The three *pions* have different electric charges, but again they have approximately equal masses and similar nuclear interactions. This kind of multiplet structure is evident for other strongly interacting particles; the *kaons* form a doublet, the *sigma hyperons* form a triplet, the *xi hyperons* form a doublet, and the *lambda hyperon* remains a singlet. See also **Particles (Subatomic)**.

The pion (*pi meson*) was first recognized in 1947 in photographic films made by C.F. Powell, P.S. Occhialini, and their collaborators of cloud chamber tracks made by cosmic rays high in the Andes. The masses of these pions were greater than those of the previously discovered muons, corresponding more closely to those predicted by K. Yukawa in his theory of the nuclear structure of the atom. The positive or negative pion has a mass 273 times that of the electron, and a charge equal in magnitude to that of the electron. Both positively charged and negatively charged pions are found in cosmic rays. Neutral pions may also be present in cosmic rays, but are produced in much greater abundance by high-energy particle accelerators and are therefore more easily detected in these laboratories. The first artificially produced pions were made in 1948 by the impact of 380 MeV alpha particles, from the Berkeley synchrocyclotron, on a target of carbon or certain metals. These were charged pions. Others were produced later by beams of protons and deuterons. The first evidence of neutral pions were the gamma-rays produced in 1950 by the impact of 175 MeV protons upon similar targets (carbon, beryllium, etc.). These gamma-rays had a minimum energy of about 140 MeV, which would be expected from the decay of a (neutral) pion into two gamma-rays. The same method is used today to produce beams of charged pions. The life of the neutral pion is so much shorter (about 10^{-16} seconds against 2.6×10^{-8} seconds) that beams cannot be produced. Unless it is captured by an atom, or reacts with another particle, a charged pion decays into a muon of the same sign and a neutrino or antineutrino. Like the other mesons the pion is a boson. It has zero spin.

Evidence of the *kaon* was found in 1944 by L. Laprince-Ringuet and M. LhÉritier in a cloud chamber photograph of a cosmic ray event. It was found again in 1947 by Rochester and Butler as a V-shaped track in a cloud chamber, the particle forming the other side of the V being probably a pion. For that reason it was first called a charged V-particle, which has been superseded by kaon See also **Quarks**.

METABOLISM. The chemical transformations occurring in an organism, from the time a nutrient substance enters it until it has been utilized and the waste products eliminated. In animals and humans, digestion and absorption are primary steps, followed by complicated series of degradations, syntheses, hydrolyses, and oxidations, in which agents such as enzymes, bile acids, and hydrochloric acid take part. These transformations are often localized with respect to organs, tissues, and types of cells involved.

Basal metabolism is the rate of total heat production of an individual who is awake but in complete mental and physical repose, at comfortable temperature and without having had food for at least 12 hours. See also **Basal Metabolism**. Under these conditions, oxidation of stored nutrients provides the sole source of energy expended and heat is measurable by calorimetry. See also **Digestion**.

META COMPOUNDS. See **Organic Chemistry**.

METAL ANODES. In electrolytic processes, the anode is the positive terminal through which electrons pass from the electrolyte. Most materials used in metal anode fabrication are characteristically expensive; use has, however, been justified by enhanced performance and reduced operating cost. An additional consideration that has had increasing influence on selection of the appropriate anode is concern for the environment.

Industrial metal anodes can generally be classified in one of two groups. The first group, chlorine-generating anodes, find application primarily in the manufacture of chlorine and caustic, sodium chlorate, and sodium hypochlorite. The second group, consisting of the oxygen-evolving anodes, do not generate a saleable product directly, but rather facilitate the desired cathodic reaction Commercial uses include high speed electrogalvanizing of steel (qv), electrowinning of base metals, plating operations, cathodic protection, electrophoretic painting, copper foil treatment, and, more recently, the primary production of copper foil itself. See also **Electrochemistry**; and **Electroplating**.

Coating Structure and Morphology

The crystal structure of metal anode coatings has been investigated using x-ray diffraction studies, x-ray fluorescence analysis, and microprobe studies in conjunction with scanning electron micrographs. However, the role of the titanium metal substrate, or that of the oxides formed when the substrate is anodized or heated in air, is not completely clear for coatings that contain titanium in their solution. Most coatings, even those not containing titanium in the formulation, exhibit traces of titanium dioxide, present either in rutile or anatase form.

Ruthenium–Titanium Oxides. The x-ray diffraction studies of ruthenium–titanium oxide coatings show that the coating components are present as the metal dioxides, each in the rutile form as well as in solid solution with each other.

It appears that the titanium metal substrate on which the coating is deposited plays an important role in the structure and morphology of the coating. The surface layer of rutile titanium dioxide normally found on oxidized titanium metal apparently acts as a seed to initiate growth of the rutile form of the oxide, rather than the anatase form. Interfacial layers of titanium suboxides, known to be electrically conductive, also act to effect a gradual transition from pure metal to pure rutile oxides. Scanning electron micrographs of ruthenium–titanium oxide coatings show a characteristic microcracked surface.

Iridium Oxide. Iridium dioxide coatings, typically used in combination with valve metal oxides, are quite similar in structure to those of ruthenium dioxide coatings.

Platinum–Iridium. There are two distinct forms of 70/30-wt % platinum–iridium coatings. The first, prepared as prescribed in British patents, consists of platinum and iridium metal. The surface morphology of a platinum–iridium metal coating is cracked, but not in the regular networked pattern typical of the DSA oxide materials. The second form consists of Pt metal but the iridium is present as iridium dioxide. Iridium metal may or may not be present, depending on the baking temperature.

Spinel Cobalt Oxides. The cobalt mixed oxide, Co_3O_4, containing Co(II) and Co(III) ions, has the spinel structure. In these coatings containing zirconium, a separate, partially crystalline phase of zirconium dioxide occurs. The coating has large microscopic pores, providing a high surface area which appears to be related to the presence of zirconium. Spinel oxides applied without the presence of zirconium are dense and closely packed coatings.

Operating Performance of Coatings

The key yardstick of performance for a coated metal anode is the period of time, measured in ampere-hours, that the coating operates before it reaches an unacceptable voltage, as measured by the single electrode potential (SEP). Factors influencing the escalation include accumulated average lifetime, operating current density, electrolyte conditions, exposure to oxygen in the anolyte compartment, and cell design.

Chlorine Anodes. In chlorine manufacture, anode operating life is limited by coating wear. The wear rate varies according to cell type. The longest anode coating life has been achieved in diaphragm chlorine cells.

Because mercury chlorine cells operate at higher current densities and because the mercury cell anode can be adjusted during operation to minimize the anode-to-cathode gap, anode coating life in these cells is much shorter. Because of limited commercial experience with anode coatings in membrane cells, commercial lifetimes have yet to be defined. Expected lifetime is 7–12 years.

Metal anode coatings commercially used for manufacture of sodium chlorate include not only the ruthenium oxide coatings, but also platinum–iridium coatings. Whereas ruthenium oxide coatings might be preferred for a longer performance life and higher resistance to process upsets, platinum–iridium coatings generally operate at higher efficiencies during the first months of operation.

Oxygen-Evolving Anodes. In the case of oxygen-evolving anodes employing iridium dioxide-based coatings, the most significant commercial experience has been in the electrogalvanizing industry where coated titanium anodes have supplanted lead and zinc anodes, and thus lead contamination of the product and waste streams.

In contrast to the coating wear limitation on anode life experienced in chlorine cells, passivation of the substrate beneath the coating is typically the limiting factor for oxygen-evolving anodes. As a result, technology has been introduced to either maintain or modify the titanium surface to increase coating adhesion and significantly improve lifetimes.

Structure Design

Each electrolytic application demands a unique approach to anode structure design and fabrication. Factors such as current distribution, gas release, ability to maintain structural tolerances, electrical resistance, and the practicality of recoating must be taken into account. The most commercially accepted design for diaphragm chlorine cells is that of the expandable anode (Fig. 1).

In mercury chlorine cells, it has been found that cells operate at lower voltages when fitted with anode structures comprised of triangular rods or of vertical blades.

The dimensionally stable characteristic of the metal anode made the development of the membrane chlorine cell possible. These cells are typically arranged in an electrolyzer assembly which does not allow for anode-to-cathode gap adjustment after assembly. Also, very close tolerances are required. The latitude that titanium affords the cell designer has made a wide variety of monopolar and bipolar membrane cell designs possible.

When used in radial cells such as for the production of copper foil and in some electrogalvanizing operations, the anode must be curved to meet the shape dictated by the cathodic drum. The anode must also achieve exact tolerances to assure that a constant anode-to-cathode gap is created and maintained.

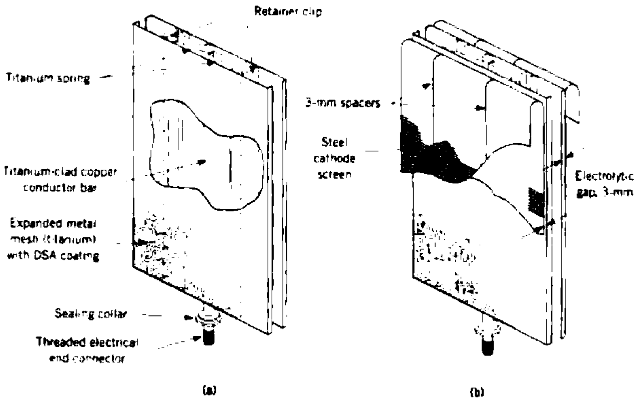

Fig. 1. Expandable anode for diaphragm chlorine cells: (**a**) clamped and (**b**) expanded

Manufacturing Technology

Manufacturing techniques for metal-coated anodes have been developed to a high level of sophistication. By the mid-1990s commercial plants were producing or recoating in excess of 50,000 anodes annually. This scale of operation requires continuous coating processes (qv) the use of electrostatic spray application, robotics, and strict process control (qv). The high cost of the coating itself demands high utilization efficiency. Quality requirements include consistent coating distribution, strong adherence, and a good surface appearance.

Environmental and Safety Factors. The primary environmental concern for the coating plant is actually the residual material on the anode structures being returned for recoating. Therefore the anode user must enact effective cleaning procedures prior to shipment. Overall, the DSA (Electrode Corp.) has made chlorine manufacture cleaner, more consistent, simpler, and therefore safer.

Economic Aspects. For the most part, coated metal anodes are made available by long-term lease rather than through outright sale. There has been a single-source supply protected by patents in most geographic areas. As the cost-saving and environmental value of this technology continues to increase, upward expectation in respect to prices is created. However, the appearance of new anode producers, together with expiration of some early patents, has created a competitive situation in some applications. This competition can be expected in turn to create a counter-balancing pressure to lower prices.

METALLIC COATINGS. Metallic coatings provide an inexpensive way to modify or control the properties of a base material. Coatings may be functional or decorative, permanent or temporary, sacrificial, or noble. The metallic coating may be continuous, or it may be patterned into discontinuous functional or decorative areas. The base material may be metallic, nonmetallic inorganic, or organic such as plastic, paper, or fiber. The common criterion for the purposes herein is that the metallic coating is functionally bonded to the base material. Galvanized zinc items, gold clad jewelry, electroplated materials, and semiconductor chips are among the most common types of materials having metallic coatings. See also **Electroplating**; and **Semiconductors**.

Metallic coatings are most often selected for protective function. Decorative ability is a common secondary function. Most coatings applied by hot dipping, such as galvanizing or aluminizing, use a film of a more chemically reactive metal over a less reactive material such as iron alloy. These are sacrificial coatings because the zinc or aluminum slowly dissolves instead of the underlying steel.

Decorative coatings must be sufficiently corrosion resistant to maintain an attractive appearance during the anticipated life of the composite product. Composites of multiple metal layers or mixtures of metallic and nonmetallic coatings are becoming increasingly common as material properties are selectively tailored. Another important function of metallic coatings is to provide wear resistance. The most technically demanding types of coatings are those grown in precisely defined multiple layers.

Plating and galvanizing are the most common methods of applying metallic coatings, but many other processes, such as hot dipping, cementation, thermal spraying, sputtering, and chemical vapor disposition, have been developed. All metallizing techniques are potential sources of pollution, a subject of increasing ecological, economic, legislative, and public health interest.

There are a plethora of commercially useful methods for applying a metallic coating. Many more techniques have been demonstrated in the laboratory. Each method has different critical parameters, i.e., maximum and minimum coating thickness producible, substrate temperature, bulk or imagewise deposition, coating adhesion value, type and cost of coating equipment, labor requirement, scrap rate, rework capability, and safety and waste disposal aspects. For convenience, metallic coating methods may be divided into classes defined by the general way in which the metal is applied, e.g., liquid-phase, gas-phase, and vacuum-phase metallizing or by direct physical or thermal bonding.

The two largest-volume processes, in terms of amount of metal used and amount of surface area coated, are the liquid-phase metallizing processes hot dip coating and electroplating.

Many of the newer coating methods give metallized coatings that are quite distinct from simple single or multiple coatings of metals or alloys. Many of these newer coatings, which cannot be made except by one or a small family of processes, are defined as much by process method as physical and chemical structure. Examples of these coatings include ion-plated surfaces, laser heat-treated surfaces, modifications of existing surfaces to predetermined depths by selective additions of atoms or heat; and Teflon–electroless nickel composite coatings.

Liquid-Phase Metallizing Techniques

Hot Dip Galvanizing. The largest single type of metallic coating process in terms of amount of metal used is hot dip galvanizing. Half of all galvanized zinc is used on steel coils, one-third is employed for coating of parts after fabrication, and the remainder for wires and tubes. The other uses, in approximate order, are electroplating, zinc-filled paints, zinc spray processes, zinc foils having conductive adhesive, and mechanical zinc plating.

In hot galvanizing, zinc is applied to iron and steel parts by immersing the parts into a bath of molten zinc. Whereas in principle almost any metal could be coated with molten zinc, this coating serves no worthwhile purpose on most metals. The combination of zinc and ferrous materials are almost uniquely suited to each other. Aluminum and cadmium are the only other similar combinations. Zinc provides iron parts with better corrosion protection by developing a coating of zinc and zinc compounds on the base metal surface.

Hot Dipping Using Other Metals. Processes include coating with aluminum, coating with 55% aluminum–zinc alloy, hot dip tin coating of steel and cast iron, hot dip terne coating, and solder coatings.

Electroplating. Many developments in electroplating have been the direct result of increased coating functionality and economy, and others of the increasing need for environmental and legislative compliance. The field of electroplating has expanded rapidly.

The most common electroplated metal is zinc, followed by nickel, copper, and chromium. Many other metals and metaloids can be electroplated, including manganese, iron, cobalt, gallium, germanium, arsenic, selenium, ruthenium, rhodium, palladium, silver, cadmium, indium, tin, lead, bismuth, mercury, antimony, gold, iridium, and platinum. Types of electroplating include fused salt plating, plating from nonaqueous solvents, and brush plating.

Chromium metal seems to be biologically harmless owing to inertness. Trivalent chromium Cr(III), one of the essential mineral nutrients, has not been shown to be harmful. Hexavalent chromium, Cr(VI), found in chromic acid and used in electroplating baths, is very toxic as well as a suspected carcinogen. Two basic types of chromium are plated: hard chromium up to 7100 μm or more, and decorative chromium at 0.25–1.0 μm. No replacement coating has been found for thick hard chromium deposits for wear resistance and parts salvage, although electroless nickel can partially substitute for chromium plating baths. Many decorative applications are being converted to Cr(III). Products from the newest Cr(III) baths are essentially equivalent to those from the older decorative Cr(VI) baths, although some cosmetic color differences exist which have prevented complete conversion to the Cr(III) baths.

Cyanide solutions formerly were ubiquitous in electroplating shops. The best cleaners contained sodium cyanide. The removal of cyanides from all plating baths has been a general goal since the latter part of the 1980s. As of this writing, cyanide-containing cleaners are rare and are only used for special purposes. Several noncyanide copper strike baths have been introduced.

The greatest tonnage decrease in cyanide plating has occurred for zinc plating. As of this writing, less than one-third of all zinc is plated from cyanide baths. The remainder is plated from alkaline noncyanide, zinc potassium chloride, and zinc ammonium chloride baths.

Chlorinated and fluorinated cleaners have been widely used as degreasers during surface preparation prior to plating. Recognition of the role of many of these solvents as either global warming gases or ozone depletion agents has led to prohibitions against their continued use. See also **Pollution (Air)**. Many new and improved cleaning systems are being developed, such as alcohol-based cleaners, emulsion cleaners, and cleaners based on natural bioproducts such as limonene. During this process a massive reformulation of many aqueous cleaners has also occurred.

Cadmium usage, illegal in most of Europe, is being discouraged elsewhere. The U.S. military has cadmium specifications for electronic, fastener, and marine equipment, which requires only cadmium. Tin is being substituted for tin–lead as a metallic etch resist during printed circuit board production.

Electroless Plating. The metallizing process known as electroless plating is mainly used for deposition of copper on plastics and for nickel–phosphorus alloy on plastics and metals. Formaldehyde is the most common copper reducing agent, giving pure coatings. Sodium hypophosphite is the agent mainly used for electroless nickel. An unusual nickel–phosphorus alloy or solid solution is formed. Unlike electroplating, electroless plating can be used on almost any substrate, metallic or nonmetallic. Often electroless plating is used as the first coating to make glass ceramic, or plastic conductive, followed by conventional electrolytic plating.

Immersion Plating. A simplified aqueous metal deposition process which does not use electric current, immersion plating works only when a metal of higher electromotive force, such as copper, is deposited on a metal of lower electromotive force, such as iron or aluminum. The coatings are typically very thin and porous. One important application is immersion plating of copper sulfate bath onto steel wire, to use as a drawing agent. Very thin immersion gold deposits are used for inexpensive jewelry.

Miscellaneous Techniques. Lasers have been used for both electroless and electrolytic plating; selective dissolution has been used from ancient times to give the appearance of a thin plated coating of precious metal; and mercury layers plated onto the surface of analytical electrodes serve as liquid metal coatings.

Gas-Phase Metallizing Techniques

Metal or Thermal Spray Coatings. These specific processes include plasma arc spray, flame spray, laser spray, and electric arc spray, depending on the energy input source. Rods, wires, and powders are used as coating material sources. Thermal spray metal and ceramic coatings have diverse properties suitable for numerous applications, including corrosion resistance, e.g., zinc and aluminum, especially against oxidation or salt water corrosion; high temperature oxidation, e.g., nickel, cobalt, and chromium alloys; electrical conductivity, e.g., radio frequency interface (RFI) shielding by zinc or tin on nonconductors; electrical resistance, e.g., insulating layers in induction heating coils and high temperature strain gauges; wear resistance, e.g., chromium–nickel–boron alloys and

carbide-containing coatings; catalytic surfaces; nuclear moderators; and dimensional buildup for salvaging worn metal parts.

A great advantage of zinc arc spray is that it can be applied to almost any plastic. Zinc arc spray, also suitable for prototypes and small lots of materials, is less suited for very small parts and parts having blind holes or complex interior surfaces, or where warpage is a problem.

Zinc arc spraying or flame spray equipment is hardly more hazardous than a welding torch, and only safety goggles and gloves are required. Safety aspects emphasize reduction of noise and vapor inhalation.

Thermal spray processes can be used to give coatings of chromium carbide or nickel chromium for erosion resistance, copper nickel indium for fretting resistance, tungsten carbide cobalt for wear and abrasion resistance, and even aluminum silicon polyester mixtures for abradability.

Carburizing and Nitriding. Several commonly used metallurgical surface treatments are applied by gas-phase reactions in a reducing atmosphere for carburizing, and in a nitrogen atmosphere for nitriding. These treatments are used to increase the surface hardness of ferrous alloys by diffusion of carbon and nitrogen at high temperature.

Pack Diffusion. Pack diffusion or cementation processes are similar to pack carburizing, and are used to coat iron, nickel, cobalt, and copper with chromium, boron, zinc (Sheradizing), aluminum, silicon, titanium, molybdenum, and other metals.

Chromizing and Related Diffusion Processes. Chromizing is similar to aluminizing. A thin corrosion and wear resistant coating is applied to low cost steels such as mild steel, or to a nickel-based alloy. In the related boronizing process, a thin boron alloy is produced for extreme hardness, wear, and corrosion resistance. Siliconizing is yet another process used especially for coating of the refractory metals Ti, Nb, Ta, Cr, Mo, and W.

Metals. Aircraft and space vehicles, turbine generators, and other such applications require high strength at high temperatures along with excellent oxidation resistance. Superalloys, i.e., complex nickel and cobalt-based alloys, and refractory metals, e.g., niobium, tungsten, molybdenum, tantalum, and their alloys, are used for applications at temperatures above 1000°C. In many case the coatings must be resistant both to oxidation and to hot corrosion by sulfidation from sulfur-bearing gases.

Two types of coatings have been used for superalloys: diffusion coatings, in which a layer of nickel, cobalt, platinum, or palladium aluminide, i.e., NiAl, CoAl, PtAl, or PdAl, is formed on the surface by diffusion; and overlay coatings, in which a complex coating material such as nickel–cobalt–chromium–aluminum–yttrium, NiCoCrAlY, is applied to the surface. Pack cementation is the most widely used process for applying diffusion coatings to superalloys.

Vacuum-Phase Metallizing Techniques

Vacuum-phase metallizing techniques all depend on the use of a vacuum as part of the metallizing process. The tonnage of metal deposited by these techniques is insignificant compared to hot dip galvanizing or plating, and the total surface area metallized is much less than that done by plating. However, the economic added value of vacuum metallizing probably exceeds that of either plating or galvanizing because of the extremely rapid growth and deep market penetration of semiconductor devices. Projections call for at least a 10% compounded annual growth rate into the twenty-first century. The state of the art in vacuum metallizing is in semiconductors processing.

Thermal Evaporation. Thermal evaporation is done in a high vacuum to minimize chemical side reactions of the evaporated active metal. Thermal evaporation is inexpensive and efficient. It is used for low cost items such as aluminized plastic sheet and decorative Christmas tinsel, second surface coating of transparent plastic auto parts, and metallization of glass and ceramics. Aluminum is the predominant metal used. Color effects such as gold or brass are achieved by applying a dyed translucent organic protective over the aluminum.

Sputtering or Glow Discharge. Sputtering can be done using both conductive and nonconductive items. A low pressure atmosphere of argon is used in the deposition vessel. This method gives excellent coating adhesion and more consistent coatings than simple vacuum deposition. It can also be applied to a wider range of materials, including complex metal alloys and oxides. The equipment and operating costs are higher than vacuum deposition, and deposition rates are lower. Reactive sputtering is a variation in which two or more deposition sources are used. This process can be used to give compounds such as silicon carbide on the surface.

Chemical Vapor Deposition. This process is distinct from simple thermal evaporation because chemical vapor deposition (CVD) depends on a chemical reaction at the surface of the part and in that way is analogous to electroless plating. This process uses a gas of one or more chemical species, which react at a heated substrate to form an appropriate film. The film can be metallic, nonmetallic, single element, or compound. Among the coatings available are copper and aluminum conductors, diamond and tantalum oxide dielectrics, lead zirconium titanate piezoelectrics, and bismuth strontium calcium cuprate superconductors. Some of the largest applications are for coating TiC and TiN on cutting tools.

Ion Implantation. Also known as ion plating, ion implantation is a high vacuum process for modifying the surface properties of any material. This is a surface modification technique rather than a surface coating technique. Semiconductors are commonly modified using this technique, because ion implantation can be done using total or imagewise scanning of the beam over the surface. Nitrogen, chromium, and phosphorus can be used to harden metals and increase the corrosion resistance. Metastable alloys can be produced that are difficult to make by other processes.

Laser Hardening and Modification. Lasers are used to surface harden ductile steels and improve the toughness to a depth of 0.35 mm or more. Lasers can also be used to bond solid or powder coatings to a surface. Typical coatings are nickel or titanium carbide on iron, and nickel, cobalt, manganese, and titanium carbide, TiC, on aluminum. Use of lasers with other specialized coating methods is common.

Metallizing by Direct Physical or Thermal Bonding

Direct bonding techniques are among the oldest types of metallizing, and the most versatile. Many methods depend on heat or pressure and an adhesive layer to glue the coating to the substrate. Methods for metallizing on a metallic surface often depend on removal or displacement of a preexisting surface oxide layer. Many metals form intermetallic alloys or self-diffuse into one another even at room temperature, but the surfaces in contact must be clean and oxide-free. Processes include lamination, mechanical plating, slurry coatings, and roll bonding or strip roll welding.

Environmental Concerns

Each type of metallic coating process has some sort of hazard, whether it is thermal energy, the reactivity of molten salt or metal baths, particulates in the air from spray processes, poisonous gases from pack cementation and diffusion, or electrical hazards associated with arc spray or ion implantation. Vacuum or inert gas operations can produce flammable dusts or powders when opened for cleaning. Most of the hazards are confined to the operator and immediate environs in the operating plant. OSHA is the primary regulator of these hazards in the United States, although many local and state agencies, especially fire departments, also regulate coatings plants. Adequate training, documentation, and protective equipment are the minimum requirements. The principal regulatory burden falls on wastes and discharges which leave the plant.

The U.S. EPA regards metallizers such as platers, surface finishers, and printed circuit board producers as among the most important source polluters for metals. Much production of electroplated items has, however, shifted from the United States to less environmentally stringent countries.

The surviving U.S. plants have embraced all types of waste treatment processes. (See also **Wastes and Pollution**). The most desired pollution prevention processes are those which reduce the total amount of waste discharged. Treatment and disposal are less strongly emphasized options. Zero wastewater discharge facilities and water recycling processes are becoming more common.

Discharge limits vary between localities and among plants. Table 1 shows federal EPA maximum discharge limits for a number of metals for a new metal-finishing installation.

Newer federal limits on metals contents of sewage sludge combined with laws on fuller treatment of the sewage sludge and its allowed disposal methods have affected limits. The metallic content of sludges from municipal waste treatment facilities is becoming of great concern.

Air pollution is recognized as a significant problem for coating facilities.

Many types of waste treatment and waste minimization processes are in common use in the metallization industry. Air scrubbers are commonly required, even for general acid fume removal from plating shops. Additionally, many newer technologies have been adapted for use in metallizing operations. These include air stripping, antimisting agents, biological destruction, carbon absorption, countercurrent rinsing, crystallization,

METALLOBIOMOLECULES. Natural products, the biologically active forms of which contain one or more metallic elements. Metallobiomolecules may be transport and storage proteins, such as cytochromes (Fe), ferritin (Fe), transferrin (Fe), ceruloplasmin (Cu), myoglobin (Fe), or hemoglobin (Fe); or they may be enzymes, such as carboxypeptidases (Zn), aminopeptidases (Mg, Mn), phosphatases (Mg, Zn, Cu), hydroxylases (Fe, Cu, Mo), or isomerases and synthetases, such as coenzymes (Co). Metallobiomolecules also may be nonproteins, such as siderophores (Fe) or chlorophyll (Mg). Ibers and Holm provide an excellent review of metallobiomolecules in *Science*, **209**, 223–235 (1980).

METALLOCENES. A class of neutral transition metal compounds containing two cyclopentadienyl (C_5H_5) ligands π-bonded to a central metal atom in a "sandwich" structure, as exemplified by ferrocene (see below).

The original metallocene, ferrocene, was first reported simultaneously and independently by two groups of workers in 1951. Miller, Tebboth, and Tremaine at British Oxygen Ltd. passed cyclopentadiene over iron powder and an ammonia catalyst; Kealy and Pauson at Duquesne University treated ferric chloride with cyclopentadienyl magnesium bromide. Both groups obtained the same orange, air-stable, hydrocarbon-soluble crystals (m.p. 173°) and proposed a sigma bonded structure for this first organometallic derivative of iron. Within a year groups at Harvard University including Woodward, Wilkinson, Rosenblum and Whiting revealed that $C_{10}H_{10}Fe$ exhibits unusual thermal stability, has no dipole moment, and undergoes typical aromatic substitution reactions; whereupon, they proposed the novel sandwich structure and advanced the name *ferrocene* to reflect both the iron content of the material and its aromaticity. X-ray crystallographic studies subsequently supported the sandwich structure, showing the preferred staggered, antiprismatic conformation in the solid state. In solution or the vapor phase the barrier to rotation of the rings has been shown to be very small.

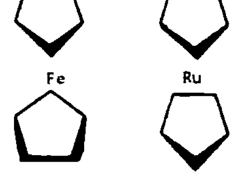
One proposed bonding scheme, using a molecular orbital model, calls for utilizing the π orbitals of the C_5H_5 group and the d_{xz}, d_{yz}, s, p_x, p_y, and p_z iron orbitals to obtain a total of six bonding orbitals with the twelve π-electrons from the rings to fill them.

After the discovery of ferrocene many additional metallocenes and their derivatives were prepared, including titanocene (green), vanadocene (purple), chromocene (scarlet), cobaltocene (purple-black) and nickelocene (green). Dicyclopentadienyl manganese (amber) is ionic, and dicyclopentadienyl mercury, tin and lead are sigma bonded; their derivatives are not properly called metallocenes. In the second and third transition series, only ruthenocene and osmocene are known as simple, neutral metallocenes; the other metallocenes are known as cations (e.g. Cp_2Ti^+) or with additional ligands such as halide or hydride attached to the metal atom, as in Cp_2TiCl_2, Cp_2ReH, Cp_2TaH_3, etc. Though several preparative approaches are known, the most general reaction leading to metallocenes is the treatment of a metal halide with sodium cyclopentadienide in tetrahydrofuran. Ideally a +2 salt of the metal is used, although excess of the cyclopentadienide will often reduce a higher valent metal halide to a lower oxidation state during the reaction.

Chemically, ferrocene undergoes many typical aromatic substitution reactions such as Friedel-Crafts acylation or alkylation, sulfonation, mercuriation, lithiation, the Villsmaier reaction and the Mannich reaction (with dimethylamine, formaldehyde and acetic acid). Its reactivity is very great ("superaromatic") and is comparable in rate to that of phenol. Mono- and disubstitution on one or both rings can be realized, though some measure of control to predominately mono- or disubstitution can be exercised by adjusting conditions.

However, the central metal atom in ferrocene imposes some limitations on the chemistry of the system or provides in some cases additional reaction pathways. For example, the central iron atom is readily and reversibly oxidized from the Fe(II) state to Fe(III) in the form of the water-soluble red-blue dichroic ferrocinium ion. This oxidation occurs with halogens or with nitric acid so that direct aromatic halogenation and nitration cannot be realized; however, halo- and nitroferrocene have been prepared by indirect methods. Aminoferrocene cannot be diazotized, presumably due to oxidative destruction of the system. Coupling with diazonium salts is anomalous; ferrocene reduces diazonium salts to phenyl radicals in aqueous or nonaqueous solution to yield Gomberg (phenylation) products. Condensation with aldehydes in acid solution gives rearranged products due to a role that the iron atom can play. The central iron atom is readily protonated in strong acid media.

In the solid state ruthenocene and osmocene prefer the eclipsed, pentagonal prismatic structure and in solution exhibit a chemistry similar to that of ferrocene. The other metallocenes, on the other hand, are quite different chemically, none of them showing the typical aromatic substitution reactions of ferrocene.



Ferrocene Ruthenocene

Cobaltocene is rapidly oxidized in air or in solution (it liberates H_2 from water, slowly) to yield the very stable yellow +1 cation, which has been reported to be stable to aqua regia. Neutral cobaltocene reacts with alkyl and acyl halides to give adducts $(C_5H_5)(C_5H_5R)Co^+X^-$ in which the substituted ring is π-bonded to the cobalt as a diene.

Nickelocene, on the other hand, is more slowly oxidized and undergoes addition of suitable activated olefins to one ring converting it to a bicyclic ligand. Some ligand replacement reactions are also known for nickelocene.

Titanocene derivatives undergo substitution reactions at the metal atom:

$$Cp_2TiCl_2 + C_6H_5Li \longrightarrow Cp_2Ti(C_6H_5)_2 + LiCl_2$$

$$Cp_2TiCl_2 + 2OCH_3^- \longrightarrow Cp_2Ti(OCH_3)_2 + 2Cl^-$$

The utility of these materials is limited and disappointing. Ferrocene has been used to promote the burning of fuel oils and as a catalyst in rocket

fuels. Its extreme thermal stability (to over 470°) spurred an interest in its derivatives as high-temperature fluids. Some polymers have been made, but they have found no substantial application. Titanocene dichloride has been shown to react with molecular nitrogen in systems containing added Grignard reagents or similar other materials.

It is generally agreed that the real importance of metallocenes lies in the effect of their discovery twenty years ago along with Ziegler's catalyst on the course and direction of organometallic chemistry. There has been a veritable explosion of interest and effort in this field during the past two decades that is unabated today. Many new materials and new insights into bonding of transition metals have evolved. Great strides in understanding of homogeneous catalysis and the design of new catalysts for hydrogenation, coupling, carbonylation, polymerization, etc., have been made. Even a closer understanding of the action of vitamin B_{12} has resulted from the new brand of organometallic chemistry, and we are moving closer to a practical method for fixation of nitrogen in solution.

METALLOGRAPHY. Study of the structure and properties of metals and alloys, principally by microscopic and x-ray diffraction methods. The term is also used in a broader sense to include the processing of metals by mechanical and heat treatments and the fabrication and testing of finished products. In this usage it is synonymous with physical metallurgy. See also **Metallurgy**.

METALLOID. A chemical element that may exhibit physical and chemical properties both of a metal and a nonmetal sometimes is referred to as a metalloid. Antimony, arsenic, and tellurium are examples. Less frequently, metalloid refers to elements, such as carbon, silicon, phosphorus, and sulfur, which are added in small amounts in the manufacture of iron and steel.

METALLOPROTEINS. Proteins, especially in solution, readily participate in a greater variety of chemical reactions than any other class of compounds of biological interest. This reactivity is a function primarily of the many polar side chains containing $-OH$, $-COOH$, $-NH_2$, $-SH$, and other groups, all of which can, to varying extents, interact with metal ions. Proteins can bind metals, some of them very tightly. However, relatively specific and nonspecific binding should be differentiated.

A negatively charged protein molecule exerting a nonspecific electrostatic attraction on metal ions would not qualify as metalloprotein. The term metalloprotein is restricted to compounds in which under natural conditions a metal ion is relatively specifically and strongly bound to a protein molecule in such a way that the compound can be isolated and shown to contain a stoichiometric amount of metal.

A variety of metal ions are found in biologically important metalloproteins. Metalloproteins occur in a wide range of biological systems. The function of the metalloproteins, as indicated in Table 1, varies widely from one compound to another.

The chemical properties of the metal in these compounds may be greatly affected by bonding to a protein ligand. The bound metal can play one of many roles. Thus, in an enzyme, the metal ion may permit the formation of a ternary complex between protein, metal and substrate or coenzyme. An instance of this role is provided by the enzyme enolase, which is unable to catalyze the equilibrium between 2-phosphoglycerate and 2-phosphopyruvate in the absence of Mg ions. In other enzymes, the metal may actually participate in electron transport by cyclic oxidation and reduction. Such is probably the case with the Cu in polyphenol oxidase. The metal may serve primarily for the maintenance of a specific spatial folding of the polypeptide chains in the protein molecule.

The strength of metal-protein bonds in metalloproteins may vary from relatively loose association to very tight binding. When the metal ion is able to dissociate with some ease from the protein, it is usually a single ligand responsible for the metal binding. Such ligand groups are mainly

TABLE 1. REPRESENTATIVE METALLOPROTEINS AND THEIR FUNCTIONS

Name	Metal	Source	Function
Hemocuprein	Cu	Erythrocytes	Unknown
Ceruloplasmin	Cu	Serum	Oxidase (probable)
Hepatocuprein	Cu	Liver	Unknown
Polyphenol oxidase	Cu	Mushroom	Enzyme
Hemocyanin	Cu	Mollusks	Respiratory pigment
Tyrosinase	Cu	Mushroom	Enzyme
Metallothionein	Cd + Zn	Kidney	Na Reabsorption (probable)
Xanthine oxidase	Mo	Liver	Enzyme
Carbonic anhydrase	Zn	Erythrocytes	Enzyme
Alcohol dehydrogenase	Zn	Yeast	Enzyme
Ferritin	Fe	Spleen	Fe storage
Transferrin	Fe	Plasma	Fe transport
Conalbumin	Fe	Eggs	Fe storage
Ferredoxin	Fe	Bacteria	Electron transport
DPNH-cytochrome *c* reductase	Fe	Heart muscle	Electron transport
Hemovanadin	V	Tunicates	Respiratory pigment

found in the amino acid side chains of the protein molecule (e.g., $-NH_2$ or $-OH$ groups). The interaction of metal and ligand may exhibit strong pH dependence because of competition between metal and hydrogen ions. Of the single ligand groups, by far the strongest is the $-SH$ group in the amino acid cysteine. Even stronger metal bonding to protein may be observed when a divalent or trivalent metal forms chelate complexes with the protein. Chelation is often indicated not only because of the strength of the bond, but also because of the specificity of the reacting site on the protein molecule for one particular metal. Such a specificity may reflect the coordination requirements of the various metals. The preferred electron donor in the formation of protein-metal coordination compounds is N, such as that of the imidazole nucleus of histidine, but S and O may also participate in this process. If the protein contains carboxyl or phosphoryl groups, strong ionic bonds between metal and protein may be formed. A completely different type of protein-metal interaction is illustrated by the Fe-containing protein ferritin. Basically, this compound consists of a coat of protein (apoferritin) surrounding a micelle of hydrated iron hydroxide. The metal can be readily and reversibly removed from the apoprotein.

See also **Chelates and Chelation**.

METALLOTHIONEINS. These are low-molecular weight, cysteine-rich proteins that bind metal ions. As reported by Furey, et al. (*Science*, **231**, 704, 1986), metallothioneins and their genes have several potential kinds of physiological activity, including: (1) the genes are induced by metal ions and glucocorticoid hormones; (2) transcription is modulated during embryonic development; (3) the genes may be involved in control of cell differentiation and proliferation; (4) the proteins may function to activate Zn requiring apo-enzymes and regulate cellular metabolism; and (5) the proteins may act as free-radical scavengers. It appears that metallothioneins are synthesized in response to ultraviolet radiation. Cadmium, in addition to zinc, is found in metallothioneins.

METALLURGY. The science and technology of metals and alloys. Process metallurgy is concerned with the extraction of metals from their ores and with the refining of metals; physical metallurgy, with the physical and mechanical properties of metals as affected by composition, processing, and environmental conditions; and mechanical metallurgy, with the response of metals to applied forces. (*From Glossary of Metallurgical Terms and Engineering Tables, American Society for Metals, with permission.*)

Early sources define metallurgy as the process of extracting metal from ores. For many metals, the primary source materials as of the 1990s are still crude metalliferous ores. For some metals however, recycled materials contribute significantly to total metal production. For example, in the United States the recycling (qv) rate of all-aluminum used beverage cans is over 50%. For an energy-intensive metal such as aluminum, this represents a substantial energy saving. Recycled aluminum requires only 5% of the energy needed to make aluminum from bauxite ore.

Metallurgy includes not only the treatment of crude ore and scrap, but also the processing of intermediates, i.e., concentrates, and wastes such as slags, tailings, etc. for contained metal values.

Definitions

The field of metallurgy has a unique and frequently very specialize vocabulary. Understanding this language helps to clarify certain concepts and processing steps. Definitions of key terms follow.

To ***concentrate*** is to take an action to intensify in strength or purity by the removal of valueless or unneeded constituents.

Electrometallurgy covers the various electrical processes for the working metals.

Flotation is the method of mineral separation in which a froth created in water by a variety of reagents floats some finely crushed minerals.

Gangue consists of the undesired minerals associated with ore, mostly nonmetallic.

Hydrometallurgy refers to the treatment of ores, concentrates, and other metal-bearing materials by wet processes.

Leaching is the extracting of a soluble metallic compound from an ore by selectively dissolving it in a suitable solvent.

A ***mineral*** is an inorganic substance occurring in nature and having a definite chemical composition or a characteristic range of chemical composition, and distinctive physical properties or molecular structure.

Mineral dressing is the physical or chemical concentration of raw ore into a product form which a metal can be recovered at a profit.

Ore is a mineral or aggregate of minerals from which a valuable constituent, especially a metal, can be profitably extracted.

Pyrometallurgy is metallurgy involved in winning and refining metals where heat is used, as in roasting and smelting.

Roasting is the heating of solids, frequently to promote a reaction with a gaseous constituent in the furnace atmosphere.

Smelting is any metallurgical operation in which metal is separated by fusion from those impurities with which it may be chemically combined or physically mixed. Scores of entries in this encyclopedia deal directly or indirectly with various aspects of metallurgy. Check the alphabetical index. In addition to each of the individual metals (aluminum, cadmium, iron, vanadium, etc.) described in separate articles in this encyclopedia, also check the following key words and phrases: alloys; amalgam; annealing; brazing; brittle fracture; calorizing (and other metal treating processes); corrosion; creep; metallography; phase diagram; powder metallurgy; temper; welding; wire drawing; wrought iron; etc.

METALS (The). In terms of classification, several of the chemical elements are referred to as metals, principally because of the metallic qualities they exhibit. The new group designating system is used here. There are several subclassifications:

Group 11: In order of increasing atomic number, these are copper, gold, and silver. Sometimes, these metals also are referred to as noble metals, principally because they sometimes occur in nature in elemental form. Gold and silver also are frequently referred to as "coinage" metals. The elements of this group are characterized by the presence of one electron in an outer shell. Although copper and gold also have other valences, all of the elements in this group have a 1+ valence in common.

Group 12: In order of increasing atomic number, these are zinc, cadmium, and mercury. The elements of this group are characterized by the presence of two electrons in an outer shell. Although mercury also has a valence of 1+, all of the elements in this group have a 2+ valence in common.

Group 4: In order of increasing atomic number, these are titanium, zirconium, and hafnium. The elements of this group are characterized by the presence of two electrons in an outer shell. Although titanium and zirconium also have other valences, all of the elements in this group have a 4+ valence in common.

Group 5: In order of increasing atomic number, these are vanadium, niobium (sometimes called columbium), and tantalum. Vanadium and tantalum have two electrons in an outer shell; niobium has one electron in its outer shell. Although niobium and vanadium also have other valences, all of the elements in this group have a 5+ valence in common.

Group 6: In order of increasing atomic number, these are chromium, molybdenum, and tungsten. Chromium and molybdenum have one electron in their outer shells; tungsten has two electrons in its outer shell. Although chromium and molybdenum also have other valences, all of the elements in this group have a 6+ valence in common.

Group 7: In order of increasing atomic number, these are manganese, technetium, and rhenium. Manganese and rhenium have two electrons in their outer shells; technetium has one electron in its outer shell. Although manganese and rhenium also have other valences, all of the elements in this group have a 7+ valence in common.

Groups 8, 9, 10: In order of increasing atomic number, these are iron, cobalt, nickel, ruthenium, rhodium, palladium, osmium, iridium, and platinum. Ruthenium, rhodium, and platinum have one electron in their outer shells; iron, osmium, cobalt, and nickel have two electrons in their outer shells; iridium has 17 outer electrons and palladium 18 outer electrons. Although all of these elements fall into one group, they appear in the classification in three subgroupings (hence the sometimes-used term *triads*): (1) iron, cobalt, and nickel each have valences of 2+ and 3+; (2) ruthenium, rhodium, and palladium each have valences of 4+, in addition to other valences; (3) osmium, iridium, and palladium each have valences of 4+, in addition to other valences.

In terms of the periodic classification, all elements here designated as the metals fall between highly alkaline elements (alkali metals and alkaline earths) at the left end of the table and the acidic elements, ending with the halogens at the right end of the table. Thus, the term "transition elements" sometimes is used to describe these in-between elements. Actually, the term transition can be applied to the differences between any series of elements within the overall classification, or between individual elements within a group—because of the gradual alteration in chemical behavior that takes place between groups and between elements.

METASTABLE NUCLEI. Nuclei in excited nuclear states that have measurable lifetimes (exceeding 10^{-10} - 10^{-9} second).

METASTABLE STATE. Three common uses of this term denote: (1) A peculiar state of pseudo-equilibrium, in which the system has acquired energy beyond that for its most stable state, yet has not been rendered unstable. Thus, by using great care, water at 760 millimeters pressure may be heated several degrees above its normal boiling point, say to 105°C, yet not boil. In this condition it has received heat energy beyond that normally required for liquid-vapor equilibrium, energy which it might be expected to release by spontaneously exploding into steam; and only a slight disturbance will precipitate that change, but the disturbance must come from some external source.

(2) The term has been used in atomic physics for various excited states, but its most general usage today is for an excited state from which all possible quantum transitions to lower states are forbidden transitions by the appropriate selection rules.

(3) In nuclear physics, the term is used to denote the states in which metastable nuclei are found.

METHACRYLIC ACID AND DERIVATIVES. Methacrylic acid, [CAS: 79-41-4], (MAA) was first prepared in 1865 by the hydrolysis of ethyl methacrylate, which was in turn obtained by dehydrating ethyl α-hydroxyisobutyrate. The polymerizability of methacrylic acid was first noted in 1880 when a white powder was obtained in a distillation of methacrylic acid. The acetone cyanohydrin process for the synthesis of methyl methacrylate via the formation of methacrylamide sulfate, which was patented in 1934, still forms the basis for the bulk of the methyl methacrylate (MMA) currently produced.

Physical Properties

Selected physical properties of various methacrylates are given in Table 1.

Reactions

Methacrylic acid and its ester derivatives are α,β-unsaturated carbonyl compounds and exhibit the reactivity typical of this class of compounds, i.e., Michael and Michael-type conjugate addition reactions and a variety of cycloaddition and related reactions. Although less reactive than the corresponding acrylates as the result of the electron-donating effect and the steric hindrance of the α-methyl group, methacrylates readily undergo a wide variety of reactions and are valuable intermediates in many synthetic procedures.

Polymerization

The vast majority of commercial applications of methacrylic acid and its esters stem from their facile free-radical polymerizability. Solution, suspension, emulsion, and bulk polymerizations have been used to advantage. Although of much less commercial importance, anionic

TABLE 1. SELECTED PROPERTIES OF METHACRYLATES

Compound	Mol wt	Mp, °C	Viscosity, mPa(= cP)	Flash point, °C	Autoignition temperature, °C
methyl[a]	100.11	48	0.53	9[b]	435

[b] Lower explosion limit (LEL) = 2.1%; upper explosion limit (UEL) = 12.5%.
[c] LEL = 1.8%; UEL to saturation.
[d] LEL = 2.0%; UEL = 8%.
[e] Made from a mixture of higher alcohols, predominantly C-12.
[f] pK_a = 8.4.
[g] Heat of polymerization = ~50 kJ/mol (12 kcal/mol).

polymerizations of methacrylates have also been extensively studied. Strictly anhydrous reaction conditions at low temperatures are required to yield high molecular weight polymers in anionic polymerization. Side reactions of the propagating anion at the ester carbonyl are difficult to avoid and lead to polymer branching and inactivation. Polymerization of methacrylates is also possible via what is known as group-transfer polymerization.

Higher Alkyl and Functional Methacrylates

Most large-scale industrial methacrylate processes are designed to produce methyl methacrylate or methacrylic acid. In some instances, simple alkyl alcohols, e.g., ethanol, butanol, and isobutyl alcohol, may be substituted for methanol to yield the higher alkyl methacrylates. In practice, these higher alkyl methacrylates are usually prepared from methacrylic acid by direct esterification or transesterification of methyl methacrylate with the desired alcohol.

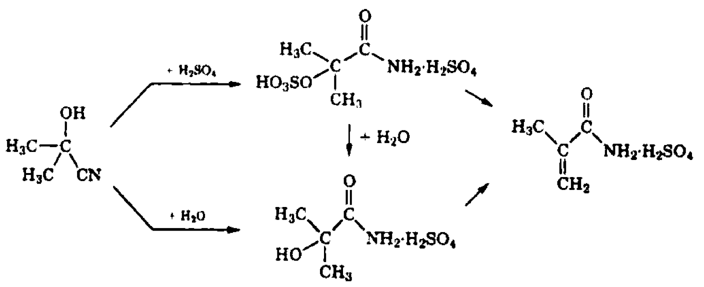
Hydroxy functional methacrylates are accessible by the reaction of methacrylic acid and ethylene oxide or propylene oxide in the presence of chromium, iron, or ion-exchange catalysts.

Manufacture and Processing

The basic feedstock for the manufacture of methyl methacrylate and methacrylic acid is, ultimately, natural gas or crude oil. It is convenient to categorize the various manufacturing routes in terms of the specific hydrocarbon raw material used. Propylene (C-3) routes require the addition of one carbon atom. Ethylene (C-2)-based routes require the addition of two carbon atoms to create the four-carbon methacrylate backbone. The commercial viability of a process is determined by the aggregate of raw material cost and utilization (process yield), operating costs (energy), waste disposal costs, environmental impact, and plant capital investment.

Research is currently directed toward development of novel technologies that may present economic advantages with respect to the conventional acetone cyanohydrin (ACH) route. Mitsubishi Gas Chemical Co. has developed and patented a modified acetone cyanohydrin-based route that does not use sulfuric acid and therefore presents the opportunity for reduced waste costs. A novel C-3 route based on the palladium-catalyzed carbonylation of methylacetylene has been developed by Shell Oil Co. There have been significant improvements in catalysts and resulting yields for key transformations in many routes since the 1980s.

MMA from Acetone Cyanohydrin (ACH). [CAS:75-86-5]. The process for conversion of acetone cyanohydrin–H_2SO_4 to methyl methacrylate through methacrylamide sulfate has been practiced commercially since 1937 and is based on technology patented by ICI in 1934. Acetone cyanohydrin is prepared via base-catalyzed reaction of acetone and hydrogen cyanide. Acetone and hydrogen cyanide are obtained as by-products from the commercial production of phenol and acrylonitrile, respectively. Hydrogen cyanide is also manufactured directly by catalytic ammoxidation of methane. Sulfuric acid is used in excess and serves as both reactant and solvent in the reaction with acetone cyanohydrin to form methacrylamide sulfate through an α-sulfatoamide intermediate.



Inhibitors are introduced at specific points in the process to prevent polymerization. Sulfuric acid serves as catalyst in a combined hydrolysis-esterification of methacrylamide sulfate to a mixture of methyl methacrylate and methacrylic acid. Conversion of methacrylamide sulfate to methyl methacrylate can be carried out using a variety of procedures for the recovery of crude methyl methacrylate and for separation of methanol and methacrylic acid for recycling. A schematic of the overall process is given in Figure 1. The overall yield based on acetone cyanohydrin is approximately 90%. Most of the world supply of MMA is still produced by this process.

Ethylene-Based (C-2) Routes. MMA and MAA can be produced from ethylene as a feedstock via propanol, propionic acid, or methyl propionate as intermediates. Propanal may be prepared by hydroformylation of ethylene over cobalt or rhodium catalysts. The propanal then reacts in the liquid phase with formaldehyde in the presence of a secondary amine and, optionally, a carboxylic acid. The reaction presumably proceeds via a Mannich base intermediate which is cracked to yield methacrolein. Alternatively, a gas-phase, crossed aldol reaction with formaldehyde catalyzed by molecular sieves (qv) may be used to form methacrolein. The methacrolein is then oxidized to methacrylic acid.

Isobutylene-Based (C-4) Routes. Isobutylene or *tert*-butyl alcohol can be converted to methacrylic acid in a two-stage, gas-phase oxidation process via methacrolein as an intermediate. The alcohol and isobutylene may be used interchangeably in the processes since *tert*-butyl alcohol readily dehydrates to yield isobutylene under the reaction conditions in the initial oxidation. Variations of this process have been commercialized.

Methacrylonitrile Process. MAA and MMA may also be prepared via the ammoxidation of isobutylene to give methacrylonitrile as the key intermediate. A mixture of isobutylene, ammonia, and air are passed over a complex mixed metal oxide catalyst at elevated temperatures to give a 70–80% yield of methacrylonitrile. Relatively modest yields are obtained in the ammoxidation reaction and the generation of a considerable acid waste stream combine to make this process economically less desirable than the ACH or C-4 oxidation to methacrolein processes.

Uses

Methacrylic acid and methacrylic esters are used in a wide variety of polymers with a broad spectrum of applications. Poly(methacrylic acid) or its neutralized salts are used as additives for detergent builders and rheology modifiers. Methacrylic esters, the most important of which is methyl methacrylate, yield hard, tough polymers in contrast to the softer

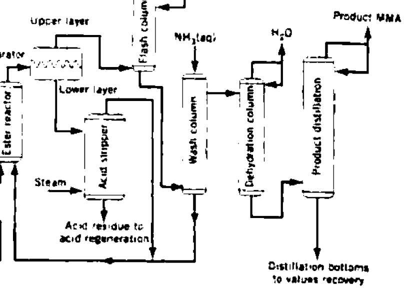


Fig. 1. MMA from acetone cyanohydrin via methacrylamide sulfate

acrylates. Copolymerization of methacrylic esters with acrylates allows the preparation of hard but flexible polymers for use in paints, polishes, and many other coatings. Methacrylate polymers are prized for their clarity, colorability, color compatibility, weatherability, and ultraviolet light stability, which allows them to be used for both indoor and outdoor applications. The principal end uses of methacrylates are in acrylic sheet and molding resins which find commercial application in signs, displays, glazing compounds, lighting fixtures, building panels, automotive components, plumbing fixtures, and appliances. They are also used as impact modifiers in poly(vinyl chloride) (PVC) siding, film, sheet, and plastic bottle manufacture.

Storage and Handling

Polymerizations of methacrylic acid and derivatives are very energetic (MAA, 66.1 kJ/mol; MMA, 57.5 kJ/mol = 13.7 kcal/mol). The potential for the rapid evolution of heat and generation of pressure presents an explosion hazard if the materials are stored in closed or poorly vented containers. To prolong usable shelf-life, commercially available methacrylic monomers are inhibited with the methyl ether of hydroquinone (MEHQ). Other commonly used inhibitors are alkylphenols and hydroquinone. Once inhibited, methacrylic acid or its esters may be handled as flammable materials. To avoid photoinitiation of polymerization, all methacrylates should be stored with minimal exposure to light.

Most unwanted polymerization events of methacrylic monomers occur because of overheating, leading to inhibitor depletion or oxygen depletion, and in turn to inhibitor inactivation. Care should be taken to avoid stagnant areas in transfer lines or pump heads where polymerization may begin and which may then act to seed polymerization of the bulk material.

The relatively high freezing point of methacrylic acid (15°C) is a problem because the inhibitor tends to partition into the liquid phase upon freezing. Thawing of the material tends to create localized pools of uninhibited methacrylic acid which are extremely susceptible to polymerization. Care should be taken to limit thawing temperatures to less than 40°C and to ensure good mixing of the thawed material. For most polymer applications the removal of the inhibitors from the monomer is unnecessary.

Health and Safety Factors

Methacrylates are slightly to severely irritating to skin and eyes and are considered potential skin sensitizers. Several lifetime exposure studies by a variety of routes (oral capsule, drinking water, inhalation) in rodents have shown it to be noncarcinogenic. Methyl methacrylate also is nonteratogenic (did not produce birth defects) after inhalation exposures. Headaches, vomiting, and drowsiness are symptomatic of overexposure to vapors. In the workplace, the pungent odor and irritant nature of the methacrylate monomers serves as a warning property and tends to keep exposures low.

Appropriate protective clothing and equipment should be worn to minimize exposure to methacrylate liquids and vapors. The working area should be adequately ventilated to limit vapors.

METHACRYLIC POLYMERS. The nature of the R group in methacrylic acid ester monomers having the generic formula $CH_2{=}C(CH_3)COOR$ generally determines the properties of the corresponding polymers. Methacrylates differ from acrylates in that the α-hydrogen of the acrylate is replaced by a methyl group. See also **Acrylic Ester Polymers**. This methyl group imparts stability, hardness, and stiffness to methacrylic polymers. The methacrylate monomers are extremely versatile building blocks. They are moderate-to-high boiling liquids that readily polymerize or copolymerize with a variety of other monomers. All of the methacrylates copolymerize with each other and with the acrylate monomers to form polymers having a wide range of hardness; thus polymers that are designed to fit specific application requirements can be tailored readily.

The uniqueness of methyl methacrylate as a plastic component accounts for its industrial use, and it far exceeds the combined volume of all of the other methacrylates. In addition to plastics, the various methacrylate polymers also find application in sizable markets as diverse as lubricating oil additives, surface coatings (qv), impregnates, adhesives (qv), binders, sealers, and floor polishes.

Physical Properties

The nature of the alkyl group from the esterifying alcohol, the molecular weight, and the tacticity determine the physical and chemical properties of methacrylate ester polymers. The physical properties of amorphous methacrylic polymers evidence a principal change in the glass-transition region. Chemical reactivity, mechanical and dielectric relaxation, viscous flow, load bearing capacity, hardness (qv), tack, heat capacity, refractive index, thermal expansivity, creep, and diffusion differ markedly below and above the transition region.

The properties of methacrylic polymers are also affected by molecular weight. Typically, mechanical properties increase as the molecular weight increases. However, beyonds some critical value, about 100,000, the increase is slight and levels off asymptotically.

Mechanical Properties. Methacrylates are harder polymers of higher tensile strength and lower elongation than their acrylate counterparts because substitution of the methyl group for the α-hydrogen on the main chain restricts the freedom of rotation and motion of the polymer backbone.

At room temperature, the first member of the linear aliphatic methacrylate series, poly(methyl methacrylate), is a hard, fairly rigid material which can be sawed, carved, or worked on a lathe. When heated above its T_g, on poly(methyl methacrylate) is a tough, pliable, extensible material that is easily bent or formed into complex shapes, and can be molded or extruded.

Optical Properties. Poly(methyl methacrylate) transmits light in the range of 360–1000 nm almost perfectly (92% compared to the theoretical 92.3%). The wavelength of visible light falls approximately between 400 and 700 nm. At a thickness of 2.54 cm or less, poly(methyl methacrylate) absorbs virtually no visible light. Beyond 2800 nm, essentially all infrared radiation is absorbed. Commercial grades of poly(methyl methacrylate) often contain uv radiation absorbers that block light in the 290–350 nm range. The absorber thus screens the user from sunburn and protects the polymer against long-term degradation from light. Poly(methyl methacrylate)'s transparency to x-rays and radiation has been found to be about the same as that of human flesh or water. Sheets of poly(methyl methacrylate) are opaque to alpha particles, and for thicknesses above 6.35 mm (0.250 in.), the polymer is essentially opaque to beta radiation; poly(methyl methacrylate) is used as a transparent neutron stopper. Most formulations of colorless sheet have high transmittance to standard broadcast and television waves as well as to most radar bands.

Many items, such as magnifiers, reducers, camera lenses, prisms, and especially complex reflex lenses widely used in automotive tail-lights, are made from poly(methyl methacrylate).

Electrical Properties. The surface resistivity of poly(methyl methacrylate) is higher than that of most plastic materials. Weathering and moisture affect poly(methyl methacrylate) only to a minor degree. High resistance and nontracking characteristics have resulted in its use in high voltage applications, and its excellent weather resistance has promoted the use of poly(methyl methacrylates) for outdoor electrical applications.

Chemical Properties

Methacrylate polymers have a greater resistance to both acidic and alkaline hydrolysis than do acrylate polymers; both are far more stable than poly(vinyl acetate) and vinyl acetate copolymers. There is a marked difference in the chemical reactivity among the noncrystallizable and crystallizable forms of poly(methyl methacrylate) relative to alkaline and acidic hydrolysis. Conventional (i.e., free-radical), bulkpolymerized, and syndiotactic polymers hydrolyze relatively slowly compared with the isotactic type. Polymer configuration is unchanged by hydrolysis.

The chemical resistance of poly(methyl methacrylate) may be summarized as follows. PMMA is not affected by most inorganic solutions, mineral oils, animal oils, low concentrations of alcohols; paraffins, olefins, amines, alkyl monohalides; and aliphatic hydrocarbons and higher esters, i.e., >10 carbon atoms. However, PMMA is attacked by lower esters, e.g., ethyl acetate, isopropyl acetate; aromatic hydrocarbons, e.g., benzene, toluene, xylene; phenols, e.g., cresol, carbolic acid; aryl halides, e.g., chlorobenzene, bromobenzene; aliphatic acids, e.g., butyric acid, acetic acid; alkyl polyhalides, e.g., ethylene dichloride, methylene chloride; high

TABLE 1. RELATIVE OUTDOOR STABILITY OF POLY(METHYL METHACRYLATE)

concentrations of alcohols, e.g., methanol, ethanol; 2-propanol; and high concentrations of alkalies and oxidizing agents.

The chemical resistance and excellent light stability of poly(methyl methacrylate) compared to two other transparent plastics is illustrated in Table 1.

Manufacture and Processing

Free-radical polymerization processes are used to produce virtually all commercial methacrylic polymers. Usually free-radical initiators (qv) such as azo compounds or peroxides are used to initiate the polymerizations. Photochemical and radiation-initiated polymerizations are also well known. At a constant temperature, the initial rate of the bulk or solution radical polymerization of methacrylic monomers is first-order with respect to monomer concentration, and one-half order with respect to the initiator concentration. Methacrylate polymerizations are markedly inhibited by oxygen; therefore considerable care is taken to exclude air during the polymerization stages of manufacturing.

A substantial fraction of commercially prepared methacrylic polymers are copolymers. Monomeric acrylic or methacrylic esters are often copolymerized with one another and possibly several other monomers. Copolymerization greatly increases the range of available polymer properties. The all-acrylic polymers tend to be soft and tacky; the all-methacrylic polymers tend to be hard and brittle. By judicious adjustment of the amount of each type of monomer, polymers can be prepared at essentially any desired hardness or flexibility. Small amounts of specially functionalized monomers are often copolymerized with methacrylic monomers to modify or improve the properties of the polymer directly or by providing sites for further reactions.

Bulk Polymerization. This is the method of choice for the manufacture of poly(methyl methacrylate) sheets, rods, and tubes, and molding and extrusion compounds. Three bulk polymerization processes are commercially important for the production of methacrylate polymers: batch cell casting, continuous casting, and continuous bulk polymerization. Approximately half the worldwide production of bulk polymerized methacrylates is in the form of molding and extrusion compounds, a quarter is in the form of cell cast sheets, and a quarter is in the form of continuous cast sheets.

Solution Polymerization. The solution polymerization of methacrylic monomers to form solution polymers or copolymers is an important commercial process for the preparation of polymers for use as coatings, adhesives, impregnates, and laminates. Typically the polymerization is done batchwise by adding monomer to an organic solvent in the presence of a soluble peroxide or azo initiator.

Emulsion Polymerization. The principal markets for aqueous dispersion polymers made by emulsion polymerization of methacrylic esters are the paint, paper, textile, floor polish, and leather industries where they are used principally as coatings or binders. Copolymers of methyl methacrylate with either ethyl acrylate or butyl acrylate are most common.

Suspension Polymerization. This method yields polymethacrylates in the form of tiny beads, which are primarily used as molding powders and ion-exchange resins. Most suspension polymers prepared as molding powders are poly(methyl methacrylate); copolymers containing up to 20% acrylate for reduced brittleness and improved processibility are also common. Suspension polymers of poly(methyl methacrylate) copolymerized with an amino or acid functional monomer, and with a di- or trivinyl monomer for cross-linking, are useful as ion-exchange resins.

Graft Polymerization. Graft copolymers are prepared by attaching one polymer as a branch to the chain of another polymer of different composition. This is usually accomplished by generating radical sites on the first polymer onto which monomer of the second polymer is grafted. The grafting may be accomplished in bulk, solution, or dispersion systems. The presence of distinct, but chemically bonded segments of two polymers often confers interesting and useful properties. Commercially, the most important methacrylate graft copolymers are the MABS and MBS polymers.

The MABS copolymers are prepared by dissolving or dispersing polybutadiene rubber in a methyl methacrylate—acrylonitrile—styrene monomer mixture. MBS polymers are prepared by grafting methyl methacrylate and styrene onto a styrene—butadiene rubber in an emulsion process. The product is a two-phase polymer useful as an impact modifier for rigid poly(vinyl chloride).

Ionic Polymerization. The anionic polymerization of methacrylic monomers to stereoregular or block copolymers is well known. These polymerizations are conducted in organic solvents, primarily using organometallic compounds as initiators. This technology is of minor commercial significance, but is of interest for the preparation of polymers of narrow molecular weight distribution and controlled molecular architecture. Methacrylate monomers do not generally polymerize by a cationic mechanism.

Health and Safety Factors

In general, methacrylate polymers are considered nontoxic. Various methacrylate polymers are used in food packaging (qv) and handling, in dentures and dental fillings (see **Dental Materials**), and as medicine dispensers and contact lenses. However, care must be exercised because additives or residual monomers present in various types of polymers can display toxicity.

During manufacture, considerable care is exercised to reduce the potential for violent polymerizations, and to reduce exposure to flammable and potentially toxic monomers and solvents.

Dust explosions ignited by static discharge are a recognized hazard encountered in the handling of poly(methyl methacrylate) powders or in the fabrication of poly(methyl methacrylate) plastic sheet. Methacrylic solution polymers are treated as flammable mixtures; latex polymers are nonflammable.

Uses

The principal U.S. market for methacrylate resins is for glazing and skylights. Other significant markets include consumer products, transportation signs and lighting fixtures, plumbing (spas, tubs, showers, sinks, etc), and panels and siding. The resins are also used in medicine, optics, and as oil additives.

METHANATION. See **Coal; Substitute Natural Gas (SNG)**.

METHANE. [CAS: 74-82-8]. CH_4, formula weight 16.04, colorless, odorless (when pure) gas, mp −182.6°C, bp −161.4°C, sp gr 0.415 (at −164°C).

Sometimes referred to as *marsh gas* or *fire damp*, methane is practically insoluble in H_2O, and moderately soluble in alcohol or ether. The gas burns when ignited in air with a pale, faintly luminous flame, forming an explosive mixture with air between gas concentrations of 5% and 13%. Methane is the principal constituent of natural gas, averaging 75% by weight. Natural gas from the Pennsylvania fields is almost 99% methane, but some gas from Kentucky fields contains as little as 23% methane. See also **Natural Gas**. Pipeline gas from several fields typically will contain about 78% methane, 13% ethane, 6% propane, 1.7% butane, and 0.6% pentane. The remaining fraction consists of gases higher in the alkyl series. While generally not referred to as such, methane can be classified as a major

fuel. The heating value of pure methane is 995Btu/ft^3 (8856 Calories per cubic meter).

Methane, as the major constituent of natural gas, is an extremely important raw material for numerous synthetic products. For most processes, it is not required to isolate and purify the methane, but the natural gas as received may be used. The high percentage of CH_4 in various feedstocks makes possible the formation of synthesis gas: $CH_4 + H_2O \longrightarrow CO + 3H_2$. The percentages of CO and H_2 in synthesis gas vary depending on the end product to be made. Synthesis gas is used widely in the manufacture of NH_3, oxo-chemicals, and methyl alcohol. See also **Synthesis Gas.**

In addition to the preparation of synthesis gas, which is used so widely in various organic syntheses, methane is reacted with NH_3 in the presence of a platinum catalyst at a temperature of about 1,250°C to form hydrogen cyanide: $CH_4 + NH_3 \longrightarrow HCN + 3H_2$. Methane also is used in the production of olefins on a large scale. In a controlled-oxidation process, methane is used as a raw material in the production of acetylene.

Most artificial gases, such as producer gas, coal gas, water gas, manufactured gas, and town gas contain a high content of methane. In addition to its use as a basic chemical and fuel, methane is of notable interest because of its role as the anchor compound of the *alkanes* (paraffin or aliphatic hydrocarbons). All of these compounds may be considered derivatives of methane.

Some methane is manufactured by the distillation of coal. Coal is a combustible rock formed from the remains of decayed vegetation. It is the only rock containing significant amounts of carbon. The elemental composition of coal varies between 60% and 95% carbon. Coal also contains hydrogen and oxygen, with small concentrations of nitrogen, chlorine, sulfur, and several metals. Coals are classified by the amount of volatile material they contain, that is, by how much of the mass is vaporized when the coal is heated to about 900°C in the absence of air. Coal that contains more than 15% volatile material is called bituminous coal. Substances released from bituminous coal when it is distilled, in addition to methane, include water, carbon dioxide, ammonia, benzene, toluene, naphthalene, and anthracene. In addition, the distillation also yields oils, tars, and sulfur-containing products. The non-volatile component of coal, which remains after distillation, is coke. Coke is almost pure carbon and is an excellent fuel. However, it may contain metals, such as arsenic and lead, which can be serious pollutants if the combustion products are released into the atmosphere.

Carbon monoxide and hydrogen react to form CH_4 in the presence of a nickel catalyst. Methane also is formed by reaction of magnesium methyl iodide in anhydrous ether (Grignard's reagent) with substances containing the hydroxyl group. See also **Grignard Reactions**. Methyl iodide (bromide, chloride) is preferably made by reaction of methyl alcohol and phosphorus iodide (bromide, chloride).

METHANOGENS. Cells that resemble bacteria in a superficial way, but that have unique genetic and metabolic characteristics. Methanogens are anaerobic, methane-producing microorganisms that occur in a wide variety of places—the gastrointestinal tract of animals, including humans, in the sediments of natural waters, in sewage treatment plant vessels and piping, and in natural hot springs. As proposed by Woese (University of Illinois) and Fox (University of Houston), the methanogens probably make up a third line of descent of cells in addition to the prokaryotes (bacteria and blue-green algae cells which do not have a well-defined nucleus) and eukaryotes (more complex cells with a nucleus). These researchers also have suggested that there may be still other kinds of cells that do not meet the criteria set down for prokaryotes and eukaryotes.

Methanogens are distinguished from bacteria on at least three counts:

(1) The cell walls do not contain muramic acid, the characteristic constituent of the peptidoglycans that form bacterial cell walls. (2) Their metabolism differs markedly from bacteria. A number of coenzymes apparently unique to methanogens have been identified. Some of these enzymes are involved in methyl transfer reactions, including the formation of methane. One of the coenzymes is possibly the smallest coenzyme yet to be discovered. The methanogens also differ in the manner in which carbon dioxide is fixed into cellular carbon. However, the pathway has not been clearly identified. (3) The RNA sequences of methanogens differ from those of other organisms. These observations have indicated to Woese and Fox that although the methanogens share a common ancestor with prokaryotes and eukaryotes, an independent line of descent branched off at possibly about the same time the other cell types diverged.

Although not fully understood, the methanogens place new challenges to the evolutionary biologists for further explanation in terms of the development of early life on earth and may be very valuable toward understanding life on extraterrestrial bodies as these may be explored over future years.

Barker (University of California at Berkeley) and Huntgate (University of California at Davis) as early as the mid-1950s noted that methanogens differ radically from bacteria.

Methanogens take part in the terminal stages of organic matter degradation and survive on carbon dioxide and hydrogen yielded by anaerobic bacteria and converting them to methane.

METHANOL. See **Methyl Alcohol.**

METHIONINE. See **Amino Acids.**

METHYL ALCOHOL. [CAS: 67-56-1]. CH_3OH, formula weight 32.04, colorless, mobile liquid with mild characteristic odor, mp −97.6°C, bp 64.6°C, sp gr 0.792. Also known as *methanol*, the compound is miscible in all proportions with H_2O, ethyl alcohol, or ether. When ignited, methyl alcohol burns in air with a pale blue, transparent flame, producing H_2O and CO_2. The vapor forms an explosive mixture with air. The upper explosive limit (% by volume in air) is 36.5 and the lower limit is 6.0.

Methyl alcohol possesses distinct narcotic properties. It is also a slight irritant to the mucous membranes. The principal toxic effect is exerted on the nervous system, particularly the optic nerves and possibly the retinae. The effect upon the eyes has been attributed to optic neuritis, which subsides, but is followed by atrophy of the optic nerve. Once absorbed, methyl alcohol is only very slowly eliminated. Coma resulting from massive exposures may last as long as 2 to 4 days. In the body, the products formed by its oxidation are formaldehyde and formic acid, both of which are toxic.

Chemical Properties

Methyl alcohol is a versatile material, reacting (1) with sodium metal, forming sodium methylate, sodium methoxide CH_3ONa plus hydrogen gas, (2) with phosphorus chloride, bromide, iodide, forming methyl chloride, bromide, iodide, respectively, (3) with H_2SO_4 concentrated, forming dimethyl ether $(CH_3)_2O$, (4) with organic acids, warmed in the presence of H_2SO_4, forming esters, e.g., methyl acetate CH_3COOCH_3, methyl salicylate $C_6H_4(OH) \cdot COOCH_3$, possessing characteristic odors, (5) with magnesium methyl iodide in anhydrous ether (Grignard's solution), forming methane as in the case of primary alcohols, (6) with calcium chloride, forming a solid addition compound $4CH_3OH \cdot CaCl_2$, which is decomposed by H_2O, (7) with oxygen, in the presence of heated smooth copper or silver forming formaldehyde. The density of pure methyl alcohol is 0.792 at 20°C compared with H_2O at 4°C (the corresponding figure for ethyl alcohol is 0.789), and the percentage of methyl alcohol present in a methyl alcohol-water solution may be determined from the density of the sample.

A common test for methyl alcohol is by its oxidation in air with a hot copper wire to form formaldehyde.

At one time, most methyl alcohol was obtained by the destruction distillation of hardwoods (hence the name *wood alcohol*) at about 350°C, along with a yield of acetic acid and small percentages of acetone in the water condensate. Interest in returning to wood as a source has revived because of fossil fuel shortages.

Production of Methyl Alcohol[1]

Synthetic methanol is one of the major raw materials of the organic chemical industry. Methanol has economic stability and a steady growth rate owing to the low costs of production and diversity of applications. Nearly all the methanol producers also make formaldehyde, which is

[1] Remainder of this entry prepared by J.R. Masson, Process Engineering Consultant, Davy McKee (Oil & Chemicals) Ltd., London, England.

the main end use (more than 50%) of methanol. The other main end uses are dimethyl terephthalate, methacrylates, methylamines (for resins, herbicides, and fungicides), methyl halides (for silicones, tetramethyl lead, butyl rubbers, paint removers, photographic films, aerosol propellants, (diminishing use), and degreasing compounds), acetic acid, and solvents.

An important process for production of synthetic protein uses methanol as feedstock. The use of methanol as a fuel, either as pure methanol, as a mixture (approximately 15%) with gasoline, or as a feedstock for synthetic gasoline is envisaged for possible large-scale application; as well as use in gas turbines for electricity generation. See also **Wastes as Energy Sources.**

There are three principal commercial grades of methanol (as defined in U.S. Federal Specification O-M-232f: June 5, 1975): *Grade A*, synthetic, 99.85% by weight (solvent use); *Grade AA*, synthetic, 99.85% by weight (hydrogen and carbon dioxide generation use); and *Grade C*, wood alcohol (denaturing use).

The most recent advances in methanol synthesis are the low- and intermediate-pressure processes of the type shown in Fig. 1. The synthesis step of this process[2] relies upon a copper-based catalyst, which gives good yields of methanol at pressures of 50 and 100 atmospheres. These pressures are substantially below those of the 250–350 atmospheres required by earlier processes. The high catalyst activity allows the synthesis reaction to take place at a relatively low temperature of 250–270°C. As a result, methanation is avoided, and byproduct formation is lower, giving increased process efficiency.

The development of this low-pressure technology has caused a major reassessment of the economics of methanol production. The energy required to compress the synthesis gas from its production pressure to the synthesis unit is reduced by a factor between 2 and 3. The lower synthesis pressure allows the exclusive use of centrifugal compressors in plants with capacities as low as 15 million gallons (0.57 million hectoliters) per year. Small producers find attractive the savings in investment, operating, and maintenance costs made possible by low-pressure operation. Plants range in capacity from 15 million gallons (0.57 million hectoliters) to 250 million gallons (9.46 million hectoliters) per year.

Synthesis gas is prepared by the steam reforming or partial oxidation of a liquid or gaseous hydrocarbon feedstock, or by direct combination of carbon dioxide with purified hydrogen-rich gases. Economic considerations usually favor the steam-reforming route for a naphtha or natural gas feedstock. In this instance, desulfurized feedstock is preheated, mixed with superheated steam, and reacted over a conventional catalyst (normally nickel-based) in multitubular reformer. The reformer usually is operated at between 15 and 30 atmospheres and at a tube outlet temperature of 840–900°C. The reforming conditions are chosen to give the most economic overall production costs. Methane slip (amount of unconverted methane) usually is greater than for conventional high-pressure synthesis processes, since the cost of compressing the additional methane is less significant with the low-pressure process. With a naphtha feedstock, an almost exact stoichiometric ratio of carbon oxides to hydrogen in the synthesis gas is achieved, but when natural gas is the feedstock, there is an inherent deficiency of carbon. Established practice for many years has been to add carbon dioxide from an external source in preparing a stoichiometric synthesis gas. Development of the low-pressure process has shown that this addition of carbon dioxide is not required and that, depending upon the cost of carbon dioxide production, the production of methanol from natural-gas feedstock alone is economic.

After heat recovery and cooling, the synthesis gas is compressed to the required synthesis pressure and passed into the synthesis loop at the suction of a circulator. The circulator, which boosts the pressure of the circulating gases to make up the total loop pressure drop, also is a centrifugal machine. Feed-gas preheating is carried out by heat exchange with the hot gases leaving the converter. Heat recovery is incorporated into the loop to recover the heat of reaction of methanol synthesis.

Synthesis takes place in a hot-wall converter over the low-pressure methanol-synthesis catalyst at 250–270°C. Temperature control of the converter is effected by injecting cold gas at appropriate levels in the catalyst bed, using specially developed distributors that provide excellent gas mixing while allowing free passage of the catalyst for easy charging and discharging. After leaving the converter and passing through the feed-gas preheater the converted gases are cooled, and crude methanol is condensed and separated from the uncondensed gases, which are recycled with makeup synthesis gas to the converter. A continuous gas purge is taken from the synthesis loop in order to remove an accumulation of inert gases. This purge is recycled to the synthesis-gas preparation section as reformer fuel. The crude methanol is reduced in pressure before passing forward to the methanol-purification section, where methanol of the required purity is produced by conventional distillation methods.

Economics in fuel gas consumption are achieved by use of recovered heat in reboiling in the distillation columns. In addition, distillation schemes

involving three or four columns have also been developed with reduced reboil heat requirements.

Health and Safety

Methanol is not classified as carcinogenic, but can be acutely toxic if ingested: 100–250 mL may be fatal or result in blindness. The principal physiological effect is acidosis resulting from oxidation of methanol to formic acid. See also **Acidosis.** Methanol is a general irritant to the skin and mucous membranes. Methanol vapor can cause eye and respiratory mucous membranes. Methanol vapor can cause eye and respiratory tract irritation, nausea, headaches, and dizziness.

Methanol does not pose an undue toxicity hazard if handled in well-ventilated areas, and is rated as a slight health hazard by the National Fire Protection Association (NFPA): http://www.nfpa.org/.

Storage and Handling. Methanol is stable under normal storage conditions. Methanol is not subject to hazardous polymerization reactions, but can react violently with strong oxidizing agents. The greatest hazard involved in handling methanol is the danger of fire or explosion. The NFPA classifies methanol as a serious fire hazard.

MEYER-SCHUSTER REARRANGEMENT. Acid catalyzed rearrangement of secondary and tertiary α-acetylenic alcohols to α,β-unsaturated carbonyl compounds: aldehydes when the acetylenic group is terminal, ketones when it is internal.

MICA. Mica is a generic term that applies to a wide range of hydrous aluminum silicate minerals characterized by sheet or plant-like structure, and possessing to varying degrees, depending on composition and weathering, flexibility, elasticity, hardness (qv), and the ability to be split into thin (1 μm) sheets. All micas form flat six-sided monochromic crystals, and possess cleavage parallel to the basal plane.

Mica exists in nature in a wide variety of compositions. Muscovite and phlogopite are the only natural micas of commercial importance. Vermiculite, although not considered a true mica by most mineralogists, is a micaceous mineral formed from the weathering of phlogopite or biotite and is also of commercial importance. Fluorophlogopite, $K_2Mg_6(Al_2Si_6O_{20})F_4$, is a synthetic mica made from pure chemical oxides.

Mica has been classified into three groups: *(1)* the mica group proper, *(2)* the clintonite or brittle micas group, and *(3)* the chlorite group. Supplementary to these are the vermiculites, which are hydrated compounds that result from the alteration of any one of the micas, but usually biotite. All minerals in these groups belong to the monoclinic crystal system, and all show plane angles of 60 and 120° on the basal section. The crystals usually form in hexagonal or rhombohedral-shaped scales, prisms, or plates. The basic structural unit of mica is a layer composed of two silicon tetrahedral sheets with a central octahedral sheet.

Muscovite is dioctahedral, having a theoretical composition of 11.8% K_2O, 45.2% SiO_2, 38.5% Al_2O_3, and 4.5% H_2O. Muscovite mica formed as a primary mineral in pegmatites and granodiorite differs in physical properties compared to muscovite mica formed by secondary alteration (mica schist). The main differences are in flexibility and ability to be delaminated. Primary muscovite is not as brittle and delaminates much easier than muscovite formed as a secondary mineral. Mineralogical properties of the principal natural micas are shown in Table 1.

Mining

Flake Mica. Flake mica is mined from weathered and hard rock pegmatites, granodiorite, and schist and gneiss by conventional openpit methods. In soft, residual material, dozers, shovels, scrapers, and front-end loaders are used to mine the ore. Often kaolin, quartz, and feldspar are recovered along with the mica. See also **Clays**; and **Silicon**.

Hard rock mining of these ore bodies requires drilling and blasting with ammonium nitrate and dynamite. After blasting, the ore is reduced in size with a drop ball and then loaded on trucks for transportation to the processing plant. Mica, quartz, and feldspar concentrates are separated, recovered, and sold from the hard rock ore.

Sheet Mica. Pockets of mica crystals are found in pegmatite stills and dikes or grandonite ore bodies. Sheet mica is mined by both underground and open-pit mining procedures. Underground mining is accomplished by driving a shaft, formed with tungsten carbide-tipped air drills, hoists, and explosives. After blasting, the mica is placed in boxes or bags for transporting to the trimming shed where it is graded, split, and cut to various specified sizes for sale.

Sheet mica is no longer mined in the U.S. Most sheet mica is mined in India.

Beneficiation Processes

Flake or Scrap Mica. In the early to mid-1900s, flake or scrap mica was mainly processed by a jigging procedure which consists of hydraulically washing a pile of bulldozed ore across a series of roll crushers and Trommel screens gaped at different size openings.

The grade of mica produced by jigging is very poor, usually about 75% concentrate, and recovery of available mica low (50%). Specifications on mica have become more stringent, therefore a more efficient processing method has been devised that provides higher quality mica, as well as more efficient recovery.

Because of improved mica processing operations, low cost earthen waste impoundment ponds have been built to store solid waste and thereby provide for a relatively cheap means of meeting new federal and state environmental laws. There are several methods of preparing ore for beneficiation after it arrives at the plant site (Fig. 1).

Flake mica is also produced as a by-product from processing feldspar ore (hard granodiorite) from mica schist which normally contains from 30–60% recrystallized muscovite mica along with quartz and iron minerals. The quartz is usually not suitable for glass sand or high purity material, however.

Sheet Mica. The preparation of sheet mica for feedstock for various punching and machining operations involves cobbing mica blocks or books

TABLE 1. MINERALOGICAL PROPERTIES OF MICAS[a]

Properties	Muscovite	Biotite	Lepidolite	Phlogopite
sp gr	2.76–3.0	2.7–3.1	2.8–3.3	2.8–2.9
luster	vitreous–pearly	splendent, sometimes submetallic	pearly	pearly
crystal	rhombic or hexagonal	pseudo-rhombohedral	hexagonal	hexagonal
colors	gray, brown, pale green, violet, yellow, dark olive-green, ruby	green, black, yellow	rose red, violet-gray, lilac, yellowish, grayish white, white	yellow-white, gray–green, pearly, brown, black

[a] Optical signs of micas are negative, crystal system is monoclinic, streak is colorless.

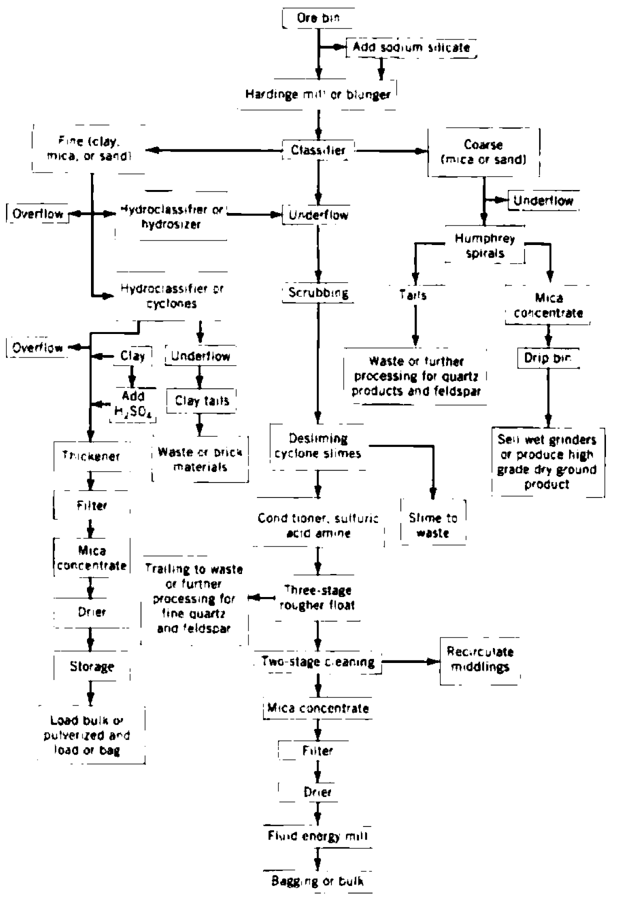

Fig. 1. Flow sheet for the acid circuit processing and recovery of mica from weathered granodiorite ore. An alkaline—cationic circuit may be used by inserting a second conditioner containing lignin sulfonate, adjusting the pH to 8.0, and adding NaOH and DRL (distilled tall oil) fatty acid to the first conditioner

to remove dirt, rock, and defective mica, trimming and splitting into sizes and thicknesses suitable for punching and milling to desired shapes, and grading the finished mica sheets according to size and quality. The waste mica resulting from cobbing and trimming (scrap mica) is often mixed with flake mica for processing by dry or wet ground procedures.

The grade determines whether the mica can be used in high technology electronic instruments, e.g., computer-aided tomography (CAT) scan, or in low technology devices, e.g., a toaster. Many types of insulators, as well as the base for electronic circuits, are formed from the high quality sheets of mica by a punch pressing operation.

Procedures for Production

The general pieces of equipment used in grinding flake mica or mica concentrate into saleable mica products are hammer mills of various types, fluid energy mills, Chaser or Muller mills for wet grinding, and Raymond or Williams high side roller mills. Another method is being developed, called a Duncan mill (J. M. Huber, Inc.), that is similar in many respects to an attrition mill. All of these mills are used in conjunction with sieves, and all but some types of hammer mills-incorporate air classifiers as a part of the circuit.

Ground Mica. This constitutes by far the largest commercial use for mica. It is largely produced from the beneficiation of weathered and unweathered pegmatites, granodiorite, and metamorphic schists, although some higher grades are produced from trimmings of sheet mica or Type A (low quality) mica blocks.

Wet ground mica products account for approximately 15% of the total mica market. Exact sizing of mica products coupled with surface treatment procedures have led to a greater use for wet ground mica in plastic compositions, particularly automobile bodies. These quality products demand a high dollar value.

Dry ground mica concentrate is processed into usable products by several different grinding methods. Relatively coarse particle sizes (1.651–0.147 mm (10–100 mesh)) are used in oil-well drilling muds, some types of welding rod coatings, asphalt (qv), roofing shingles, and some other types of fillers (qv). These products are ground on a hammer mill in closed circuit with a sieve. Roofing micas produced from mica schist are often ground in a Raymond or Williams high side roll mill in closed circuit with an air classifier and a sieve. The finer particle-size micas ≤0.147–0.044 mm (−100 to −325 mesh), used mainly in textured paints and joint cement compounds, are ground on several types of fluid energy mills, but generally a mill of the Majacs type. The finest dry ground mica product is ground with superheated steam (Micronized, KMG Minerals).

Testing of Mica

There are several conventional tests required by consumers of ground mica. They include screening and the determination of bulk density, true specific gravity, chemical analysis, moisture, free silica, refraction index, oil absorption, brightness, grit content, and aspect ratio.

By-Products of Mica

The main by-products of mica processing plants are kaolin, quartz, and feldspar. Some plants produce all of these products for sale.

Mica Market

Sheet Mica. Good quality sheet mica is widely used for many industrial applications, particularly in the electrical and electronic industries, because of its high dielectric strength, uniform dielectric constant, low power loss (high power factor), high electrical resistivity, and low temperature coefficient. Mica also resists temperatures of 600–900°C, and can be easily machined into strong parts of different sizes and shapes.

Built-Up Mica. When the primary property needed for a particular application is insulation, built-up mica made by binding layered mica splittings together serves as a substitute for the more expensive sheet mica. The principal uses for built-up mica are segment plate, molding plate, flexible plate, heater plate, and tape.

Wet Ground Mica. Wet ground mica is used because of its unique properties, i.e., luster, slip and sheen, and high aspect ratio. It is used in wallpaper and coated paper, nacreous pigments, as a coating for rubber, in outdoor house paint, and in aluminum paints. Mica is used in all types of sealers for porous surfaces, such as wallboard masonry, and concrete blocks, to reduce penetration and improve holdout and as a filler in plastics to improve its electrical and thermal resistance and its insulating qualities. See also **Sealants**.

Dry Ground Mica. Dry ground mica produced by hammer milling and screening is used in oil-well drilling, coatings for roofing shingles, roofing felt, and for some types of welding rod flux.

The largest use for fine, dry ground mica is in the manufacture of wallboard joint cements. Ground mica that is essentially ≤0.147 mm-100 mesh and ~70% passing a 0.044 mm (325 mesh) Tyler sieve is used in the joint compound mixture as a filler and extender. These compounds are used to fill joints between panels of gypsum plaster board. Mica contributes to making a nonabsorbing smooth surface that reduces shrinkage and eliminates cracks. It is also used in the finished coating on ceilings and to prepare thermal insulation and acoustical qualities of ceiling tile and prefabricated concrete. See also **Calcium**.

Fine particle-size dry ground mica is also used as an extender and filler in certain texture and traffic paints. Mica particles are stronger than iron and not brittle like other inerts. It is an antifriction, antifouling, antisettling, anticorrosive, antitarnish, and antisiege agent. It is a superior reinforcing pigment that acts as a sealer over porous surfaces and reduces penetration and flushing; moreover, it improves the moisture resistance of protective coatings and adhesion to all types of surfaces.

Micronized mica is a trade name (KMG Minerals, formerly English Mica Co.) for a very fine particle-size dry ground product, usually ground with superheated steam in a special fluid energy mill and used as a replacement for wet ground mica in certain types of paints. Micronized mica, preferably calcined, is also used in cosmetic applications, i.e., nail varnishes, lipsticks, eyeshadows, and barrier cream, because is has the advantages of high ultraviolet light stability, excellent lubricity, skin adhesion, and compressibility. Some of these micas are coated with oxides like titanium and iron.

Environmental and Health Regulations

Mica mining is subjected to local, state, and federal laws. The Mining, Safety and Health Administration (MSHA) regularly monitors mica mining operations for safety violations.

Both state air and water environmental departments together with the U.S. EPA regulate and oversee air and water quality associated with mica mining operations. Most states have land management departments that regulate dam safety, erosion, sedimentation, and reclamation. The mica mines must control erosion and sedimentation and restore the mined out areas. This is accomplished either by backfilling or contouring and seeding operations, or in cases where this is impractical or undesirable, lakes for water-related recreation may be built. The Corps of Engineers have jurisdiction over laws governing wetlands.

Health regulations are supervised by county and state health departments. There are no known health problems caused by the mica crystal, however, most industrial mica products contain some free silica particles that can cause silicosis and some states require employees who work in mica plants to receive an annual x-ray.

MICELLE. An electrically charged colloidal particle, usually organic in nature, composed of aggregates of large molecules, such as found in surfactants and soaps. The term is also applied to the casein complex in milk.

See also **Colloid Systems**.

MICHEL, HARTMUT (1948–). Awarded Nobel prize for chemistry in 1988, along with Johann Deisenhofer and Michel Huber, for work that revealed the three-dimensional structure of closely-linked proteins that are essential to photosynthesis. Doctorate awarded in 1977 by the University of Wurtzburg, Germany.

MICROCHEMISTRY. A branch of analytical chemistry that involves procedures that require handling of very small quantities of materials. Specifically, it refers to carrying out various chemical operations (weighing, purification, quantitative and qualitative analysis) on samples ranging from 0.1 to 10 mg; this often involves use of a microscope, and still more often chromatography. See also **Microscopy (Chemical)**.

MICROCRYSTALLINE. A form in which a number of high-polymeric substances have been prepared. They include cellulose, chrysotile asbestos, amylose (starch), collagen, nylon, and certain mineral waxes. On the microscopic level, these substances are composed of colloidal microcrystals connected by molecular chains. The process involves breaking up the network of microcrystals (by acid hydrolysis in the case of cellulose) and separating them by mechanical agitation. The size range of the microcrystals is from 2.5 to 500 nanometers (millimicrons). The products form extremely stable gels that have a number of commercial use possibilities. Petroleum-derived waxes of high molecular weight have been available in microcrystalline form for many years. Chlorophyll has a naturally microcrystalline structure.

MICROEMULSIONS. There is no official or universally accepted definition of what constitutes a "microemulsion."

However, the concept of microemulsions holds a central role within the field of surfactant technology. Perhaps the most fundamental fact captured by the term is that, contrary to a popular saying, oil and water can mix. See also **Surfactants**.

Definition of a Microemulsion

The term *micro*emulsion implies a system which (like an emulsion) contains droplets of oil or water, but in which the droplets are too small to scatter light see also **Colloid Systems**.

A microemulsion is a true, thermodynamically stable, liquid solution that contains water, oil, and at least one amphiphile. Typically the oil is a mineral oil or hydrocarbon, but it may be almost any nonpolar compound. The oil and the amphiphile may be single, pure components; or (as in most commercial formulations), the oil, amphiphile, or both may contain an indefinitely large number of compounds.

Microemulsions and Phase Diagrams

The existence or nonexistence of a microemulsion depends not only on the presence of certain classes of compounds (i.e., components), but also on the concentrations of these components. The number of phases present and their compositions, when presented in graphical form, constitute a phase diagram. Moreover, as specified by Gibbs' phase rule, amphiphile–oil–water–phase diagrams form characteristic patterns that change in qualitatively similar ways when the temperature, pressure, concentrations, or molecular structures of the components are changed. Thus, phase diagrams offer not only another way to define microemulsions, but also a rigorous way to clarify differences in terminology and usage.

Figure 1 illustrates the phase diagram of an amphiphile–oil–water system such as $C_4H_9OC_2H_4OH$ ("4E1")–decane–water or $C_6H_{12}(OC_2H_4)_2OH$ ("C6E2")–tetradecane–water. For a real surfactant, such as C12E4, the diagram would be more complicated, because of the occurrence of liquid crystalline phases. Samples whose compositions fall within the tie-triangle of Figure 1 form three liquid phases, of compositions, *T*, *M*, and *B* (corners of the tietriangle). Each pair of adjacent corners of the tietriangle is connected by a binodal curve (as well as by a side of the tietriangle). Compositions between a side of the tietriangle and the adjacent binodal curve form two conjugate phases in equilibrium with each other; each such pair of phases is connected by a tieline. For two of the binodals the compositions of the conjugate phases can become closer and closer and their connecting tielines shorter and shorter, until the phase compositions and the end points of the tielines become identical at a plait point. Any composition outside of the tietriangle and the three binodal curves forms only a single liquid phase. On the amphiphile–water side of the phase diagram these single-phases contain only amphiphile and water (no oil); on the amphiphile–oil side of the phase diagram these single-phases contain only amphiphile and oil (no water).

By the most general definition of a microemulsion, every phase described by Figure 1 would be a microemulsion. When two (or even three) phases are simultaneously present, little (except confusion) is gained by giving the different phases the same name. Accordingly, along the binodal curves (which describe the compositions of conjugate phases) only compositions between the two plait points are termed microemulsions. Other conjugate phases are called oleic phases or aqueous phases, respectively, depending on whether their main component is oil or water.

In Figure 1, the pairs (or triad) of phases that form in the various multiphase regions of the diagram are illustrated by the corresponding

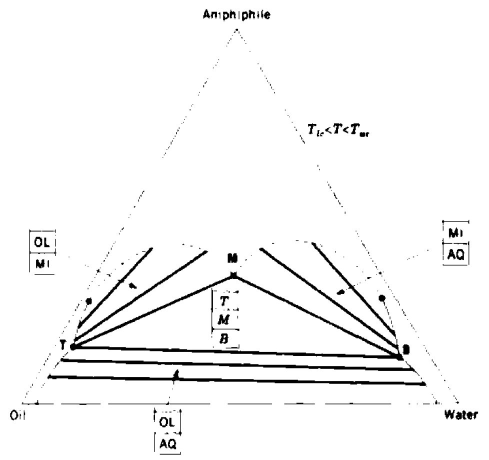

Fig. 1. Phase diagram of an amphiphile-oil-water system that forms a middle-phase microemulsion, definition of microemulsion, and illustration of the pairs (and triad) of phases formed in the various multiphase regions of the diagram. Boundaries: —, aqueous (AQ): — — —, oleic (OL): — — — —, limiting microemulsion (MI)

test-tube samples. Except in rare cases, the densities of oleic phases are less than the densities of conjugate microemulsions and the densities of microemulsions are less than the densities of conjugate aqueous phases. Thus, for samples whose compositions lie within the oleic phase-microemulsion binodal, the upper phase (i.e., layer) is an oleic phase and the lower layer is a microemulsion. For compositions within the aqueous phase-microemulsion binodal, the upper layer is a microemulsion and the lower layer is an aqueous phase. When a sample forms two layers, but the amphiphile concentration is too low for formation of a middle phase, neither layer is a microemulsion. Instead the upper layer is an oleic phase ("oil") and the lower layer is an aqueous phase ("water").

In three-phase systems the top phase, *T*, is an oleic phase, the middle phase, *M*, is a microemulsion, and the bottom phase, *B*, is an aqueous phase. Microemulsions that occur in equilibrium with one or two other phases are sometimes called "limiting microemulsions," because they occur at the limits of the single-phase region.

Temperature and Salinity Scans

The locations of the tietriangle and binodal curves in the phase diagram depend on the molecular structures of the amphiphile and oil, on the concentration of cosurfactant and/or electrolyte if either of these components is added, and on the temperature (and, especially for compressible oils, on the pressure).

Often the identities (aqueous, oleic, or microemulsion) of the layers can be deduced reliably by systematic changes of composition or temperature. Thus, without knowing the actual compositions for some amphiphile and oil of points *T*, *M*, and *B* in Figure 1, an experimentalist might prepare a series of samples of constant amphiphile concentration and different oil–water ratios, then find that these samples formed the series (*a*) 1 phase, (*b*) 2 phases, (*c*) 3 phases, (*d*) 2 phases, (*e*) 1 phase as the oil–water ratio increased. As illustrated by Figure 1, it is likely that this sequence of samples constituted (*a*) a "water-continuous" microemulsion (of normal micelles with solubilized oil), (*b*) an upper-phase microemulsion in equilibrium with an excess aqueous phase, (*c*) a middle-phase microemulsion with conjugate top and bottom phases, (*d*) a lower-phase microemulsion in equilibrium with excess oleic phase, and (*e*) an oil-continuous microemulsion (perhaps containing inverted micelles with water cores).

Physical Properties and Applications

The current or potential industrial applications of microemulsions include metal working, catalysis, advanced ceramics processing, production of nanostructured materials, dyeing, agrochemicals, cosmetics, foods, pharmaceuticals, and biotechnology. Environmental and human-safety aspects of surfactants are receiving considerable attention. See also **Nanotechnology (Molecular)**.

Microemulsions became well known from about 1975 to 1980 because of their use in "micellar-polymer" enhanced oil recovery (EOR). This technology exploits the ultralow interfacial tensions that exist among top, microemulsion, and bottom phases to remove large amounts of petroleum from porous rocks, that would be unrecoverable by conventional technologies. Since about 1990, interest in the use of this property of microemulsions has focused on the recovery of chlorinated compounds and other industrial solvents from shallow aquifers. The latter application is sometimes called surfactant-enhanced aquifer remediation (SEAR).

Microemulsions and Macroemulsions

Operationally, it is not always easy to determine whether a given sample is a microemulsion or macroemulsion. However, the formal differences between microemulsions and macroemulsions are well defined. A microemulsion is a single, thermodynamically stable, equilibrium phase; a macroemulsion is a dispersion of droplets or particles that contains two or more phases, which are liquids or liquid crystals.

From the definitions of microemulsions and macroemulsions and from Figure 1, it immediately follows that in many macroemulsions one of the two or three phases is a microemulsion. Until recently, it was thought that all nonmultiple emulsions were either oil-in-water (O/W) or water-in-oil (W/O). However, the phase diagram of Figure 1 makes clear that there are six nonmultiple, two-phase morphologies, of which four contain a microemulsion phase. These six two-phase morphologies are oleic-in-aqueous (OL/AQ, or O/W) and aqueous-in-oleic (AQ/OL, or W/O), but also, oleic-in-microemulsion (OL/MI), microemulsion-in-oleic (MI/OL), aqueous-in-microemulsion (AQ/MI), and microemulsion-in-aqueous (MI/AQ).

MICROENCAPSULATION. Microencapsulation is the coating of small solid particles, liquid droplets, or gas bubbles with a thin film of coating or shell material. Here, the term microcapsule is used to describe particles with diameters between 1 and 1000 μm. Particles smaller than 1 μm are called nanoparticles; particles greater than 1000 μm can be called microgranules or macrocapsules.

Many terms have been used to describe the contents of a microcapsule: active agent, actives, core material, fill, internal phase (IP), nucleus, and payload. Many terms have also been used to describe the material from which the capsule is formed: carrier, coating, membrane, shell, or wall. In this article the material being encapsulated is called the core material; the material from which the capsule is formed is called the shell material.

Table 1 lists representative examples of capsule shell materials used to produce commercial microcapsules along with preferred applications.

Microcapsules can have a wide range of geometries and structures. Figure 1 illustrates three possible capsule structures. Parameters used to characterize microcapsules include particle size, size distribution, geometry, actives content, storage stability, and core material release rate.

Encapsulation Process

Classification of the many different encapsulation processes is useful. Previous schemes employing the categories chemical or physical are unsatisfactory because many so-called chemical processes involve exclusively physical phenomena, whereas so-called physical processes can utilize chemical phenomena. An alternative approach is to classify all encapsulation processes as either Type A or Type B processes. Type A processes are defined as those in which capsule formation occurs entirely in a liquid-filled stirred tank or tubular reactor. Emulsion and dispersion stability play a key role in determining the success of such processes. Type B processes are processes in which capsule formation occurs because a coating is sprayed or deposited in some manner onto the surface of a liquid or solid core material dispersed in a gas phase or vacuum. This category also includes processes in which liquid droplets containing core material are sprayed into a gas phase and subsequently solidified to produce microcapsules. Emulsion and dispersion stabilization can play a key role in the success of Type B processes also.

Many Type A and Type B processes are similar. For example, solvent evaporation is a key step in most spray dry encapsulation protocols (Type B) and protocols involving solvent evaporation from an emulsion (Type A). The difference in these protocols is that evaporation in the former case occurs directly from a liquid to a gas phase, whereas in the latter case evaporation involves transfer of a volatile liquid from a dispersed phase to a continuous liquid phase from which it is subsequently evaporated. Another example is encapsulation by gelation. In Type A gelation processes, the droplets that are gelled and become microcapsules are formed by dispersion in a liquid phase and are gelled in this phase. In Type B gelation processes, droplets formed by atomization or extrusion into a gas phase are subsequently gelled either in the gas phase or a liquid gelling bath.

TABLE 1. SHELL MATERIALS USED TO PRODUCE COMMERCIALLY SIGNIFICANT MICROCAPSULES

Shell material	Regulatory status	Chemical class	Encapsulation process	Applications
gum arabic	edible	polysaccharide	spray drying	food flavors
gelatin	edible	protein	spray drying	vitamins
gelatin-gum arabic[a]	nonedible[b]	protein-polysaccharide complex	complex coacervation	carbonless paper
ethylcellulose	edible	cellulose ether	Wurster process or polymer—polymer incompatibility	oral pharmaceuticals
polyurea or polyamide	nonedible	cross-linked polymer	interfacial polymerization	agrochemicals and carbonless paper
aminoplasts	nonedible	cross-linked polymer	*in situ* polymerization	carbonless paper, fragrances, and adhesives
maltodextrins	edible	low molecular weight carbohydrate	spray drying and desolvation	food flavors
hydrogenated vegetable oils	edible	glycerides	fluidized bed	assorted food ingredients

[a] Treated with glutaraldehyde.
[b] For intended application, i.e., carbonless paper.

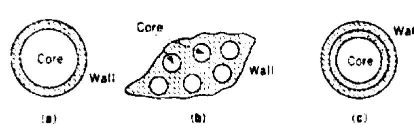

Fig. 1. Schematic diagrams of several possible capsule structures: **(a)** continuous core/shell microcapsule in which a single continuous shell surrounds a continuous region of core material; **(b)** multinuclear microcapsule in which a number of small domains of core material are distributed uniformly throughout a matrix of shell material; and **(c)** continuous core capsule with two different shells.

Most Type A processes might be classified as chemical processes, whereas most Type B processes are classified as mechanical processes. Representative examples of both types of processes follow. Type B processes tend to be promoted by organizations that sell and service equipment for producing microcapsules. Most Type A processes are not promoted by equipment manufacturers, but are developed and used by organizations that produce microcapsules.

Type A processes	Type B processes
complex coacervation	spray drying
polymer–polymer incompatibility	fluidized bed
interfacial polymerization at liquid–liquid and solid–liquid interfaces	interfacial polymerization at solid–gas or liquid–gas interfaces
in situ polymerization	centrifugal extrusion
solvent evaporation or in-liquid drying	extrusion or spraying into a desolvation bath
submerged nozzle extrusion	rotational suspension separation (spinning disk)

Applications

Microcapsules are used in a number of pharmaceutical, graphic arts, food, agrochemical, cosmetic, and adhesive products. Other specialty products also exist, thus the concept of microencapsulation has been accepted by a wide range of industries. In order to illustrate how microcapsules are used commercially, it is appropriate to describe a number of commercial microcapsule-based products and the role that microcapsules play in these products.

Carbonless copy paper is by far the largest single commercial application of microcapsules. This product consumes thousands of tons of capsules annually. Figure 2, a schematic diagram of a three-part business form, illustrates the concept of carbonless copy paper.

Success of all carbonless paper products depends on the microcapsules, leuco dyes, and reactive coating. A number of leuco dyes are available.

The concept of microencapsulation has intrigued the pharmaceutical industry for many years, because it offers the possibility of providing a number of important new oral and parenteral dosage forms. Microcapsules in oral dosage forms could conceptually taste-mask bitter pharmaceuticals, provide extended release *in vivo*, provide enteric release, improve the stability of incompatible drug mixtures, provide resistance to oxidation, reduce volatility, and distribute a drug in many small carrier particles so that effects of the drug on the sensitive walls of the stomach are minimized. Microencapsulated parenteral formulations could provide prolonged delivery of drugs with short half-lives *in vivo* and perhaps even achieve targeted drug delivery. For these reasons, microencapsulation has received much attention by pharmaceutical scientists. Several microcapsule-based oral pharmaceutical formulations which offer some of these features are available.

The use of microcapsules for a variety of biomedical and biological applications has been promoted for many years. Several biomedical microcapsule applications are in clinical use or have approached clinical use. One application is the use of air-filled human albumin microcapsules as ultrasound contrast agents. Another biomedical application of microcapsules is the encapsulation of live mammalian cells for transplantation into humans. The purpose of encapsulation is to protect the transplanted cells or organisms from rejection by the host.

A number of food ingredients or additives have been encapsulated and are available commercially. Solid ingredients encapsulated are typically water-soluble and are encapsulated with a hydrophobic or hydrophilic coating material usually applied by the Wurster process. Both types of coating materials are well-accepted food-grade products (see **Food Additives**).

The microencapsulation of pesticides (qv) and herbicides (qv) has been an active area of development that has produced several commercial products. The function of the microcapsules is to prolong activity while reducing mammalian toxicity, volatilization losses, phytotoxicity, environmental degradation, and movement in the soil. Ideally, encapsulation would also reduce the amount of agrochemical needed.

Advertising inserts that utilize encapsulated perfumes and flavors contain a coating of scent-filled capsules which break and release scent when the insert is torn open are widely used as a marketing tool, primarily for new perfumes. Children's crayons loaded with encapsulated scents are appearing on the market. The capsules break during the drawing process thereby releasing a scent characteristic of the drawn object.

Microcapsules are used in several film coatings other than carbonless paper. Encapsulated liquid crystal formulations coated on polyester film are used to produce a variety of display products including thermometers. Polyester film coated with capsules loaded with leuco dyes analogous to those used in carbonless copy paper is used as a means of measuring line and force pressures. Encapsulated deodorants that release their core contents as a function of moisture developed because of sweating represent

another commercial application. Microcapsules are incorporated in several cosmetic creams, powders, and cleansing products.

A majority of the fasteners used in automobiles in the U.S. are coated with microcapsules loaded with an adhesive. Other uses include encapsulated ammonium polyphosphate incorporated in plastics that acts as a fire-retardant and microencapsulated oil-field chemicals for use by the oil industry.

MICROGRAVITY AND MATERIALS PROCESSING. The development of space transportation systems during the past several years has drawn attention to materials processing in a reduced gravity environment. Actually, exploratory work in this area has been proceeding since the early *Apollo* missions to the moon. For example, materials processing experiments were carried out during the *Skylab* program and on the *Apollo-Soyuz* test program fight. More recently, tests have been conducted on some of the *Space Shuttle* projects and the International Space Station (ISS).

Effects of Reduced Gravity. The reduced gravity of space offers a unique environment for materials processing. It is untrue, of course, to claim that a state of zero gravity is achieved as, for example, on space flights as currently experienced. Rather, the gravity is greatly reduced—to about 10^{-6} g. Hence, the term *micro* rather than *zero* gravity is more appropriate to use here. It is interesting to note that spacecraft in low earth orbit may experience changes in the gravitational field, referred to as *g-jitter*, which are caused by such factors as maneuvering the craft while in orbit, atmospheric drag, and even movement of the crew within the spacecraft. The *g-jitter* phenomenon can cause "spikes" in the gravitational field, ranging from 10^{-2} g to 10^{-1} g. These may have an adverse effect upon on-board experiments and processes.

Manned or unmanned orbital spaceflight is not the only possibility for reduced-gravity studies of materials processing. Drop tubes and towers, aircraft, and sounding rockets also offer opportunities for varying levels and time periods of reduced gravity. Time spent in low gravity and payload size are the limiting factors for earth-based facilities. Drop tube experiments provide 2.5 to 4.5 seconds at 10^{-8} g to 10^{-9} g for free falling droplets, whereas a drop tower allows an entire experimental package, weighing 100 kg, to be tested. By flying in parabolic flight paths, aircraft ranging in size from a KC-135 to a single-seat F-104 can provide 10^{-1} g to 10^{-2} g for 15 to 60 seconds for payloads ranging from 10 to 35 kg. Sounding rockets provide up to 300 seconds at 10^{-5} g. When compared with the duration time provided by an orbiting space platform, the earthbound methods are quite brief.

One effect of the reduction of gravitational forces experienced in space is the virtual elimination of *buoyancy-driven convection*. Convection within a fluid medium arises when the medium is subjected to a nonvertical thermal gradient. Temperature differences create density gradients as gases or liquids expand upon heating. In the presence of a gravitational field, the less dense volume of the medium is displaced by a denser, cooler volume, resulting in the circulation of gases or liquids, commonly known as convective flow.

A more unstable form of convection occurs when a denser fluid lies above a less dense fluid, corresponding to a situation where the medium is heated from below. If viscous forces outweigh the buoyant forces within the medium, this unstable condition can be maintained. If the buoyancy is greater than the viscosity, however, the volume element rises too quickly, resulting in spontaneous flow, which takes the form of cells or vortex rolls.

Concentration gradients caused by chemical reaction within a fluid medium may also cause convection. In this case, density gradients occur when a particular chemical component is consumed or produced by reaction.

Convective flow is mathematically characterized by the Grashof number *Gr*, which represents the ratio of buoyant to viscous forces. The Grashof number is given by the expression

$$Gr = \frac{gl^3\beta\Delta T}{\mu^2}$$

where g is the gravitational acceleration; β the coefficient of expansion; ΔT the temperature gradient; and μ the kinematic viscosity. In an earth-based experiment, convection can be reduced somewhat within practical limits by altering the geometry of a given system or minimizing temperature gradients. Conducting a similar experiment in low earth orbit can reduce the value of *Gr* by six orders of magnitude.

Because convection and diffusion occur simultaneously in an earth-based process, corresponding studies in a microgravity environment can help identify the effects of these two phenomena on a given process such as crystal growth.

The reduced gravity of space can also be used to process materials in a container-free environment. This feature of microgravity processing is particularly advantageous when a material of high purity is desired, or for achieving a high degree of supercooling in a sample. Containerless processing is especially useful for obtaining glasses and alloys.

The presence of a gravitational field causes substances of differing densities to separate out. In microgravity, however, this gravity-induced separation is eliminated, thereby producing a more uniform mixture. This effect is useful in the processing of alloys and organic polymers.

Representative Microgravity Experiments

Biological Materials. The degree of purity of biological materials severely limits their usefulness. Electrophoresis is a commonly used method of separation and purification of substances such as cells, enzymes, and proteins. This technique relies upon the fact that surface charge distribution, and thus mobility in an electric field, vary from one material to another. The degree of separation, product yield, and purity are limited by convection which is caused by concentration gradients within the process medium.

A continuous flow electrophoresis (CFE) process has been used to effect separation of biological materials in microgravity. The absence of convection permits continuous processing of relatively large volumes of material, higher yields, finer separation, and higher product purity than are possible on earth. Erythropoietin, which is produced by the kidneys and controls red blood cell production in the body, has been produced by CFE on board the *Shuttle*. The first CFE experiment performed in 1982 in *Spacelab* yielded 463 times more material than comparable earth-based processes. Separation rates were boosted in later flights to yield 700 times more material having a fourfold increase in purity over products obtained on earth.

Polymers. Research efforts in the area of organic polymer growth in space seek to take advantage of the absence of phase separation due to density differences. On earth, density differences in nonhomogeneous mixtures of organic liquids produce buoyancy-driven convection and cause immiscible liquids to separate. These phenomena affect the growth of organic polymers, causing flaws in the final product. In the absence of phase separation and convection, more uniform mixtures can be produced. Secondary effects such as surface tension can also be utilized to obtain more perfect polymers and organic compounds.

One type of experiment performed in space was the diffusive mixing of organic solutions (DMOS) study conducted by the 3M Corporation. The DMOS experiments mixed different types of organic solutions to yield crystalline material. The purpose of the study was to determine the effect of microgravity upon the ordering of organic molecules upon crystallization. The crystals grown in the experiment were not only significantly larger than similar crystals grown on earth, but possessed much better optical and electrical properties as well.

The dominance of surface tension, due to the lack of convection in microgravity, has been used to produce perfectly round spheres of polystyrene-latex. The spheres are grown in space by the coalescence of an emulsion. Under conditions where surface tension controls the process, droplets do not readily break up, thereby allowing large spheres to coalesce. As a result, large, perfect spheres, having a diameter of up to 30 mm, can be produced in space. In comparison, a maximum diameter of 5 mm can be

produced on earth. These spheres are offered commercially for reference and calibration applications. As such, they are the first commercial products to be made in space.

Physical Metallurgy. One obstacle to the processing of alloys on earth is that components of a given mixture are often immiscible. As a result, density differences cause the components to separate as the bulk melt cools. By eliminating this gravity-driven separation, the manufacture of alloys can benefit from a microgravity environment.

Several alloy systems have been studied in space. In general, these experiments have yielded promising results, showing that finer, more homogeneous mixtures of components can be obtained in microgravity. In space, reduced convection in the melt apparently reduces microsegregation and heat transfer. This allows materials possessing highly directional physical properties, such as magnetic coercivity and microstructure, to be produced.

Containerless processing is also of interest in physical metallurgy, as it provides opportunities to study thermophysical properties of high temperature metals and alloys, avoid sample contamination due to contact with container walls, and observe the solidification of materials that have been rapidly cooled from the melt.

Containerless processing is accomplished on earth under the influence of gravity by using electrostatic, acoustic, or electromagnetic energy to levitate a sample. Sample size is limited, however, by power requirements for levitation. The application of the forces necessary to levitate a substance also induces a certain amount of mixing and heating. Gravity-driven convection is also present in this situation and can cause unwanted mixing of liquid samples.

To date, containerless processing in near zero gravity has been limited to drop tube experiments, which provide a few seconds of low gravity for small drops of material. Alloys studied in this fashion have been undercooled as much as 500°C, which corresponds to a cooling rate of greater than 10^6 K/sec. Samples obtained in these experiments have exhibited metastable or peritectic phases which are extremely difficult to obtain under normal conditions.

Some levitation of samples will still be necessary to carry out containerless processing in space, although the magnitude of the forces necessary to do so will be small relative to those required in earth-based work. Levitation would be necessary only to avoid contact between sample and container, so larger samples could be used in space-based experiments.

Other metallurgy experiments scheduled for space will examine the role of macrosegregation in the processing of metals, the feasibility of using directional solidification in the processing of different classes of alloys, and the manufacture of alloys which cannot be produced on earth due to density induced separation.

Glasses. The manufacture of glasses also benefits from containerless processing in space. As with alloys, the purity of glasses can be affected by contact and subsequent reaction with container walls. In the case of glass processing, however, contact between sample and reactor wall also causes crystallization, and hence loss of the amorphous glassy state. In addition, less viscous glasses require high cooling rates in order to prevent crystallization. By avoiding contact-induced nucleation during cooling, containerless processing may be used to obtain larger, high purity samples of such glasses.

As mentioned previously, some levitation is required in microgravity to maintain sample positioning. Several designs, some of which are capable of processing temperatures up to 1600°C, have been developed for use in space experiments.

Glass processing experiments that have already been flown on the *Shuttle* have been concerned with melt homogenization, bubble behavior in molten glass spheres, preparation of glass microballoons, and comparing properties of space-produced glasses with those manufactured on earth. Results to date indicate that glasses having different microstructures than those of glasses processed on earth can be obtained. Galliacalcia, sodium-borate, and lead-silica glasses have been selected for the above experiments. The list of glasses to be studied will be expanded to include materials that are particularly difficult to produce on earth. Among these materials are heavy cation (Zr, Hf, Th) glasses that tend to react with containers, and silica glasses that must be processed at high temperatures.

Crystal Growth. Single crystals of both organic and inorganic substances can be grown from either the vapor or liquid phase, using several different experimental techniques. Gravity-driven convection affects the motion of these fluid media, greatly affecting the mixing and transport of individual chemical components. Experiments aimed at examining the effects of eliminating buoyancy-driven convection upon different crystal growth techniques have been performed on *Skylab*, the *Apollo-Soyuz* mission, and several *Space Shuttle* flights.

Growth of crystals from the vapor relies upon the presence of a temperature gradient. Concentration gradients of vapor species and subsequent migration from a source region to a seed crystal, substrate, or deposition region are caused by this temperature difference. In the case of physical vapor transport (PVT), solid source material vaporizes at one temperature. The gaseous vaporization products migrate, usually through an atmosphere of inert gas, to another temperature where solid material condenses. In space, the PVT method has been used to grow highly ordered organic thin films onto silicon wafer substrate and large single crystals of germanium selenide.

Another PVT experiment examined the growth of HgI_2 onto a seed crystal. This substance has potential for use as a radiation detector. Due to its high density, however, the HgI_2 crystal structure readily deforms during earth-based processing. Large crystals of HgI_2 have been grown by the PVT method aboard *Spacelab 3*. Growth times in space were considerably less than those normally required on earth. Performance of the space-grown crystals as radiation sensors is matched by only the very best crystals obtained on earth.

Unlike PVT, chemical vapor transport (CVT) utilizes a highly reactive gaseous substance—such as a halogen or metal halide—to transport source material to a region of the reaction container where single crystals condense from the vapor. In earth-based CVT studies, under conditions where buoyancy-driven convection drives the overall transport process, crystal size is generally small. The morphology of crystals grown under these conditions is often poor; surfaces are marked by large numbers of defects and irregular growth steps. In contrast, space-grown crystals grown by chemical vapor transport are much larger, have smoother growth steps, and fewer defects. Chemical homogeneity within these crystals is also considerably better than in similar crystals grown on earth.

The presence of convection also affects crystal growth from the melt. Single crystals of Te-doped InSb were grown from the melt on *Skylab*. The crystals obtained in space were free of striations caused by convection-driven growth rate fluctuations that are normally seen on earth. Future space experiments will examine the growth of electronic materials such as GaAs from a solution subjected to an electric current.

MICRONUTRIENTS (Soil). See **Fertilizer**.

MICROSCOPY (Chemical). Use of a microscope primarily for study of physical structure and identification of materials. This is especially useful in forensic chemistry and police laboratories. Many types of microscopes are used in industry; most important are the optical, ultra-, polarizing, stereoscopic, electron, and X-ray microscopes. Organic dyes of various types are used to stain samples for precise identification.

MICROWAVE SPECTROSCOPY. A type of adsorption spectroscopy used in instrumental chemical analysis that involves use of that portion of the electromagnetic spectrum having wavelengths in the range between the far infrared and the radiofrequencies, i.e., between 1 mm and 30 cm. Substances to be analyzed are usually in the gaseous state. Klystron tubes are used as microwave source.

MIDGLEY, THOMAS, JR. (1889–1944). An American chemist and inventor. One of the most creative and brilliant chemists of his era. Midgley's early work was in the field of rubber chemistry and technology, especially in the development of synthetic and substitute rubbers that were being introduced in the 1930s. He worked with Kettering at General Motors and then became vice president of Ethyl Corporation, as well as of the Ohio State University Research Foundation. His innovative genius was responsible for the development of organic lead compounds for antiknock gasoline and later for the discovery of fluorocarbon refrigerants for which he did the basic research. He was recipient of many of chemistry's highest honors including the Nichols medal, the Perkin medal, and the Priestly medal.

MIESCHER DEGRADATION. Adaptation of the Barbier-Wieland carboxylic acid degradation to permit simultaneous elimination of three carbon atoms, as in degradation of the bile acid side chain to the methyl ketone stage. Conversion of the methyl ester of the bile acid to the tertiary alcohol, followed by dehydration, bromination, dehydrohalogenation, and oxidation of the diene yields the required degraded ketone.

MIGNONAC REACTION. Formation of amines by catalytic hydrogenation of aldehydes and ketones in liquid ammonia and absolute ethanol in the presence of a nickel catalyst.

MILK AND MILK PRODUCTS. Intricate chemical and microbiological problems arise in the production, processing, and distribution of milk products. Milk is a complex mixture of fat (4%), protein (3.5%), carbohydrate (4.8%) and mineral components (0.7%) and is an excellent bacterial growth medium; hence the need for care and cleanliness in handling.

Milk Fat

Milk fat or butterfat is a mixture of triglycerides of various fatty acids. Milk fat also contains a small percentage of cholesterol (0.37%), a substance characteristic of fats and oils of animal origin in contrast to those of plant origin which contain plant sterols. The phospholipids, lecithin, caphalin, and sphingomyelin are present in milk within the range of 0.03–0.04%. These are fatlike substances containing phosphorus and nitrogen. They have emulsifying properties and are associated with the fat-globule surfaces; hence their tendency to concentrate in butter and buttermilk.

Milk fat is distinguished from all other fats in that it is the only one containing butyric acid (C_4) as a component of glycerides. This acid occurs in the fat in a concentration of approximately 10 mole % and the total of C_6, C_8, and C_{10} fatty acids accounts for another 10 mole % of the component fatty acids. These acids (C_4–C_{10}) are often called the volatile fatty acids of milk fat. In the free form, they have a pungent characteristic flavor which is important in many types of cheese.

The deterioration of milk fat is an important cause of off-flavor development in dairy products and its control requires technical understanding of the processes involved. Three major types of deterioration associated with milk fat are recognized:

(1) *Rancidity*, due to free volatile fatty acids liberated from the glycerides by enzymic (lipase) hydrolysis. Lipases are normal components of raw milk, and are inactivated by the heat of pasteurization.

(2) *Tallowiness or oxidation*, due to autoxidation of unsaturated fatty acids with the production of flavorful unsaturated aldehydes. These reactions are accelerated by oxygen, high storage temperatures, and copper catalysts. Oxidation is usually the primary cause for spoilage of dried whole milk, cream, butter, and butteroil.

(3) *Heat-generated flavors*, due to the formation of lactones and methyl ketones from hydroxy and keto acid precursors, which occur in trace quantities in milk fat. These flavors are considered to be desirable in fried and baked goods and are partly responsible for the unique condiment properties of butter in food preparation. However, they are undesirable in dried whole milk and evaporated milk where the objective is to make a bland product as much like fresh milk as possible.

Proteins

The proteins of milk fall into two groups: casein, precipitable by both acid and proteolytic enzymes such as rennin; and whey proteins, which are acid soluble but heat-denaturable. There is about 3% casein in milk, the removal of which leaves a whey of approximately 1.0% nitrogenous matter. Of this 0.6% is heat-coagulable protein and 0.4% is nonheat-coagulable. The latter fraction is composed of protein-like fragments of a proteose or peptone nature plus other nitrogenous substances. Among these are small percentages of urea, creatin, creatinine, uric acid, and various forms of amino nitrogen.

Casein exists in milk as a calcium caseinate-calcium phosphate complex; the ratio of these components is approximately 95.2 to 4.8. The dispersed casein particles appear to be spherical in shape and of various sizes. The size distribution of the casein micelles is not constant, but varies with aging, heating, concentration, and other processing treatments. Processing alters the water-binding of casein and this in turn affects the apparent viscosity of products that contain casein. Changes in hydration have not been measured quantitatively although the casein particles of raw milk appear to consist of one volume of water-free protein and three volumes of solvate liquid.

The whey or serum proteins have been partially resolved into three relatively homogeneous, crystallizable proteins: (1) β-lactoglobulin (50% of total serum protein), (2) an albumin resembling the albumin of bovine blood (5% of the serum protein), and (3) α-lactalbumin (12% of the serum protein).

On heat denaturation, the serum proteins show decreased solubility at pH 4.7 and in concentrated salt solutions. There is some variability in response toward heat treatment, but complete denaturation will occur during heating within the range of 60 to 80°C for periods of time up to two hours. There is practically no denaturation during normal pasteurization. Heat increases the activity of the sulfhydryl groups and the sulfhydryl titer can be employed as a measure of denaturation. The –SH groups are readily oxidized in liquid systems and consequently they appear to act as antioxidants to protect milk fat in dairy products. The fat of fluid milk, heated to produce a high –SH titer, shows increased resistance to oxidation and this carries through to the dried product which exhibits superior storage stability, if it is made from high heat milk. The high sterilization temperature to which evaporated milk is subjected and the low oxygen content in the can protect this product from development of oxidized and tallowy flavors during storage. See **Proteins**.

Milk is widely used as an ingredient for bread and other baked goods to which it adds substantial nutritional value. Milk is heated when used in bread to avoid softening of the dough and reduction of loaf volume. Why heat improves the baking properties of milk is not clear, but good baking properties have long been associated with low whey-protein-nitrogen values.

Lactose

The sugar of milk, lactose ($C_{12}H_{22}O_{11}$), occurs in the milk of all mammals. It is mildly sweet with a final solubility in water of 10.6% at 0°C, 17.8% at 25°, 29.8% at 49°, 58.2% at 89°. Lactose, on hydrolysis by acid or the enzyme lactase, yields a mixture of approximately equal parts of glucose and galactose, together with a small but variable quantity of oligosaccharides. The products of lactose hydrolysis are much more soluble than the original disaccharide. Lactose is a reducing sugar which is converted to lactobionic acid on mild oxidation. Two forms which differ in solubility and optical rotation are known. Alpha-lactose hydrate crystallizes at ordinary temperatures with one molecule of water, but this is lost with the formation of the anhydrous form during heating to a temperature between 149 and 200.3°F. Anhydrous β lactose, more soluble than alpha, crystallizes from supersaturated lactose solutions above 200.3°F. Solid beta-hydrate has never been prepared. The crystalline alpha-hydrate is stable in dry air at room temperatures, but both anhydrous forms readily absorb moisture and change to alpha-hydrate at ordinary temperatures. Alpha-lactose crystallizes out in some dairy products and because of the hardness of its crystals and their slow and limited solubility, "sandy" products may result.

The crystallization of lactose in frozen concentrated milk has been associated with a denaturation of casein which ultimately appears as a gel structure in the thawed product. Gelation in frozen milk can be retarded by enzymic hydrolysis of part of the lactose before freezing or by addition of a polyphosphate salt.

Lactose, when fermented by lactic bacteria, is the source of the lactic acid formed in sour milk and whey. Lactose is helpful in establishing a slightly acid reaction in the intestine, which assists in calcium assimilation.

Mineral Components

When milk is heated to a temperature high enough to volatilize the water and oxidize the organic constituents, the residue of inorganic oxides that remains is called the milk ash; its major components are: K_2O, CaO, Na_2O, MgO, Fe_2O_3, P_2O_5, Cl, and SO_3. The calcium and phosphorus of the ash are of special interest because of their nutritional importance and because calcium phosphate is part of the casein micelle, influencing its physiochemical behavior toward coagulation with rennin, acid, and heat. Minor inorganic constituents are present in milk in trace amounts, i.e., iron, copper, zinc, aluminum, manganese, iodine, and cobalt.

Miscellaneous Components

The hydrogen-ion concentration of milk increases slightly with age, after milking, as natural carbon dioxide escapes. Most samples of cow's milk vary within the range of pH 6.5–6.7. Titratable acidity of fresh milk which

may vary from 0.13 to 0.16%, expressed as lactic acid is an arbitrary measurement influenced by the protein and salt-buffer systems present in the particular sample. Citrates, phosphates, and carbonates are the principal buffers in milk.

Milk contains some important vitamins. The vitamin D content may vary from 30 I.U. per quart in summer to 6 in winter, depending upon the feed and the sunlight which reach the cow. Both pasteurized and evaporated milk are often fortified by the addition, on a fluid basis, of 400 I.U. of vitamin D per quart. Vitamins A, D, and E (alpha-tocopherol) are fat-soluble and stable at the heat treatments used in processing milk and milk products. The remaining vitamins are water-soluble and of varying stability. Vitamins B_1 (thiamine) and C (ascorbic acid) are partially destroyed by heat, while B_6 and B_{12}, are relatively heat-stable. Vitamin B_2 (riboflavin) is heat-stable but it is quickly destroyed by light. In spite of the varying sensitivity of the water-soluble vitamins toward heat, pasteurized milk is a good source of all the milk vitamins except C.

Two types of enzymes in milk are important: those useful as an index of heat treatment and those responsible for bad flavors. Phosphatase is destroyed by the heat treatments used to pasteurize milk; hence its inactivation is an indication of adequate pasteurization. Lipase catalyzes the hydrolysis of milk fat which produces rancid flavors. It must be inactivated by pasteurization or more severe heat treatment to safeguard the product against off-flavor development. Other enzymes reported to have been found in milk include catalase, peroxidase, protease, diastase, amylase, oleinase, reductase, aldehydrase, and lactase.

MILLER INDICES. In mineral crystallography the identity of a crystal face consists of a series of whole numbers which are the products of their parameters relating to that face by their inversion, and where required the clearing of fractional values. A parameter is the relative intercept of a crystallographic axis on a given crystal face.

Assuming parameter values on a given crystal face to be $1a$, $1b$, $\frac{1}{2}c$ would on inversion yield 1, 1, $\frac{2}{1}$ parameters $1a$, $1b$, $2c$ would on inversion yield 1, 1, $\frac{1}{2}$ and parameters of $3a$, $2b$, $6c$ would on inversion yield $\frac{1}{3}$, $\frac{1}{2}$, $\frac{1}{6}$. Clearing the fractions in each instance would yield Miller indices of (112), (221) and (231) respectively.

The three Miller indices for a crystal face in all systems except the hexagonal, which requires four indices, are always given in the same order as their crystallographic axes, a, b, c, respectively: a^1, a^2, a^3, in the isometric system; a^1, a^2, c, in the tetragonal system; and a^1, a^2, a^3, c, in the hexagonal.

If the parameter intercepts for a given face are unknown, general indices (hkl) may be used if that face intercepts all three axes; four in the hexagonal, with general indices $(hkil)$. If a crystal face cuts two axes and parallels the third, general indices would be identified as $(h0l)$, $(0kl)$, or $(hk0)$ as applicable to that face; in the hexagonal system as $(h0hl)$, etc.

See also **Crystal**; and **Mineralogy**.

MILLERITE. The mineral millerite is nickel sulfide, NiS, whose slender hexagonal interwoven crystals so suggestive of hairs has led to the application of the name "capillary pyrites." It occurs also as radiated masses and coatings. It is brittle; hardness, 3–3.5; specific gravity, 5.48–5.52; luster, metallic; color, brass-yellow, often with an iridescent tarnish. Millerite is found in association with other nickel-bearing minerals and other sulfides. European localities are Bohemia, Westphalia, Wales, etc.; and in the United States at Antwerp, New York; with pyrrhotite in Lancaster County, Pennsylvania; at St. Louis, Missouri; Keokuk, Iowa; and Milwaukee, Wisconsin. In Canada millerite occurs in Oxford, Quebec, and in the famous Sudbury District, Ontario. It is used as an ore of nickel. Millerite was named for the English mineralogist, W.H. Miller.

MIMETITE. The mineral mimetite is a chloro-arsenate of lead corresponding to the formula $Pb_5(AsO_4)_3Cl$. It is monoclinic (pseudohexagonal); brittle; hardness, 3.5; specific gravity, 7.0–7.25; luster, resinous; color, usually yellow to brown but may be colorless or white; translucent. Mimetite is a rather rare secondary mineral occurring in altered lead deposits. Found in Bohemia; Saxony; Cornwall and Cumberland, England; South West Africa; Mexico; and in the United States, in Pennsylvania and Utah. The name mimetite is derived from the Greek word meaning imitator, because of the similarity of mimetite and pyromorphite. See also **Pyromorphite**.

MINERAL NUTRIENTS. Minerals that are essential to life are the source of metals and other inorganic elements involved in the most fundamental processes. For example, oxygen, required by the cells of animals, is utilized with the aid of metal complexes. In humans both iron-containing hemoglobin and zinc-containing carbonic anhydrase play pivotal roles in binding oxygen and delivering it to the cells. Moreover, enzymes developed to protect cells from high levels of oxygen also contain metals. One such class of protective enzymes is known as the superoxide dismutases (SODs). These contain metals such as manganese, copper, zinc, and iron. Mutations in the copper- and zinc-containing superoxide dismutase gene have been linked to amyotrophic lateral sclerosis.

As for other biological substances, states of dynamic equilibrium exist for the various mineral nutrients as well as mechanisms whereby a system can adjust to varying amounts of these minerals in the diet. In forms usually found in foods, and under circumstances of normal human metabolism, most nutrient minerals are not toxic when ingested orally. Amounts considerably greater than the recommended dietary allowances (RDAs) can generally be eaten without concern for safety (Table 1).

Some elements found in body tissues have no apparent physiological role, but have not been shown to be toxic. Examples are rubidium, strontium, titanium, niobium, germanium, and lanthanum. Other elements are toxic when found in greater than trace amounts, and sometimes in trace amounts. These latter elements include arsenic, mercury, lead, cadmium, silver, zirconium, beryllium, and thallium. Numerous other elements are used in medicine in non-nutrient roles. These include lithium, bismuth, antimony, bromine, platinum, and gold. The interactions of mineral nutrients with carbohydrates, fats, and proteins, minerals with vitamins (qv), and mineral nutrients with toxic elements are areas of active investigation.

The amount of each element required in daily dietary intake varies with the individual bioavailability of the mineral nutrient.

The Principal Elements

Calcium. Calcium, the most abundant mineral element in mammals, comprises 1.5–2.0 wt % of the adult human body, over 99 wt % of which is present in bones and teeth. About 48% of serum calcium is ionic, ca 46% is bound to blood proteins, the rest is present as diffusible complexes, e.g., of citrate. The calcium ion level must be maintained within definite limits.

Bones act as a reservoir of certain ions, in particular Ca^{2+} and PO_4^{3-}, which readily exchange between bones and blood. Bone structure comprises a strong organic matrix combined with an inorganic phase which is principally hydroxyapatite, $3\ Ca_3(PO_4)_2 \cdot Ca(OH)_2$. Bones contain two forms of hydroxyapatite. The less soluble crystalline form contributes to the rigidity of the structure. The crystals are quite stable, but because of the small size present a very large surface area available for rapid

TABLE 1. ESSENTIAL MINERAL NUTRIENTS

Element[a]	Body content, mg/kg body wt	Daily requirement, mg
	PRINCIPAL ELEMENTS	
calcium	14,000–20,000	800–1,200[b,c]
phosphorus	11,000–12,000	800–1,200[b,c]
sulfur	1,600–2,500	[d]
potassium	2,000–3,500	2,000
sodium	1,500–1,600	500
chlorine	1,200–1,500	750
magnesium	270–500	280[b,c,e]; 350[b,f]
	TRACE AND ULTRATRACE ELEMENTS	
iron	60–66	10[b,f]; 15[b,e]
fluorine	37	1.5–4.0[b]
zinc	33–50	12[b,c,e]; 15[b,f]
silicon	15–16	5–20
copper	1.0–2.5	1.5–3.0
boron	0.69	0.5–1.0
selenium	0.2–0.3	0.055[b,c,e]; 0.07[b,f]
iodine	0.2–0.4	0.15[b,c]
manganese	0.2–4.0	2.0–5.0[b]
molybdenum	0.1–0.5	0.075–0.25[b]
chromium	0.06–0.2	0.05–0.2[b]
cobalt	0.02	0.003[g]
tin	0.2	
vanadium	0.14	<0.01
nickel	0.07–0.14	<0.10

[a] Generally not ingested in elemental form.
[b] Values are for adults.
[c] Increased amounts are required during pregnancy and lactation.
[d] Adequate intake with adequate intake of protein.
[e] Value for females.
[f] Value for males.
[g] As vitamin B_{12}.

exchange of ions and molecules with other tissues. There is also a more soluble intercrystalline fraction. Bone salts also contain small amounts of magnesium, sodium, carbonate, citrate, chloride, and fluoride. Osteoporosis is reported to result when bone resorption is relatively faster than bone formation. The calcium ion, necessary for blood-clot formation, stimulates release of bloodclotting factors from platelets. See also **Blood**; and **Anticoagulants**.

In normal adults, the blood Ca^{2+} level is established by an equilibrium between blood Ca^{2+} and the more soluble intercrystalline calcium salts of the bone. Additionally, a subtle and intricate feedback mechanism responsive to the Ca^{2+} concentration of the blood that involves the less soluble crystalline hydroxyapatite comes into play. The thyroid and parathyroid glands, the liver, kidney, and intestine also participate in Ca^{2+} control.

In addition to hypocalcemia, tremors, osteoporosis, and muscle spasms (tetary), calcium deficiency can lead to rickets, osteomalacia, and possibly heart disease. These, as well as Paget's disease, can also result from faulty utilization of calcium. Calcium excess can lead to excess secretion of calcitonin, possible calcification of soft tissues, and kidney stones when combined with magnesium deficiency.

Phosphorus. Eighty-five percent of the phosphorus, the second most abundant element in the human body, is located in bones and teeth. Whereas there is constant exchange of calcium and phosphorus between bones and blood, there is very little turnover in teeth. The Ca:P ratio in bones is constant at about 2:1. Every tissue and cell contains phosphorus, generally as a salt or ester of mono-, di-, or tribasic phosphoric acid, as phospholipids, or as phosphorylated sugars. Phosphorus is involved in a large number and wide variety of metabolic functions. Examples are carbohydrate metabolism, adenosine triphosphate (ATP) from fatty acid metabolism, and oxidative phosphorylation.

The formation of phosphate esters is the essential initial process in carbohydrate metabolism. See also **Carbohydrates**. The glycolytic, i.e., anaerobic or Embden-Meyerhof pathway comprises a series of nine such esters. The phosphogluconate pathway, starting with glucose, comprises a succession of 12 phosphate esters. Cyclic adenosine monophosphate (cAMP), produced from ATP, is involved in a large number of cellular reactions including glycogenolysis, lipolysis, active transport of amino acids, and synthesis of protein. Inorganic phosphate ions are involved in controlling the pH of blood. The principal anion of intercellular fluid is HPO_4^{2-}.

Phospholipids, components of every cell membrane, are active determinants of membrane permeability. They are sources of energy, components of certain enzyme systems, and involved in lipid transport in plasma. Because of their polar nature, phospholipids can act as emulsifying agents. The structure of most phospholipids resembles that of triglycerides except that one fatty acid radical has been replaced by a radical derived from phosphoric acid and a nitrogen base, e.g., choline or serine.

Phosphorus is an essential component of nucleic acids, polymers consisting of chains of nucleosides, a sugar plus a nitrogenous base, and joined by phosphate groups. In ribonucleic acid (RNA), the sugar is D-ribose; in deoxyribonucleic acids (DNA), the sugar is 2-deoxy-D-ribose.

Phosphorus nutrient deficiency can lead to rickets, osteomalacia, and osteoporosis, whereas an excess can produce hypocalcemia. Faulty utilization of phosphorus results in rickets, osteomalacia, osteoporosis, and Paget's disease, and renal or vitamin D-resistant rickets.

Sulfur. Sulfur is present in every cell in the body, primarily in proteins containing the amino acids methionine, cystine, and cysteine. Inorganic sulfates and sulfides occur in small amounts relative to total body sulfur, but the compounds that contain them are important to metabolism. Sulfur intake is thought to be adequate if protein intake is adequate and sulfur deficiency has not been reported.

Although sulfur is in the same group of the Periodic Table, Group 16(VIA), as oxygen, sulfur functions much more like phosphorus, Group 15(VA), in biological systems. In fat metabolism, sulfur plays a key role analogous to that of phosphorus in carbohydrate metabolism. Fatty acid synthesis and degradation begin and end with the same compound, acetyl-S coenzyme A (acetyl–SCoA).

Detoxification systems in the human body often involve reactions that utilize sulfur-containing compounds. For example, reactions in which sulfate esters of potentially toxic compounds are formed, rendering these less toxic or nontoxic, are common as are acetylation reactions involving acetyl–SCoA. Another important compound is *S*-adenosylmethionine (SAM), the active form of methionine. SAM acts as a methylating agent, e.g., in detoxification reactions such as the methylation of pyridine derivatives, and in the formation of choline (qv), creatine, carnitine, and epinephrine. Sulfur nutrient deficiency results in retarded growth, and faulty utilization in homocystinuria.

Sodium and Potassium. Whereas sodium ion is the most abundant cation in the extracellular fluid, potassium ion is the most abundant in the intracellular fluid. Small amounts of K^+ are required in the extracellular fluid to maintain normal muscle activity. Some sodium ion is also present in intracellular fluid.

Sodium ion acts in concert with other electrolytes, in particular K^+, to regulate the osmotic pressure and to maintain the appropriate water and pH balance of the body. Homeostatic control of these functions is accomplished by the lungs and kidneys interacting by way of the blood. Sodium is essential for glucose absorption and transport of other substances across cell membranes. It is also involved, as is K^+, in transmitting nerve impulses and in muscle relaxation. Potassium ion acts as a catalyst in the intracellular fluid, in energy metabolism, and is required for carbohydrate and protein metabolism.

Maintenance of the appropriate concentrations of K^+ and Na^+ in the intra- and extracellular fluids involves active transport, i.e., a process requiring energy. Sodium ion in the extracellular fluid (0.136–0.145 *M* Na^+) diffuses passively and continuously into the intracellular fluid (<0.01 *M* Na^+) and must be removed. This sodium ion is pumped from the intracellular to the extracellular fluid, while K^+ is pumped from the extracellular (ca 0.004 *M* K^+) to the intracellular fluid (ca 0.14 *M* K^+). The energy for these processes is provided by hydrolysis of adenosine triphosphate (ATP) and requires the enzyme Na^+–K^+ ATPase, a membrane-bound enzyme which is widely distributed in the body. In some cells, e.g., brain and kidney, 60–70 wt % of the ATP is used to maintain the required Na^+–K^+ distribution.

Sodium and potassium ions are actively absorbed from the intestine. As a consequence of the electrical potential caused by transport of these ions, an equivalent quantity of Cl^- is absorbed. The resulting osmotic effect causes absorption of water.

Selective excretion and reabsorption of Na^+ and K^+ are accomplished by means of the kidney tubular cell membranes. The volume of

extracellular fluid is directly related to the Na^+ concentration which is closely controlled by the kidneys. Homeostatic control of Na^+ concentration depends on the hormone aldosterone. The kidney secretes a proteolytic enzyme, rennin, which is essential in the first of a series of reactions leading to aldosterone. In response to a decrease in plasma volume and Na^+ concentration, the secretion of rennin stimulates the production of aldosterone resulting in increased sodium retention and increased volume of extracellular fluid.

Salt-free or low salt diets often are prescribed for hypertensive patients. However, sodium chloride increases the blood pressure in some individuals but not in others. Conversely, restriction of dietary NaCl lowers the blood pressure of some hypertensives, but not of others. Genetic factors and other nutrients, e.g., Ca^{2+} and K^+, may be involved. The optimal intakes of Na^+ and K^+ remain to be established.

Potassium and/or sodium deficiency can lead to muscle weakness and sodium deficiency to nausea. Hyperkalemia resulting in cardiac arrest is possible from 18 g/d of potassium combined with inadequate kidney function. Faulty utilization of K^+ and/or Na^+ can lead to Addison's or Cushing's disease.

Chlorine. The chlorides are essential in the homeostatic processes maintaining fluid volume, osmotic pressure, and acid–base equilibria. Most chloride is present in body fluids; a little is in bone salts. Chloride is the principal anion accompanying Na^+ in the extracellular fluid. Less than 15 wt % of the Cl^- is associated with K^+ in the intracellular fluid. Chloride passively and freely diffuses between intra- and extracellular fluids through the cell membrane. If chloride diffuses freely, but most Cl^- remains in the extracellular fluid, it follows that there is some restriction on the diffusion of phosphate.

Some of the blood Cl^- is used for formation in the gastric glands of hydrochloric acid, HCl, required for digestion. Hydrochloric acid is secreted into the stomach where it acts with gastric enzymes in the digestive processes. The chloride is then reabsorbed with other nutrients into the blood stream. Chloride is actively transported in gastric and intestinal mucosa. In the kidney, chloride is passively reabsorbed in the thin ascending loop of Henle and actively reabsorbed in the thick segment of the ascending loop, i.e., the distal tubule. In the chloride shift, Cl^- plays an important role in the transport of carbon dioxide.

Numerous neurotransmitter receptors, e.g., glutamate, γ-aminobutyric acid (GABA), and benzodiazepine (called the valium receptor), have been identified as chloride channel proteins. The genetic defect in cystic fibrosis involves defective-functioning chloride channel proteins with excessive Cl^- loss. Deficient Cl^- during development adversely affects language skills in humans, as well as impaired growth in infants and metabolic alkalosis.

Fruit and vegetable juices high in potassium have been recommended to correct hypokalemic alkalosis in patients on diuretic therapy. Apparently the efficacy of this treatment is questionable. A possible reason for ineffectiveness is the low Cl^- content of most of these juices. Because Cl^- is high only in juices in which Na^+ is high, these have to be excluded.

Magnesium. In the adult human, 50–70% of the magnesium is in the bones associated with calcium and phosphorus. The rest is widely distributed in the soft tissues and body fluids. Most of the nonbone Mg^{2+}, like K^+, is located in the intracellular fluid where it is the most abundant divalent cation. Magnesium ion is efficiently retained by the kidney when the plasma concentration of Mg^{2+} falls; in this respect it resembles Na^+. The functions of Na^+, K^+, Mg^{2+}, and Ca^{2+} are interrelated so that a deficiency of Mg^{2+} affects the metabolism of the other three ions.

Magnesium is essential in numerous metabolic processes. It is the activator of many enzymes, e.g., adenyl cyclase, alkaline phosphatases, and the phosphokinases, pyrophosphatases, and thiokinases. Because the phosphokinases are required for the hydrolysis and transfer of phosphate groups, magnesium is essential in glycolysis and in oxidative phosphorylation. The thiokinases are required for the initiation of fatty acid degradation. Magnesium is also required in systems in which thiamine pyrophosphate is a coenzyme.

As an activator of the phosphokinases, magnesium is essential in energy-requiring biological processes, such as activation of amino acids, acetate, and succinate; synthesis of proteins, fats, coenzymes, and nucleic acids; generation and transmission of nerve impulses; and muscle contraction.

Regulation of serum Mg^{2+} appears to result from a balance among intestinal absorption, renal reabsorption, and excretion. The controlling factor is probably the renal threshold.

A severe magnesium deficiency in humans is seldom encountered except as a secondary effect resulting from numerous disease states, e.g., chronic alcoholism with malnutrition, acute or chronic renal disease, long-term Mg^{2+}-free parenteral feeding, protein–calorie malnutrition, and hyperthyroidism. In these situations, it is difficult to attribute specific clinical manifestations to magnesium deficiency. The specific role of magnesium in cardiovascular disease, e.g., arrythmia, spasms, or ischemia, remains a subject of conflicting research findings.

Neuromuscular irritability, convulsions, muscle tremors, mental changes such as confusion, disorientation, and hallucinations, heart disease, and kidney stones have all been attributed to magnesium deficiency. Excess Mg^{2+} can lead to intoxication exemplified by drowsiness, stupor, and eventually coma.

Trace Elements and Ultratrace Elements

Iron. The total body content of iron, i.e., 3–5 g, is recycled more efficiently than other metals. There is no mechanism for excretion of iron and what little iron is lost daily, i.e., ca 1 mg in the male and 1.5 mg in the menstruating female, is lost mainly through exfoliated mucosal, skin, or hair cells, and menstrual blood.

A large percentage of the iron in the human body is in hemoglobin: 85 wt % in the adult female, 60 wt % in the adult male. The remainder is present in other iron-containing compounds involved in basic metabolic functions, or in iron transport or storage compounds.

Absorption of iron from food to maintain homeostasis, tightly controlled, increases in instances of increased demands, such as during pregnancy and lactation, and iron-deficiency states which are the result of blood loss or iron-deficiency anemia resulting from inadequate iron intake. Iron absorption is greatly reduced in the normal individual when iron stores are adequate or excessive. Absorption is enhanced by acid conditions and reducing agents. Heme iron from animal sources is absorbed more readily than nonheme iron from cereals and vegetables.

A system of internal iron exchange exists which is dominated by the iron required for hemoglobin synthesis. For formation of red blood cells, iron stores can furnish 10–40 mg/d of iron, as compared to 1–3 mg from dietary sources. Only ca 10 wt % of ingested iron actually is absorbed. Transferrin is essential for movement of iron and without it, as in genetic absence of transferrin, iron overload occurs in tissues. This hereditary atransferrinemia is coupled with iron-deficiency anemia. The iron overload in hereditary or acquired hemochromatosis results in fully saturated transferrin and is treated by phlebotomy.

Iron deficiency is a significant worldwide nutritional problem and cause of anemia which can also lead to a decreased resistance to infection. Insufficient dietary iron intake; iron losses, e.g., bleeding and parasite infestation; and malabsorption of iron are the principal causes. The groups at greatest risk for developing iron-deficiency anemia are menstruating females, pregnant or nursing females, and young children. Children can experience impaired psychomotor development and intellectual performance.

Iron toxicity resulting from excess absorbable iron ingestion is rare except in Africa where fermented beverages made in large iron pots have levels of iron approaching 80 mg/L in a brew where the pH is very low. This results in Bantu siderosis which can result in hemochromatosis, i.e., damage to various organs from excessive storage of iron. This condition can cause numerous disease states, e.g., hepatic fibrosis and diabetes in 80% of the cases of idiopathic hemochromatosis patients. Iron overload is frequently a complication of repeated blood transfusions in anemias, e.g., thalassemia. The lethal dose of ferrous sulfate for a two-year old is 2 g; for an adult the lethal dose is from 200–300 g.

Fluorine. Fluoride is present in the bones and teeth in very small quantities. Human ingestion is from 0.7–3.4 mg/d from food and water.

Fluoridation of public water supplies, a common practice throughout much of the United States, may be an effective means of significantly reducing the incidence of dental caries. See also **Fluorine**. Concern regarding the narrow range of safety between effective and toxic fluoride concentrations has been expressed and poisoning from excessive fluoride, fluorosis, added to public water has been reported. Assertions that fluoridation of water supplies increases the incidence of cancer have not been substantiated.

Excess fluoride ingestion damages developing teeth, causing mottling, chalky-white coloration, and pitting.

Zinc. The 2–3 g of zinc in the human body are widely distributed in every tissue and tissue fluid. About 90 wt % is in muscle and bone; unusually high concentrations are in the choroid of the eye and in the prostate gland. Almost all of the zinc in the blood is associated with carbonic anhydrase in the erythrocytes. Zinc is concentrated in nucleic acids, and found in the nuclear, mitochondrial, and supernatant fractions of all cells.

Zinc is essential for the function of many enzymes, either in the active site, i.e., as a nondialyzable component, of numerous metalloenzymes or as a dialyzable activator in various other enzyme systems.

Zinc-hormone interactions include hormonal influence on absorption, distribution, transport, and excretion of zinc and zinc influence on synthesis, secretion, receptor binding, and function of numerous hormones. Zinc enhances pituitary activity by increasing circulating levels of growth hormone, thyroid-stimulating hormone, luteinizing hormone, follicle-stimulating hormone, and adrenocorticotropin. The role of zinc in insulin action is recognized but not well understood. Zinc is required for maintenance of normal plasma concentrations of vitamin A and for normal mobilization of vitamin A from the liver.

Zinc was confirmed as essential for humans in 1956 and deficiency symptoms were reported in 1961. The size of the human fetus is correlated with zinc concentration in the amniotic fluid and habitual low zinc intake in the pregnant female is thought to be related to several congenital anomalies in humans. Low zinc intakes result in hypogonadism, dwarfism, mental retardation, low serum and red blood cell zinc in humans and animals, and retarded growth and teratogenic effects on the nervous system in rats.

In children suffering from marginal zinc deficiency, impaired taste acuity, poor appetite, and suboptimal growth can be reversed upon zinc supplementation. Accelerated wound healing occurs in humans upon zinc supplementation, suggesting that marginal zinc deficiency in humans may be more widespread than has been thought. Zinc supplementation has also been effective in alleviating symptoms of active rheumatoid arthritis in clinical trials. Acrodermatitis enteropathica, a hereditary disease that involves aberrant zinc metabolism, responds to oral zinc supplementation. Excessive zinc intake may interfere with copper metabolism.

Silicon. Silicon comes mainly from ingestion of silicates, primarily from vegetables. It is found in the serum as silicic acid, $Si(OH)_4$, and normal blood serum levels are ca 1 mg/100 mL regardless of intake because of efficient kidney excretion of excess. Silicon is necessary for calcification, growth, and as cross-linking material in mucopolysaccharide formation. Silicon is especially helpful in situations where the diet is low in calcium or high in aluminum, or thyroid function is inadequate. The human requirement may be 5–20 mg/d. Silicon deficiency may lead to altered metabolism of connective tissue and bone and/or aluminum accumulation in the brain.

Copper. All human tissues contain copper. The highest amounts are found in the liver, brain, heart, and kidney. In blood, plasma and erythrocytes contain almost equal amounts of copper, i.e., ca 110 and 115 mg/100 mL, respectively.

In plasma, ca 90 wt % of copper is in the metalloprotein ceruloplasmin, also known as a_2-globulin, mol wt 151,000, which contains 8 atoms of copper per molecule. Ceruloplasmin has been identified as a ferroxidase(I) which catalyses the oxidation of aromatic amines and of Fe^{2+} to Fe^{3+}. The ferric ion is then incorporated into transferrin which is necessary for the transport of iron to tissues involved in the synthesis of iron-containing compounds, e.g., hemoglobin. Lowered levels of ceruloplasmin interfere with hemoglobin synthesis.

Copper deficiency is characterized by poorly formed collagen which leads to bone fragility and spontaneous bone fractures in animals, and also results in cardiac hypertrophy. Abnormal electrocardiographs have been noted when low copper diets were fed to humans. Anemia, neutropenia, and bone disease have been reported in children having protein calorie malnutrition (PCM) and accompanying hypocupremia. At least two genetic diseases involving copper are known: Wilson's disease, an autosomal recessive disease, usually detected in adulthood, and Menke's kinky-hair syndrome.

Analytical data indicate that many diets contain less than the RDA for copper. Excessive copper has been reported to be fatal for oral dose levels of copper sulfate of 200 mg/kg body weight for a child and 50 mg/kg for adults.

Boron. The essentiality of boron, first accepted for higher plants in 1923, then for animals, was recognized in 1981 for human metabolism. Boron is reported to help maintain function or stability of cell membranes and is thought to be involved with hormone reception and transmembrane signaling. Enhanced need for boron may develop with nutritional or metabolic stress involving other nutrients, e.g., magnesium deprivation or physiological changes in calcium metabolism. Boron depletion impairs cognitive function. Organs known to contain the highest levels of boron are bone, spleen, and thyroid. An excess of boron can, however, cause seizures in infants, riboflavinuria, and gastrointestinal upset.

Selenium. Selenium, thought to be widely distributed throughout body tissues, is present mostly as selenocysteine in selenoproteins or as selenomethionine. Animal experiments suggest that greater concentrations are in the kidney, liver, and pancreas and lesser amounts are in the lungs, heart, spleen, skin, brain, and carcass.

The most clearly documented role for selenium is as a necessary component of glutathione peroxidase. Selenium is also involved in the functions of additional enzymes, e.g., type I iodothyronine deiodinase, leukocyte acid phosphatase, and glucuronidases. A role for selenium in electron transfer has been suggested as has involvement in nonheme iron proteins. Selenium and vitamin E appear to be necessary for proper functioning of lysosomal membranes. A role for selenium in metabolism of thyroid hormone has been confirmed.

Alkali disease and blind staggers of grazing livestock in the western U.S. were reported as the result of selenium poisoning. There are unusually high concentrations of selenium in certain plants, because of selenium-accumulating properties, or in ordinary plants growing on highly seleniferous soils. No treatment for this type of poisoning is known, thus excess selenium in the animal diet must be avoided. Prolonged ingestion of up to 600 mcg/d of selenium did not produce toxic effects in humans. Toxic effects in humans have been reported, however, from chronic ingestion of food in China supplying 5 mg/d of Se, and from supplements in the U.S. of 27–2387 mg/d of Se. Effects include hair loss, changes in the nails, gastrointestinal upset, and peripheral neuropathy.

Pure selenium deficiency, without concurrent vitamin E deficiency, is not generally seen except in animals on experimental diets. In China, selenium deficiency in humans has been associated with Keshan disease, a cardiomyopathy seen in children and in women of child-bearing ages, and Kashin-Beck disease, an endemic osteoarthritis in adolescents. Selenium may have anticarcinogenic effects possibly because of the antioxidant properties of selenium compounds.

Iodine. Of the 10–20 mg of iodine in the adult body, 70–80 wt % is in the thyroid gland. See also **Iodine (In Biological Systems)**. The essentiality of iodine, present in all tissues, depends solely on utilization by the thyroid gland to produce thyroxine and related compounds. Well-known consequences of faulty thyroid function are hypothyroidism, hyperthyroidism, and goiter. Dietary iodine is obtained from eating seafoods and kelp and from using iodized salt.

The functions of the thyroid hormones and thus of iodine are control of energy transductions. These hormones increase oxygen consumption and basal metabolic rate by accelerating reactions in nearly all cells of the body. A part of this effect is attributed to increase in activity of many enzymes. Additionally, protein synthesis is affected by the thyroid hormones.

In many parts of the world, simple goiter is endemic and usually results from dietary iodine deficiency or goiterogens in foods which bind iodine. Iodine deficiency disorders (IDD) include cretinism, myxedema, hypothyroidism, and goiter. In technologically advanced countries, the problem of iodine deficiency has been minimized by the use of iodized salt. Faulty utilization of iodine can lead to Grave's disease. A sodium iodide excess can also produce goiter and an excess of 500 mg/kg body weight can be fatal.

Manganese. The adult human body contains ca 10–20 mg of manganese widely distributed throughout the body. The largest Mn^{2+} concentration is in the mitochondria of the soft tissues, especially in the liver, pancreas, and kidneys. Manganese concentration in bone varies widely with dietary intake.

Manganese is essential for normal body structure, reproduction, normal functioning of the central nervous system, and activation of numerous enzymes. An excess of manganese can lead to neural damage and possible impaired insulin production.

In animals, manganese deficiency results in wide-ranging disorders, e.g., impaired growth, abnormal skeletal structure, disturbances of reproduction, and defective lipid and carbohydrate metabolism. Although overt manganese deficiency has not been induced in humans, some forms of epilepsy

in humans and animals and a decrease in glucose tolerance in animals have been linked to low levels of manganese in the tissue.

Molybdenum. Molybdenum is a component of the metalloenzymes xanthine oxidase, aldehyde oxidase, and sulfite oxidase in mammals. Two other molybdenum metalloenzymes present in nitrifying bacteria have been characterized: nitrogenase and nitrate reductase. The molybdenum in the oxidases, is involved in redox reactions. The heme iron in sulfite oxidase also is involved in electron transfer. Foods rich in molybdenum include legumes, dark green vegetables, liver, whole-grain cereals, and milk. Xanthine oxidase, mol wt ca 275,000, present in milk, liver, and intestinal mucosa, is required in the catabolism of nucleotides. Xanthine oxidase is also involved in iron metabolism.

A copper-molybdenum antagonism involving sulfate occurs in animals, i.e., large amounts of molybdenum and sulfate can depress copper absorption. Cattle grazing on pasturage of high Mo content succumb to teart or peat scours, characterized by diarrhea and general wasting. Control involves increasing copper intake. The Cu–Mo antagonism has been observed in humans. Significant increases in urinary copper excretion have been observed with increasing Mo intake.

Molybdenum deficiency in humans results in deranged metabolism of sulfur and purines and symptoms of mental disturbances. Toxic levels produce elevated uric acid in blood, gout, anemia, and growth depression. Faulty utilization results in sulfite oxidase deficiency, a lethal inborn error.

Chromium. Chromium(III) potentiates the action of insulin and may be considered a cofactor for insulin. Chromium is thought to form a complex with insulin and insulin receptors.

Studies of elderly people and mildly diabetic patients showed significant improvement in the glucose tolerance test (GTT) when chromium supplementation of 150–200 μg/d was given. In other tests, these positive results were not obtained. It is possible that not all subjects are capable of utilizing inorganic chromium to the same extent. Some may require a preformed GTF (glucose tolerance factor). Chromium chloride supplementation has been effective in normalizing impaired glucose tolerance in malnourished children and in patients receiving total parenteral nutrition for a long time. The most available form of chromium is GTF obtained from brewer's yeast. Chromium deficiency may also lead to atherosclerosis and peripheral neuropathy.

Cobalt. Cobalt is nutritionally available only as vitamin B_{12}. Although Co^{2+} can function as a replacement *in vitro* for other divalent cations, in particular Zn^{2+}, no *in vivo* function for inorganic cobalt is known for humans. In ruminant animals, B_{12} is synthesized by bacteria in the rumen.

In pernicious anemia, the bone marrow fails to produce mature erythrocytes as a result of defective cell division, a consequence of impaired DNA synthesis which requires vitamin B_{12}. If the disease goes untreated, extensive neurological damage, e.g., irreversible degeneration of the spinal cord by demyelinization, may occur because of faulty fatty acid metabolism.

Vitamin B_{12} deficiency commonly is caused by inadequate absorption resulting from a lack or insufficient intrinsic factor (IF). Intrinsic factor is a glycoprotein, mol wt ca 50,000, which binds vitamin B_{12} in a 1:1 molar ratio. The B_{12}-IF complex, formed in the stomach, is absorbed in the ileum. Absorption in this part of the intestine occurs because of the specific characteristics of the cells of the microvilli (brush border) of the ileum. The IF remains in the intestine attached to the epithelial cells. Transport of B_{12} into the blood stream requires Ca^{2+}. In the blood, B_{12} is bound to transcobalamin II (transport protein). Whatever bound B_{12} is not utilized immediately is stored in the liver. With increasing quantities of dietary B_{12}, the fraction that is absorbed decreases. Generally, vitamin B_{12} is excreted in the urine, but with large intake, some is excreted in the bile. A nutritional excess of cobalt can lead to polycythemia.

Tin. The widespread use of canned foods results in a daily intake of tin that is ca 1–17 mg for an adult male. At this level it has not been shown to be toxic. Some grains also contain tin. Too much tin can adversely affect zinc balance and iron metabolism. Essentiality has not been confirmed for humans. It has been shown for the rat. An enhanced growth rate results from tin supplementation of low tin diets. Animals on deficient diets exhibit poor growth and decreased feed efficiency.

Vanadium. Vanadium is essential in rats and chicks. Estimated human intake is less than 4 mg/d. In animals, deficiency results in impaired growth, reproduction, and lipid metabolism, and altered thyroid peroxidase activities. Vanadium may play a role in the regulation of (NaK)-ATPase, phosphoryl transferases, adenylate cyclase, and protein kinases.

Nickel. There is considerable evidence for the essentiality of nickel in animals. Various pathological manifestations of nickel deficiencies have been observed in chicks, cows, goats, pigs, rats, and sheep. Average intake is reported to be about 60–260 μg/d, and a dietary requirement for humans of less than 100 μg/d has been suggested. *In vitro* studies have shown nickel to be an activator of several enzymes.

Arsenic. Arsenic is under consideration for inclusion as an essential element. No clear role has been established, but arsenic, long thought to be a poison, may be involved in methylation of macromolecules and as an effector of methionine metabolism.

Health and Safety Factors

Under unusual circumstances, toxicity may arise from ingestion of excess amounts of minerals. This is uncommon except in the cases of fluorine, molybdenum, selenium, copper, iron, vanadium, and arsenic. Toxicosis may also result from exposure to industrial compounds containing various chemical forms of some of the minerals. Aspects of toxicity of essential elements have been published.

Efficient homeostatic controls of mammalians generally prevent serious toxicity from ingestion of the mineral nutrients. Toxicity may occur under conditions far removed from those of nutritional significance or for individuals suffering from some pathological conditions. Because of very low concentrations in foods, the trace elements are not toxic under normal nutritional conditions. Exceptions are selenium and iron.

MINERALOGY. The science of mineralogy is concerned with the formation, occurrence, properties, composition, and classification of minerals. Various definitions of a mineral have been proposed. Possibly, the most acceptable may be, "a naturally occurring inorganic substance, usually crystalline, possessing a relatively definite chemical composition and physical characteristics." It should be pointed out that some naturally formed organic substances, particularly of an economic resource nature, are sometimes classified as minerals.

Although in its broadest application, mineralogy is as ancient as human civilization, mineralogy is a modern science, the mineralogist taking full advantage of all modern tools and instruments for exploration, analysis, testing, and study of minerals. Several major scientific advances in the materials field have stemmed from the study of minerals as will be pointed out shortly.

Presumably in the early ages man used minerals as weapons. Through the passage of time and attainment of knowledge regarding certain mineral characteristics man learned, notably initially by accident but later by design, that the content of minerals provided essential materials for his expanding needs. Very early, the natural form and beauty of certain minerals became objects for personal adornment. Later it was found that both the form and the innate beauty of minerals were enhanced by cutting and polishing them. Although the science of mineralogy touches the life of every person, a fundamental understanding of minerals is not common.

Modern mineralogy is the product of research and discovery by many persons. Robert Hooke (1665) foretold the atomic theory by constructing models of alum crystals out of leaden musket balls. Nicolaus Steno (1669)

discovered the constancy of interfacial angles between corresponding faces of quartz crystals from many localities. This was later formalized by Rome de l'Isle (1764) under his *law of constancy of crystal interfacial angles*. In 1784, René Just Haüy proposed the theory of *integral molecules* by stacking calcite rhombs to show that structural units could produce exact external facial planes of various forms of calcite crystals. Haüy is known as the "father" of geometrical crystallography. A great advance in mineral studies was made in 1828 when Nicol invented the nicol prism for investigating the behavior of polarized light in crystallized minerals. In 1912, Max von Laue, a student of Roentgen, theorized that the wavelengths of x-rays and atomic spacing of crystals may be of the same magnitude. Laue found that the diffracted rays, when passed through a crystal, substantiated his theory. This discovery opened up an entirely new field of mineral research, i.e., *crystal chemistry*.

Origin of Minerals

Minerals are products of formation and deposition from Earth's natural open solution systems, as opposed to substances formed as products of closely controlled laboratory systems, and thus may vary in many instances from an exact chemical content and formula. Minerals crystallizing from such open solution systems utilize effectively the ions required to form the mineral, but may incorporate within that structure other nonessential ions foreign to it. The incorporation of those foreign ions may, under favorable conditions of chemical affinity, replace certain specific elements named in the given formula. Or there may be defects in the space lattice of the mineral, e.g., vacancies in the crystalline structure comparable to a classroom with X number of seats orderly arranged where, under ideal conditions, each seat would be occupied by a student. Owing to some extraneous circumstance one or more students may be absent, yet the total seating capacity and orderly arrangement would remain constant. Deviations of the first type may be a product of included impurities in the structure; of the second type, by occupancy of a foreign compatible element in the vacant space(s) of the host crystal structure. See "**Isomorphism and Diadochy**" later in this article.

In other minerals, the formula may vary within restricted limits, such as (Zn, Fe) S for sphalerite, where ferrous iron substitutes for zinc within the sphalerite structure. Two factors prevail in such chemical substitution within a given mineral structure: (1) reasonably comparable ionic radii (approximately, but not strictly limited to (±15%); and (2) maintenance of electrical neutrality of the compound. In the event the substituting ions have a different valence or charge, electrical neutrality may be obtained by an accompanying substitution elsewhere within the crystal structure. Basically, a mineral is a homogeneous inorganic solid with an ordered atomic arrangement, which places it in the category of a crystalline material and possessing a definite, though not a fixed chemical formula.

Natural systems strive toward a state of equilibrium when all component units attain their lowest energy level. The respective energy level of the elements within any mineral is dependent upon the physical environment, principally the temperature, pressure, and chemical substances present, at the time and place of its formation. Any later change in its environment may cause a change in the mineral's composition and form. Whatever the primary or intermediate environmental conditions may have been, the mineral as observed, represents its present equilibrium energy state or crystal structure.

Matter exists in three states—gaseous, liquid, and solid.* In the gaseous state, the elements move freely about within their environment, their only contact being haphazard collisions. Elements in the liquid state are in closer contact with each other, but still retain freedom of mobility. The solid state is characterized by the chemical elements combining under atomic bonds of various types and strengths into a structured system. For any element within the structure, there are equivalent elements in a definite three-dimensional crystalline pattern. Under restricted circumstances, two or more minerals may form in contact with one another in such a manner as to preclude their complete development as single crystals. Those minerals which develop fully and which exhibit well-formed polyhedral (many sides) facial planes are referred to as being *euhedral*. Those minerals that exhibit no facial planes are referred to as *anhedral*. Imperfectly formed crystals are referred to as *subhedral*. Crystalline minerals, where the crystallinity can be determined only by aid of a microscope, are said to be *microcrystalline*. Where the materials are so finely divided as to be discernible only by x-ray analysis they are referred to as *cryptocrystalline*. The rate of crystallization plays an important part in the resultant crystalline character of minerals.

* Traditional concepts. Details on more advanced concepts on the states of matter are given elsewhere in this volume.

Crystalline solids are bonded together by electrical forces, which originate in the constituent atoms. The position of the respective unit particles within the crystal structure are determined by geometric factors, along with considerations of electrical neutrality and lattice energy. One type of bond is produced by the lending or borrowing of electrons in an attempt to complete the outer electron shell of the atom. A stable compound is formed when the outer shell is complete and the mutual attraction is termed an *ionic bond*. For example, sodium with one electron in its outer electron shell lends that electron to a neutral chlorine atom with seven electrons in its outer electron shell. The result is a stable electron shell for each ion (charged atom) which then join by electrostatic attraction in a crystal structure to form sodium chloride, NaCl. Minerals so bonded are of moderate hardness, readily soluble, and poor conductors of electricity and heat.

The bond produced by the sharing of electrons by which a stable configuration is achieved is termed a *covalent bond*. For example, chlorine with seven electrons in its outer shell needs one additional electron to achieve stability. If its nearest neighbor is another chlorine atom, the two atoms combine in such a way that the one electron serves in the outer shell of each atom, thus achieving a stable configuration. Diamond is another example of this type. Carbon with four electrons in its outer shell mutually shares the four electrons with four adjoining carbon atoms, thus achieving a stable configuration by completing the shell with eight electrons. This type of electron-sharing or covalent bonding is the strongest of all chemical bonds. Minerals so bonded are generally insoluble, possess a high degree of stability, and are nonconducting.

Metallic bonds consist of a structure of positive ions through which free electrons can drift. The structure of metals may be envisioned as a mesh of electrons that surround the atomic nuclei and bind them together. This electron mobility produces minerals of generally a low hardness and of high electrical and thermal conductivity.

The *Van der Waals* bond is a very weak attraction between atoms, usually between essentially neutral atoms or groups of atoms. These neutral and essentially uncharged structure units are held together within the crystal lattice by virtue of small residual charges on their surfaces. This type of bonding is rare in minerals. Minerals so bonded often display ready cleavage and low hardness. For example, the foliated scales of graphite are linked weakly together by Van der Waals bonds.

Every mineral is a product of the redistribution or recombination of its component chemical elements to form a stable substance. The process is known as *crystallization*. The process may involve *precipitation* of chemical elements from aqueous solutions at the earth's surface; or from siliceous melts (magmas) from the earth's interior. In either situation, the process is dependent upon the degree of concentration of the constituent chemical elements present and the temperature/pressure conditions. Precipitation from vapor also is possible. An example is the hot vapor, rich in sulfur dioxide, which is emitted from vents associated with volcanoes. Upon becoming exposed to the cooler atmosphere, crystal sulfur is deposited around those vents. Snow crystals are another example of precipitation from vapor.

Crystal Structure

Associated chemical units become systematically arranged in the crystal structure, which is constructed from a single motif that develops repetitively. The resulting three-dimensional array is called the *space lattice* of the crystal. The lattice or framework is defined by three directions and by the distance along those directions where the motif repeats itself. Because the units within the structure adhere to a strict arrangement, the external facial planes of a crystal represent the limiting surfaces of that growth and are an external expression of its internal atomic order. Crystals are formed, therefore, where constituent atoms or ions are free to combine in constant chemical proportions and are an expression of the environmental conditions that promote their formation.

Periodic repetitions of a space lattice cell in three dimensions from the original cell will completely partition space without overlapping or omissions. It is possible to develop a limited number of such three-dimensional patterns. Bravais, in 1848, demonstrated geometrically that there were but fourteen types of space lattice cells possible, and that these fourteen types could be subdivided into six groups called *systems*. Each system may be distinguished by symmetry features, which can be related to four symmetry elements:

1. *Symmetry with respect to a point.* If through a central point in a geometric figure, lines are drawn from a point on one side of the figure to a similar point equidistant on the other side, the figure is symmetrical to a point.

2. *Symmetry with respect to a plane.* A geometrical figure is symmetrical with respect to a plane when for each edge, solid angle, or face on one side, there is a corresponding edge, solid angle, or face on the other side of that plane. One side is, in fact, a mirror image of the opposite side. That plane is called a *plane of symmetry.*

3. *Symmetry with respect to a line.* If during a complete revolution of 360° about a given axis, a geometrical figure repeats itself in appearance two or more times, it is said to be symmetrical with respect to a line, or to an *axis of symmetry.* Possible axes of symmetry are twofold, threefold, fourfold, and sixfold. A rotation of onefold or 360° is equivalent to no rotation at all.

4. When a crystal is rotated about an axis and inverted about the central point and at that point repeats itself, it is said to have an *axis of rotary inversion.* It is a twofold axis of rotary inversion if the geometrical figure is rotated 180° and then inverted. Additionally, there are threefold, fourfold, and sixfold axes of rotary inversion possible.

Within each of the six crystal systems, there are specific *crystal classes.* Each class displays distinctive symmetry elements. There are 32 possible classes distributed among the six crystal systems. One of the crystal classes within each system possesses all of the symmetry elements that are characteristics of its space lattice cell. These are called the *holohedral* class of that system. Other classes within each system possess somewhat fewer symmetry elements and are called *merohedral* classes.

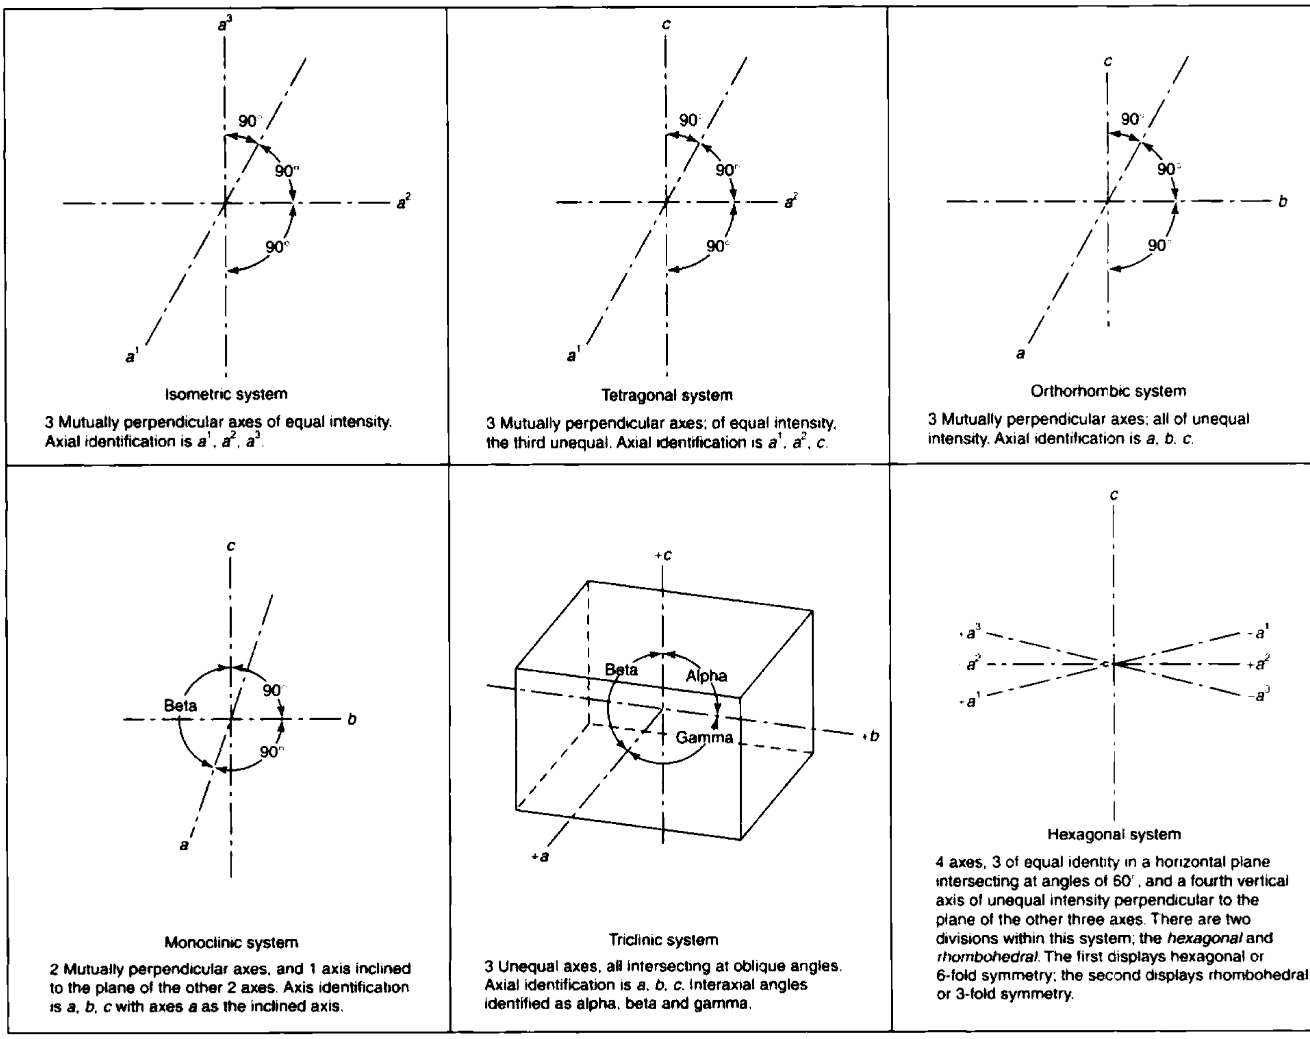
It is significant to note that in most geometrical situations regarding crystal study, the distinguishing characteristic is symmetry, not geometry. This is especially true in the case of a mineral such as pyrite (FeS_2) which assumes a cubic shape, but its symmetry, controlled by the three sets of opposing striations on its crystal faces, identify it as belonging to a much lower order symmetry than that of a true cube.

The six crystal systems are identified by hypothetical lines of reference known as *crystallographic axes,* and their angular relationship to each other. Crystal orientation and axial order are given as: (1) front to back; (2) right side to left side; and (3) top side to bottom side. The front, right, and top side axial ends represent the positive ends of those respective axes. The back, left, and bottom side ends are designated as the negative ends. The relative intensity of crystal growth along those axes gives to each crystal face a distinctive identifying character. This character is evidenced by the physical similarity of equivalent facial planes on the crystal and their relationship to the crystallographic axes of that form. The six systems, their crystallographic axes, and interaxial angular relationship are defined and illustrated in the Fig. 1.

Crystallographic identification of facial planes on a crystal become possible through assignment of numerical values to a face which represents its relationship to the crystal axes. *Parameters,* or relative intercepts, are obtained by plotting coordinates of crystal faces with respect to their crystallographic axes. The actual distances of axial intercepts of the crystal face are determined and expressed as a unit of measurement. The product of these values is known as *Miller indices.*

A Miller indices face on the front face of a cube would be (100), signifying that face intersects the a^1 axis at 1 unit length from the center of the crystal, and is parallel to axes a^2 and a^3, or intersects those axes at infinity. In this system, zero (0) is the numerical substitute for infinity. A (111) Miller indices face identifies that facial plane as intersecting each of the three crystallographic axes of that form at 1 unit length from the crystal center.

The Miller Indices identify the orientation of a face in relationship to its axes of reference regardless of its size and position on the crystal. Haüy first proposed this basic law of crystallography—"crystal faces make simple



Isometric system
3 Mutually perpendicular axes of equal intensity. Axial identification is a^1, a^2, a^3.

Tetragonal system
3 Mutually perpendicular axes; of equal intensity, the third unequal. Axial identification is a^1, a^2, c.

Orthorhombic system
3 Mutually perpendicular axes; all of unequal intensity. Axial identification is a, b, c.

Monoclinic system
2 Mutually perpendicular axes, and 1 axis inclined to the plane of the other 2 axes. Axis identification is a, b, c with axes a as the inclined axis.

Triclinic system
3 Unequal axes, all intersecting at oblique angles. Axial identification is a, b, c. Interaxial angles identified as alpha, beta and gamma.

Hexagonal system
4 axes, 3 of equal identity in a horizontal plane intersecting at angles of 60°, and a fourth vertical axis of unequal intensity perpendicular to the plane of the other three axes. There are two divisions within this system; the *hexagonal* and *rhombohedral.* The first displays hexagonal or 6-fold symmetry; the second displays rhombohedral or 3-fold symmetry.

Fig. 1. Crystallographic axes and interaxial angular relationship of six crystal systems

rational intercepts on suitable crystal axes." Inasmuch as the intercepts are simple, it follows that the Miller indices should likewise be simple whole numbers.

See also **Crystal**; and **Miller Indices**.

Crystal Forms

Form is used here to designate the general outward appearance of a crystal, specifically to a group of crystal faces that bear identical relationships to the crystal's symmetry elements. It is essentially a geometric form with equivalent facial planes in their relationship to the crystal lattice symmetry elements. In this regard, an octahedron in the isometric system would be identified as a "closed form," inasmuch as its eight equivalent faces totally enclose the crystal space; its form identification would be {111}, enclosed in braces. Even though the crystal faces may be equivalent they may vary widely in size and distance from the crystal center, owing to irregular or distorted development during their formation. Braces shown around the Miller indices, e.g., {111} signify form identification, as opposed to Miller indices shown in parentheses, e.g. (111), which identify a specific crystal face only. In crystals possessing different lengths of their crystallographic axes general form {*hkl*} would be used. The hexagonal system with four axes requires a four-unit form identification.

In the isometric system, crystals are recognized by their geometrical forms, e.g., cube, octahedron, trapezohedron, pyritohedron, and so on. In all other systems, crystal faces are given specific names, which refer to their relationship with their respective crystallographic axes. The most common facial forms in these systems are *pedion, pinacoid, dome, prism*, and *pyramid*. Crystal forms bear specific relationships to symmetry axes or planes, and not to the general shape of the crystal.

Physical Mineralogy

This aspect of mineralogy is concerned with several observable physical characteristics, such as color, hardness, lustre, fracture, cleavage, magnetic properties, radioactivity, fluorescence, and specific gravity.

Color. The color of a mineral is a product of selective absorption of certain wave lengths of visible white light by atoms within the mineral structure. A mineral color may be indicative of a species, but more often is of descriptive value only. There are two broad classification categories of color in minerals—*allochromatic* and *idiochromatic*. Allochromatic minerals are those which occur with variable colors, such as quartz, SiO_2; corundum, Al_2O_3; and calcite, $CaCO_3$. Color in such minerals may be a product of included foreign elements, rate of crystallization, or a defective lattice structure. Idiochromatic minerals are those in which the color is a characteristic constant, such as the green of malachite, $Cu_2CO_3(OH)_2$; the blue of azurite, $Cu_3(CO_3)_2(OH)_2$; the black of magnetite, Fe_3O_4; and the red of cinnabar, HgS. The actual color of most minerals can be obtained by rubbing the mineral on an unglazed porcelain plate and observing the powder (streak) of that mineral left on the plate. This test is essential in certain instances inasmuch as many minerals display a physical color foreign to their actual color, e.g., hematite may appear black or blue, but its streak color is always red.

Hardness. The hardness of a mineral is its resistance to scratching. Testing for hardness is based upon the premise that all minerals possess such resistance to a lesser or greater degree. The Mohs scale of hardness has been universally adopted to test this physical property. In the list below, the ascending numeric order of the mineral named will scratch all of those of lower order.

1 Talc
2 Gypsum
3 Calcite
4 Fluorite
5 Apatite
6 Orthoclase
7 Quartz
8 Topaz
9 Corundum
10 Diamond

In a relative sense, minerals from 2 to 2.5 hardness can be scratched by a fingernail; 4 by a penny, and 5 to 6 by a knife blade or piece of glass.

This scale is strictly relative and nonlinear because there is a much wider differential, for example, between corundum and diamond than between topaz and corundum. Hardness also varies according to crystallographic direction in certain minerals. This test should always be made on a freshly broken area because certain minerals are subject to surface alteration. A hardness test on an altered area can be misleading.

The hardness (Mohs scale) of several minerals is given in Table 1.

Lustre. The lustre of a mineral is a product of both light reflection and refraction. Reflection is the governing factor in translucent to opaque minerals; refraction in transparent minerals. There are two broad categories in describing lustre—*metallic* and *nonmetallic*. Minerals of nonmetallic lustre are further subdivided into categories, such as vitreous (glass); adamantine (diamond); resinous (sphalerite); silky (asbestos); waxy (chalcedony and opal); greasy (some quartz and diamonds); and pearly (talc or mica).

Fracture. The product of irregular breaking of a mineral is termed fracture. Categories include conchoidal or conch-like (quartz); uneven (serpentine); and hackly (copper). Fracture in a mineral is unrelated to its crystal structure.

Cleavage. The cleavage of a mineral is the product of regular breaking of the mineral along specific surfaces related to the mineral's internal structure. The cleavage plane is always parallel to a possible crystal face and, therefore, is a reflection of the atomic structure of the mineral. Three planes of cleavage are present in the cube and rhombohedron. Four cleavage planes produce an octahedron, six planes a dodecahedron, both of which fall within the isometric system.

Magnetic Properties. A few minerals possess the property of being attracted by a magnet and they are known as *ferromagnetic* minerals. The more common ferromagnetic minerals are magnetite, Fe_3O_4, and pyrrhotite, $Fe_{1-x}S$. Those minerals which are natural magnets are known as *lodestones*. Most minerals are affected to some extent in a magnetic field. The minerals that are repelled are known as *diamagnetic*; those that are weakly attracted are known as *paramagnetic*.

Radioactivity. Basically, this involves the spontaneous disintegration of uranium and thorium minerals. Both of these mineral species disintegrate at a steady rate that is completely unaffected by external chemical or mechanical conditions. The end-product of this disintegration is lead within the mineral structure. Geophysicists are able to determine the geologic age of a specific uranium or thorium mineral and its host environment by measuring the amount of lead present and computing the known time required to produce this amount. With the impetus of atomic energy, many previously unknown uranium minerals were uncovered and identified.

Fluorescence. This is the property of certain minerals to absorb ultraviolet radiation and convert that energy into visible light. The rays energize certain elements within the mineral, causing the excitation of electrons in the orbital shell. If the activating source is removed and visible light continues for a period of time following, the phenomenon is known as *phosphorescence*. The visible light continues until the electrons return to their normal orbital electron shell.

Specific Gravity. The density or specific gravity of a substance is the amount by which that substance decreases in apparent weight when first weighed in air, followed by weighing in water. The density is obtained by dividing the weight of the substance in air by the loss of its weight in water.

TABLE 1. HARDNESS OF REPRESENTATIVE MINERALS

Mohs scale			
Agate	6–7	Galena	2.5
Alabaster	1.7	Garnet	6.5–7
Andalusite	6.5–7.5	Graphite	0.5–1
Aragonite	3.5	Kaolinite	2.0–2.5
Asbestos	5.0	Magnetite	6
Barite	3–3.5	Marble	3–4
Beryl	7.8	Mica	2.8
Corundum	9	Opal	5.5–6.5
Diatomaceous earth	1–1.5	Pumice	6
Dolomite	3.5–4	Pyrite	6–6.5
Emery	7–9	Serpentine	3–4
Flint	7	Tourmaline	7–7.5

Isomorphism and Diadochy

Isomorphism is the substitution of an atom, ion, or radical for another within a mineral structure. The degree of substitution is controlled largely by two factors: (1) temperature, and (2) ionic size. Only ions of similar size will readily substitute for one another.

Under certain conditions, isomorphism may be either partial or complete. The spinel, garnet, and amphibole mineral groups represent a complete isomorphous series. Partial isomorphism is exemplified by chemical components displaying extensive ionic substitution at high temperature levels, as evidenced by the nearly complete random mixing of potassium and sodium in microcline $KAlSi_3O_8$ and albite $NaAlSi_3O_8$ feldspars. Reducing temperature causes segregation of their component content according to their respective radii, which then group together, forming two separate mineral phases. This phenomenon is known as *exsolution* and is shown by the mixed feldspar known as perthite, common in igneous and high-grade metamorphic rocks. Other isomorphous examples include calcite and siderite; magnesite and siderite.

Diadochy is a term applied to the substitution of foreign atoms/ions within the same space lattice of a crystal atomic structure. Diadochic substitution refers only to specific crystal structures, as substitution elements may be diadochic in one structure and not in another. For example, excess Al^{3+} (0.57kX) may substitute diadochically for Fe^{3+} (0.64kX) in the epidote structure, thereby producing clinozoisite; when within the dolomite structure, Fe^{2+} (0.83kX) substitutes for Mg^{2+} (0.78kX), ankerite is the product; marmatite (ferroan sphalerite) results when Fe^{2+} (0.83kX) replaces Zn^{2+} (0.83kX) within the sphalerite structure. Diadochy involves the actual substitution/replacement of a given compatible element for another within a crystal structure, which, as in isomorphism, may be either partial or complete. In like manner, high temperature contributes materially to such substitution.

Polymorphism

Polymorphism is the capability of a substance to exist in more than one crystal form. The basic controlling factors appear to be temperature-pressure conditions at the time of formation, which controls the type of atomic packing within the structure. Examples of polymorphism are given in Table 2.

Pseudomorphism

Pseudomorphism is the change of the original chemical composition of a substance into some other equally definite compound by the action of natural agencies. Pseudomorphism exists when the external crystalline form of a mineral is inconsistent with its internal chemical composition and atomic structural arrangement. It is always a secondary process. The altered substance is known as a *pseudomorph*.

Types of pseudomorphic alteration include:

Substitution. This is a process whereby silica replaces wood fiber to form silicified (petrified) wood. Quartz replacing fluorite is another example. In the latter instance, the original fluorine in the fluorite is removed by silica-rich solutions that first remove the fluorine and then substitute silica in its place.

Incrustation. This is a process whereby one mineral forms a crust over another mineral, e.g., prehnite over anhydrite crystals. Later solutions may remove the anhydrite, but the space occupied by the anhydrite remains as a cast surrounded by the prehnite.

Alteration results from the addition of new material or partial removal of original material from a mineral, e.g., anglesite after galena; or gypsum after anhydrite.

Paramorphism results when the internal crystal structure of a mineral is changed to a polymorphous form, yet retaining the external crystal form of the original mineral, e.g., aragonite after calcite.

TABLE 2. REPRESENTATIVE POLYMORPHIC FORMS

Chemical composition	Mineral	Crystal system	Specific gravity
Carbon	Diamond	Isometric	3.5
Carbon	Graphite	Hexagonal	2.2
Al_2SiO_5	Sillimanite	Orthorhombic	3.2
Al_2SiO_5	Kyanite	Triclinic	3.7
FeS_2	Pyrite	Isometric	5.0
FeS_2	Marcasite	Orthorhombic	4.9

Twinning

Twinning in crystals results from the intergrowth of two or more individuals in such a way as to yield parallelism in the case of certain parts of the different individuals and, at the same time, other parts of the different individuals are in reverse positions in respect to each other. For example, an octahedral crystal of magnetite is twinned when one-half of the crystal is rotated 180° parallel to an octahedral facial plane. This type of twinning is known as *spinel twinning*, owing to its common occurrence in the spinel group of minerals.

Mineral aggregates are often grouped together to form compound crystal structures. Such groupings may be a product of irregular and accidental growth which do not conform to basic twinning laws. Two or more intergrown crystals should not arbitrarily be labeled as twins unless their twin relationship can be established.

Rock Types, Associated Minerals and Their Uses

Minerals are the basic building blocks of all rock types found in the earth's crust. Rocks are classified into three broad categories: *igneous, sedimentary*, and *metamorphic*.

Igneous rocks have their origin deep within the earth's interior from molten magmas of siliceous (silica-rich) melts. The rocks resulting from deep-seated solidification are known as *plutonic*; while those that have been extruded on the surface as lava flows are termed *extrusives*. Plutonic rocks are products of slow cooling and possess well-formed crystalline structure, e.g., granite. Extrusive rocks are products of fast cooling and occur as glassy or microcrystalline masses, e.g., obsidian and basalt.

Minerals occurring in igneous rocks possess crystalline character, but their rate of precipitation from the parent melt prevented their development as euhedral crystals and thus they occur as granular (anhedral) aggregates within these rocks. The more prominent component minerals include quartz, feldspar, and feldspathoid family members, micas, pyroxenes, amphiboles, and olivine. Zircon, magnetite, ilmenite, hematite, apatite, pyrite, and garnet are commonly associated in these rock types.

Pegmatites represent a residual phase of igneous depositions, characterized by extremely coarse crystalline material, that results from the presence of associated volatiles, e.g., water vapor, carbon dioxide, sulfur dioxide, and others, which decrease the viscosity and facilitate crystallization. Quartz, feldspar, and mica are the more common minerals found in this environment, but such bodies are also hosts for many rare minerals and several types of gem stones, e.g., beryl, tourmaline, and topaz.

Sedimentary rocks are products of deposition from either the mechanical or chemical breakdown of all preexisting rock types. Precipitation from aqueous bodies rich in soluble salts produces economically valuable beds of halite and gypsum. Weathering of iron-bearing rocks has produced extensive deposits of hematite. Limestone, chalk, and diatomite are products of biochemical precipitation. Minerals commonly associated with sedimentary rocks include calcite, galena, sphalerite, pyrite, marcasite, fluorite, barite, celestite, and quartz.

Metamorphic rocks are those that have undergone a reconstitution or redistribution of the chemical elements contained in the original formations to new mineral species. The process of change involves attaining a state of equilibrium of the constituent elements with the newly imposed environment. Chlorite, biotite, garnet, staurolite, andalusite, kyanite, and sillimanite, with ubiquitous quartz, are a few of the more common minerals associated with metamorphic rocks.

Minerals of Primary Industrial and Economic Importance

Economically valuable mineral occurrences are the products of particular types of worldwide geological formations that are, or have been, hosts to such minerals. In each occurrence, the minerals found represent the products of geological processes, which include:

1. The character and concentration of the mineral components within the source magmas from which the minerals were formed.
2. Secondary deposition from either percolating solutions or gaseous emanations from intrusive formations, causing chemical reactions within the intruded formations.
3. Precipitation from chemically supersaturated solutions.
4. Alluvial deposits resulting from the erosion weathering of the original host rocks.

Minerals that are a product of the first type of formation include the basic native metals, gold, silver, and copper.

Gold is primarily a product of deposition from ascending hydrothermal solutions associated genetically with siliceous-rich igneous rocks. Pyrite and other sulfide minerals are common associates within which the gold is often physically admixed. Surficial weathering of such deposits removes the sulfides, leaving free gold as a residual deposit. Erosion of these deposits results in alluvial deposits of placer gold, both as flakes and nuggets. Other characteristics and the uses for gold are described under **Gold**.

Silver occurs both as native ore and in combination with various silver sulfide minerals. Native silver is predominantly a product of primary deposition from hydrothermal solutions. Minor occurrences are products of oxidation of silver sulfide minerals with which the native ore is secondarily associated. See also **Silver**.

Native copper commonly occurs in the oxidized zones of copper deposits in association with cuprite, malachite, and azurite. The native copper deposits on the Michigan Keeweenaw Peninsula represent an exceptional occurrence. The copper occurs there as veins within igneous trap rocks interbedded with conglomerates. See also **Copper**.

Similar and valuable minerals include cinnabar (mercury); antimony (for type metal and battery plates); galena (lead and silver); argentite, pyrargyrite, and proustite (silver); sphalerite (zinc); chalcocite, chalcopyrite, bornite, malachite, azurite, and cuprite (copper); nickeline and pentlandite (nickel); bauxite (aluminum); magnetite, hematite, and goethite (iron).

Diamonds were found originally as loose crystals in geologically ancient alluvial stream beds. Later, their host formations were found to be a basic igneous rock (kimberlite) in the Republic of South Africa. Diamonds are the products of extremely high-temperature, high-pressure environment and are composed of pure carbon. See also **Diamond**.

Trap rocks (basalts) are products of volcanic action, either as extensive lava flows, or as intrusive dikes in preexisting rocks. Secondary mineralization within such rocks from circulating waters produces interesting suites of zeolitic minerals, such as analcime, heulandite, natrolite, stilbite, mesolite, and others.

These minerals possess the ability to exchange ions contained in the mineral structure for those in solutions. This facility promotes the use of zeolitic minerals (or their synthetic counterparts) as water softeners. Water rich in calcium (hard water), when passed in solution through a tank containing zeolites, loses the calcium ions by absorption in the zeolite structure, with substitution of calcium ions by sodium ions. A reverse process may be initiated with the sodium ions replacing calcium ions in the structure, thereby reconstituting the original zeolite composition. See also **Zeolite Group**.

Halite, gypsum, and anhydrite are products of precipitation from large bodies of supersaturated salt water. The salt and gypsum of commerce are derived from such deposits. See also **Gypsum**; and **Sodium Chloride**.

Landlocked inland seas and lakes become enriched with various soluble elements from waters draining into those basins. Sylvite and carnallite are valuable for their potassium content. They represent the final evaporation products of landlocked bodies of supersaturated sea water. Two famous localities are Stassfurt, Germany and near Carlsbad, New Mexico. Minerals formed from the evaporation of boron-rich waters include borax, kernite, colemanite, and ulexite. See also separate alphabetical entries for these minerals. The only known locality for kernite is the Mohave Desert in California, where a deposit of great extent exists—with potential reserves of millions of tons beneath the desert floor.

Pegmatites are valuable mineral sources. These formations represent the residual phase of igneous crystallization from magmas rich in siliceous content. As crystallization of their component elements proceeds, these magmas become increasingly enriched with volatile substances (mineralizers), such as water vapor, carbon dioxide, chlorine, fluorine, phosphorus, and others. The volatiles reduce the viscosity of the residual magmas and facilitate crystallization, as previously mentioned. When the residual liquids are injected into cooler rocks, they crystallize from their peripheral borders inward. The great mobility of the constituents enhances the growth of large mineral crystals—a characteristic feature of pegmatite bodies. Beryl and spodumene crystals from pegmatites attain sizes in terms of feet and tons. Feldspar, quartz, and mica crystals of comparable character are not uncommon.

There are two genetic pegmatite types—*simple* and *complex*. Simple pegmatites are recognized by their coarse texture and normal granite components, e.g., quartz, feldspar, and mica. Pegmatites produce the feldspar of commerce and mica for industrial and commercial uses. See also **Feldspar**; and **Mica**. Complex pegmatites are characterized by the presence of rare elements, in addition to the normal feldspar, quartz, and mica. Such bodies are also hosts for many semiprecious gem stones, such as amethyst, rose quartz, topaz, tourmaline, beryl, and chrysoberyl. Many rare-earth minerals obtained from complex pegmatite minerals include columbite/tantalite (columbium or niobium; tantalum), lepidolite, triphylite, spodumene, amblygonite (lithium), zircon (zirconium), and monazite (thorium oxide).

A most unusual pegmatite occurs near Ivigtut, Greenland. This consists of a cryolite with subordinate siderite, chalcopyrite, galena, and sphalerite. Cryolite is a fluoride of sodium and aluminum. For many years, cryolite was mined from this single occurrence for use as a flux in the electrolytic recovery of aluminum from bauxite, the major ore source of aluminum. Synthetic sodium aluminum fluoride essentially has replaced the need for natural cryolite. See also **Aluminum**; **Bauxite**; and **Cryolite**.

Quartz and tourmaline crystals once were commercially important for their piezoelectric properties as radio oscillation wafers and other electronic and instrumental uses. Synthesized quartz crystals have largely replaced the need for natural quartz for such applications.

Nuclear fission reactors are supplied with materials from uranium-bearing minerals of primary origin, e.g., uraninite/pitchblende, and other uranium-bearing minerals of secondary origin, e.g., carnotite, tyuyamunite, torbernite, and autunite.

Minerals of economic importance within sedimentary formations include, but are not limited to fluorite, barite, phosphorite, and oolitic hematite. Fluorite is utilized as a flux in steelmaking and when of high quality as lenses and prisms in the optical industry. Barite is an essential mineral used in gas- and oil-well drilling. Phosphorite, a product of chemical precipitation from seawater, when treated with sulfuric acid, produces superphosphate fertilizer. Oolitic hematite deposits of extensive size are important sources of iron ore.

Garnet is a common mineral component in metamorphic rocks. A major occurrence of this type is at the summit of Gore Mountain, North River, in Warren County, New York. The garnet is a composite of almandine and pyrope with a hardness exceeding that of most world garnets. Gore Mountain garnet retains sharp cutting edges even when crushed to submicron size, making it an outstanding abrasive. It is used extensively as an abrasive (garnet paper) and as a glass-polishing agent in the optical industry.

Titaniferous iron ores, represented by the mineral ilmenite, occur within crystalline metamorphic environments. These ores are the major source of titanium. See also **Titanium**.

Major sources of industrial (non-fuel) minerals are shown in Table 3.

Ocean Sources of Minerals

Mineral requirements for future world needs has focused increased attention to potential ocean resources. Major attention has been directed to petroleum resources. Associated with the petroleum are salt domes or bedded salt deposits, often with anhydrite and sulfur. Their potential is dependent upon development of economically feasible recovery methods. Not enough is known at this time about the origin of sulfur to satisfactorily predict precise occurrences. The Frasch process is presently being utilized in certain offshore deposits of this type. The economics of sulfur also may be affected by availability of large quantities of the element from Claus recovery units used in connection with the desulfurization of flue gases.

Valuable deposits of detrital sands and lime muds occur on the continental shelves of many world areas. These can be recovered by dredging operations. Diamonds are presently being recovered by means of vacuum suction tubes from detrital subsea sands adjacent to the Orange River section off the south-western African coast. Dependent upon the nearshore geology, it is known that iron, copper, and coal deposits extend into the subsea areas. In several world areas (Scotland and Japan for coal; Finland and Canada for iron ore; the English coast for tin and copper) deposits have been mined from underground entrances from the adjacent land areas. Sphene and zircon, plus other heavy minerals, have been noted in Texas offshore sediments.

Phosphorite, a major source of phosphorus, is known to occur both as nodular masses and crusts on rocks in subsea areas. Although enormous amounts of phosphorite are accessible in relatively shallow water, marine phosphorites have not been economically competitive with terrestrial supplies.

Metallic sulfides of copper, zinc, and iron have been found in central oceanic rocks and muds under conditions that indicate their deposition

TABLE 3. MAJOR SOURCES OF INDUSTRIAL (NONFUEL) MINERALS

ALUMINUM
Major source is bauxite (gibbsite and boehmite). Deposits are found worldwide, except in Antarctica. Major producers: Australia; Caribbean countries; Venezuela; Brazil; Indonesia.

CHROMIUM
Nearly all chromium ores are found in the Republic of South Africa and Zimbabwe.

COBALT
Zaire, Zambia, and Russia.

COPPER
Chile, United States, Russia, Canada, Zambia, and Zaire.

GOLD
Republic of South Africa; Russia, Brazil, and the United States (not extensive).

IRON
Russia, the United States, Brazil, Australia, and China.

LEAD
United States, Russia, Australia, and Canada

MANGANESE
United States, Japan, and Western Europe. (Major reserves are in South Africa and Russia)

NIOBIUM (Columbium)
Brazil and Canada

NICKEL
Russia, Canada, Australia, and Indonesia.

PLATINUM-GROUP METALS
Russia and Republic of South Africa.

SILVER
United States. (Silver is mined in more than 53 countries.)

TANTALUM
Thailand, Australia, and Brazil.

TITANIUM
Russia, Japan, United States

ZINC
Canada, Russia, Australia, Peru, and United States.

Source: U.S. Bureau of mines.

from hydrothermal solutions. Such solutions, rich in carbon dioxide, leached metallic elements from both basic rock masses and sedimentary formations with which they came in contact. When such solutions ascended, with concomitant cooling, the minerals were precipitated in the overlying sediments.

Manganese and iron oxides occur as nodular masses in many subsea world areas. They presently are of more interest for their copper, nickel, and cobalt content than for the manganese. Most extensive occurrences are at great ocean depths, as much as 3,500 to 4,500 meters. Fullest exploitation of these deposits and the metallic sulfides will require not only additional technical knowledge for their initial recovery, but also for their refinement to a marketable form. Again, the economics depends upon future demands for the metals as the continental deposits become depleted. Beyond these considerations, the persistent problem of ownership of oceanic resources must be solved as a condition of large-scale recovery. See also **Manganese**.

Lunar Rocks

Geological specimens collected on the *Apollo* lunar missions are indicative of an anhydrous igneous origin. There are three major rock types: (1) a potassium-rich basalt; (2) anorthosite; and (3) an iron, titanium-rich basalt. The first two types are prevalent in the highland areas; the latter in the maria terrain. They occur as crystalline vescicular masses, breccias, and regolithic mantle dust. The absence of an atmosphere and weathering processes on the moon has left the rocks and their component minerals unchanged through eons of time since their formation. Secondary mineralization, therefore, is generally absent and the rocks exhibit a rather limited mineralogy.

Lunar rocks differ in their chemical content rather than type of rock from their terrestrial counterparts. They consistently contain more titanium and chromium, less sodium, and most are richer in iron content. Lunar plagioclase, the major mineral component of anorthosite, is almost always the calcium-rich anorthite, $CaAl_2Si_2O_8$, indicating extreme magmatic differentiation. Lunar basalts are olivine-rich and have been found to be from 3 to 10 times richer in ilmenite (titaniferous iron) as compared with terrestrial basalts.

Clinopyroxene materials, which are common in terrestrial basalts, are well represented in lunar rocks. They include diopside, hedenbergite, johannsenite, aegerine-augite, spodumene, jadeite, augite, pigeonite, omphacite, and fassaite. The more prominent lunar mineral species noted include ilmenite, with rutile intergrowths in certain subfloor maria basalts, cristobalite/tridymite, and pyroxferroite, a mineral closely related in both structure and composition to terrestrial pyroxmangite. Accessory minor minerals include troilite, chromite, ulvospinel, apatite-whitlockite, potash feldspar, quartz, hafnium-rich baddeleyite, and perovskite. Two newly classified species have been recorded—armalcolite, an iron-magnesium titanate, named after *Apollo* astronauts *Arm* strong, *Al* drin, and *Col* lins; and zirkelite, an oxide of calcium, iron, thorium, uranium, with titanium, niobium, and zirconium. Euhedral iron crystals in a pyroxene-rich vug of recrystallized breccia were recovered on the *Apollo 15* mission.

Tiny translucent-to-opaque glassy spherules are prominent in the lunar regolith, within which ilmenite (as thin plates) with minor olivine are present.

Lunar mineralogy is generally analogous to that of terrestrial basalts, the major difference being the lack of oxygen during crystallization which has resulted in the presence of free iron and the exotic minerals, such as troilite, pyroxferroite, armalcolite, and zirkelite. The bulk mineralogy, however, is quite similar to terrestrial rocks with pyroxene, plagioclase, ilmenite, and olivine as the dominant minerals.

Phase equilibrium research of mineral solids has revealed vital information regarding their molecular structure. Application of knowledge gained from this research has extended into the fields of metallurgy, glass and ceramics, and a more adequate interpretation of mineral geology.

Mariner 9 fly-by of Mars revealed a surface terrain of massive blocks of tumbled character cut by ridges and graben-type troughs. Huge volcanic peaks dominate a pock-marked landscape. Extensive channels characteristic of concentrated erosive powers of torrential floods were also evident, as were braided stream systems emanating from what were resolved to be plateau-type elevations.

Viking spacecraft equipped with a hoe-type scoop and spectrometer analyzed the surface soil to be of a character suggestive of an igneous mafic rock origin, rich in magnesium and iron. The *Viking Landers'* spacecraft analysis of the surface soil chemical composition by x-ray fluorescence revealed a low SiO_2 concentration (~45%) with iron as Fe_2O_3 near 20%. Further analysis revealed that the regolith mantle soil consisted essentially of iron-rich clay mineral with iron hydroxide, and minerals of sulfate and carbonate content with approximately 1% water by weight. Magnets attached to *Viking's* scoop attracted magnetic material aggregates. It is quite probable that the magnetic material represents a component part of that regolith and possibly the soil is enriched by both magnetite (Fe_3O_4, color black) and maghemite (γ-Fe_3O_4, color yellowish-brown). The yellowish-brown surface color may be the product of thin coating of hydrated iron oxides, with nontronite/montmorillionite as the host soil.

Much remains to be resolved before final definitive answers can be given in this area of planetary investigation and evaluation.

Classification of Minerals

Minerals are classified in groups, according to their chemical composition, based upon the dominant anion or anionic group. The system works well in various ways. Generally, the dominant anion or anionic group brackets minerals of corresponding characteristics which tend to occur in quite similar environments. The dominant chemical subdivisions are:

Elements. Minerals composed of uncombined chemical elements, e.g., Au, gold; Ag, silver; Cu, copper; although minor impurities may be present within the structure.

Sulfides. Minerals composed of compounds of metals with sulfur.

Sulfosalts. Minerals composed of compounds of semimetals with sulfur.

Halides. Minerals composed of compounds of metals with fluorine, chlorine, bromine, and iodine.

Oxides and Hydroxides. Minerals composed of compounds of the metallic elements with oxygen.

Carbonates. Minerals composed of compounds of a metal with the carbonate radical CO_3.

Borates. Minerals composed of compounds of a metal with the borate radical, BO_3.

Nitrates. Minerals composed of compounds of a metal with the nitrate radical, NO_3.

Sulfates. Minerals containing the sulfate radical, SO_4.

Chromates. Minerals containing the chromate radical, CrO_4.

Molybdates. Minerals containing the molybdate radical, MoO_4.

Tungstates. Minerals containing the tungstate radical, WO_4.

Phosphates. Minerals containing the phosphate radical, PO_4.

Arsenates. Minerals containing the arsenate radical, AsO_4.

Vanadates. Minerals containing the vanadate radical, VO_4.

Silicates. This mineral classification encompasses the largest group of mineral species and includes most of the important rock-forming minerals, such as the feldspars, feldspathoids, pyroxenes, amphiboles,

TABLE 4. MINERALS DESCRIBED IN THIS ENCYCLOPEDIA

ARSENATES
- Annabergite
- Erythrite
- Mimetite
- Scorodite

BORATES
- Boracite
- Borax
- Colemanite
- Inyoite
- Kernite
- Ulexite

CARBONATES
- Aragonite
- Azurite
- Barytocalcite
- Bastnasite
- Calcite
- Cerussite
- Chalk
- Dolomite
- Magnesite
- Malachite
- Phosgenite
- Rhodochrosite
- Siderite
- Smithsonite
- Strontianite
- Travertine
- Witherite

CHROMATES
- Crocoite

ELEMENTS
- Amalgam
- Antimony
- Bismuth
- Copper
- Diamond
- Electrum
- Gold
- Graphite
- Mercury
- Platinum
- Plumbago
- Quicksilver
- Silver
- Sulfur

HALIDES
- Atacamite
- Carnallite
- Chlorargyrite
- Cryolite
- Fluorite
- Halite
- Sylvite

MOLYBDATES
- Wulfenite

NITRATES
- Niter
- Soda-Niter

OXIDES AND HYDROXIDES
- Alabandite
- Alexandrite
- Anatase
- Bauxite
- Brookite
- Brucite
- Cassiterite
- Cat's-Eye

micas, olivine, and quartz. Silicon is the basic chemical element, as the name implies. The small silicon cation combines with four oxygens to form an SiO_4 tetrahedral structure. The SiO_4 formula leaves a net negative charge, which requires additional combinations with other tetrahedra or anions to effect a neutral balance. The type and degree of such tetrahedral combinations control the final structural character and act as a convenient classification of the silicate mineral family.

Subclassification of silicates are:

Nesosilicates, with each tetrahedron existing within the structure as isolated SiO_4 units.

Sorosilicates involve the pairing of SiO_4 tetrahedra. The shared-oxygen anion represents the link between these tetrahedra.

Cyclosilicates involve two oxygens from each SiO_4 tetrahedron combining with oxygen in adjacent tetrahedral units to form *ring* structures.

Inosilicates are the product of oxygen sharing between adjacent tetrahedra to form *single* or *double* chains. In the single-chain structure, two oxygens from each tetrahedra combine with adjacent tetrahedra. In the double chain, half of the tetrahedra share three oxygens, while the other half share only two.

Phyllosilicates involve the sharing of three oxygens in each tetrahedron with adjacent tetrahedrons to form *sheet* structures. Minerals in this classification are usually flaky in character and relatively soft.

Tectosilicates involve the sharing of all four oxygens in each tetrahedral unit with adjacent tetrahedrons to form a three-dimensional *framework* of SiO_4 units linked together. The product is a strongly bonded structure with a silicon-oxygen ratio of 1:2. The greater portion of the earth's crust is composed of minerals found within this classification.

Most minerals exhibit a variation in their chemical composition, with the exception of the elements (see preceding list). The substitution of one ion for another is common, since minerals crystallize in solutions of complex composition.

A full listing of all minerals described separately in this encyclopedia is given in Table 4.

MIRROR NUCLIDES. Pairs of nuclides, having their numbers of protons and neutrons so related that each member of the pair would be transformed into the other by exchanging all neutrons for protons and vice versa.

MISCIBILITY. The ability of two or more substances to mix, and to form a single, homogeneous phase.

MISSLE PROPELLANTS. See **Rocket Propellants**.

MITCHELL, PETER D. (1920–1992). A British biochemist who was the recipient of the Nobel prize for chemistry in 1978 for his contribution to the understanding of biological energy transfer through the formulation of the chemiosmotic theory.studies of cellular energy transfer. A graduate of Cambridge and recipient of many awards, he was the Director of Research, Glynn Research Institute.

MITSUNOBU REACTION. Intermolecular dehydration reaction occurring between alcohols and acidic components on treatment with diethyl azodicarboxylate and triphenyl phosphine under mild neutral conditions. The reaction exhibits stereospecificity and regional and functional selectivity.

MIXING AND BLENDING. These operations are important to chemical research and processing. In exploratory work in the laboratory the effects of mixing may be very great, and it is essential that the desired type and amount of mixing can be reproduced or can be varied by known amounts. The primary purpose of mixing is to distribute components as uniformly as possible; temperature distribution is frequently a major purpose. These may be followed by a chemical reaction or a transfer of matter between phases, and by a transfer of heat for temperature control. The mixer produces mechanical effects only. Molecules of themselves will diffuse, but mixing impellers produce flow which results in forced convection and mixing. Hence, reactants can be brought to an interface as rapidly as desired by controlling the fluid motion. Most fluid mixing is done by rotating impellers.

Both large scale (mass flow) motion and small scale (turbulent) motion are ordinarily required to bring about rapid mixing. The discharge stream from an impeller initiates the large scale flow pattern. Turbulence is generated mostly by the velocity discontinuities adjacent to the stream of

fluid flowing from the impeller, and also by boundary and form separation effects. Turbulence spreads throughout the mass flow and is carried to all parts of the container. Some mixing operations require relatively large mass flows for best results, whereas others require relatively large amounts of turbulents. There is usually an optimum ratio of flow to turbulence for a desired mixing operation, whether it is a simple blending of immiscible liquids or a mass transfer followed by chemical reaction.

In the research laboratory it is important to recognize the effect of mixing on reaction rate or on other performance criteria. Energy must be supplied to produce fluid motion, thus, to compare mixing with different equipment or with different sizes of the same type impeller, it is essential that the comparisons be made on the basis of equal power input.

For the same power, the ratio of flow to turbulence from mixing impellers can be varied by changing the size and speed of the impeller. Figure 1 illustrates the differences in mass flow and turbulence which can be achieved for the same power input for dimensionally similar impellers. A large-diameter low-speed impeller produces a large ratio of flow to turbulence, whereas a small-diameter high-speed impeller will give a small ratio. Curve A, Figure 2, illustrates a reaction best accomplished by large flow and small turbulence. This curve, which is typical of blending operations, shows that the rate of blending increases to a maximum with a large impeller as impeller diameter is increased (and impeller speed is decreased) with power input constant.

Curve B of Figure 2 is typical of gas-liquid contacting operations. Here the rate pf mass transfer between phases increases to a maximum at small impeller diameter and then decreases as impeller diameter is increased. The significance is that more turbulence is available with the small impeller and that turbulence is more important than flow in this operation.

In all bench-scale and pilot plant work where mixing is important, the effect of the impeller diameter-turbine diameter ratio should be determined so that the type of flow motion best suited to the operation can be found. If an optimum ratio is found, it becomes the basis for large scale design.

Mixing Vessels, Flow Patterns, and Impellers. Flow motion is dependent upon the shape and fitting of the container, the shape and position of the rotating impeller, and the physical properties of the fluid. The best mixing is usually one which produces lateral and vertical flow currents, and these currents must penetrate to all portions of the fluid; swirling motion should be avoided. Cylindrical vessels provide the best environment for mixing.

The most useful impellers are the simple flat paddle, the marine-type propeller, and the turbine. If any of these are on a vertical shaft rotating on the center line of a cylindrical vessel, the fluid motion will be one of rotation. A vortex forms around which the liquid swirls. A minimum of turbulence and of vertical and lateral flow motion will result. very little power can be applied.

Rotary motion (and surface vortex) can always be stopped by inserting projections in the body of the fluid; when these are at the side if the tank they are called baffles, and this is the method most commonly used to obtain good mixing in large industrial equipment. The propeller with baffles will produce an axil flow pattern, Fig. 3, and the paddle and turbine will produce radial flow, Fig 4.

Motionless Mixers. Mixing of molten polymers has been a problem in the plastics industry for many years mainly because of the high viscosity

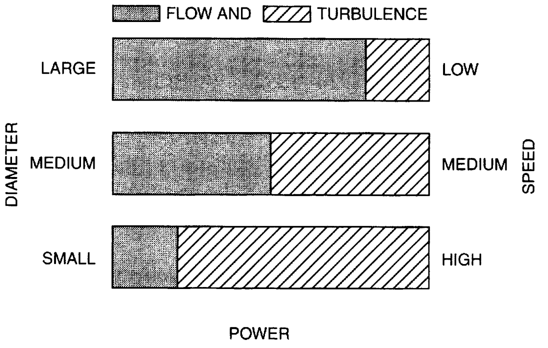

Fig. 1. Constant power, effect of impeller size, and speed on flow and turbulence

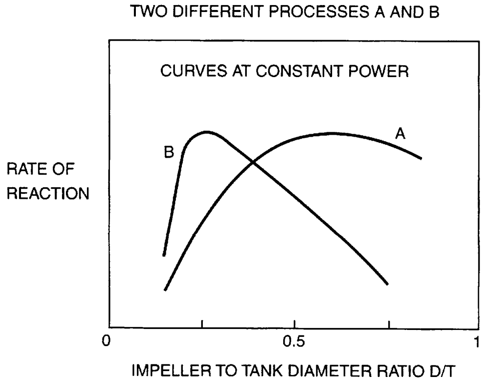

Fig. 2. Effect of impeller size on reaction rate at equal power output

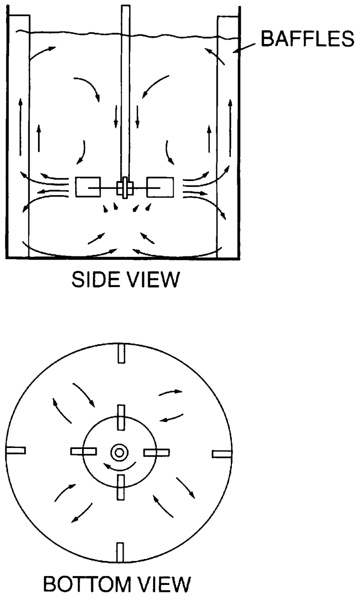

Fig. 3. Typical flow patterns from axial flow impeller in baffled tank

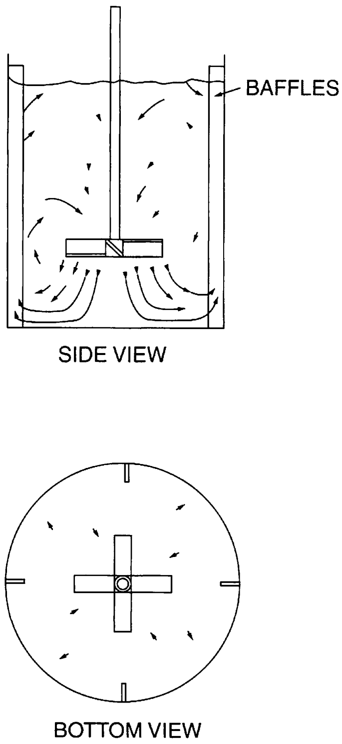

Fig. 4. Radial flow pattern for flat blade turbine positioned on center in baffled tank

of the melt. Blending of color concentrations, fillers, stabilizers, and other additives have sometimes been difficult to achieve efficiently with traditional mixing approaches, such as the extruder screw and other rotating devices. These problems have been partially solved through the application of so-called motionless mixers. A stationaly baffle installed in a pipe can utilize the energy of the flowing fluid to produce mixing. Turbulent conditions are required for this simplistic approach. In recent years, more sophisticated motionless mixers have been developed. One design consists of a number of short right- and left-hand helices. The opposite hand helices are welded together so that their leading edges are 90 degrees to the trailing edge of the preceeding element. The mixing unit is housed in a tube or pipe for in-line installation. Materials entering the static mixer experiences flow division at the leading edge of each element. As the flow divides, it follows the semicircular channel of each element and repeatedly divides at succeeding junctions of additional elements, resulting in flow division and radial mixing. Other approaches involving complex geometric stationary elements have been developed. Some of these units also can function for heating and cooling as well and mixing. [See "Motionless Mixers in Plastic Processing," Schott, Weinstein, and LaBombard, *Chem. eng. Progress*, **71**(11) 52–58 (1975)].

Automatic Blending Systems. For a number of industrial applications, in-line blending of liquids and solids has replaced former batch-type operations. In these systems, all components flow together simultaneously to a central collection point where they combine to form the finished product. A modern in-line blending system is shown in Fig. 5. The blend controller will normally utilize microprocessor technology with a cathode-ray tube (CRT) display. Each fluid component is pumped from a storage tank, through a strainer, and then through a flowmeter, with the meter and valve carefully selected for prevailing process conditions (viscosity, temperature, pressure, flow rates). The signal from the flowmeter is fed to the blend controller which compares the actual flow rate to the desired flow rate. For minor components, such as dyes or additives, it is sometimes

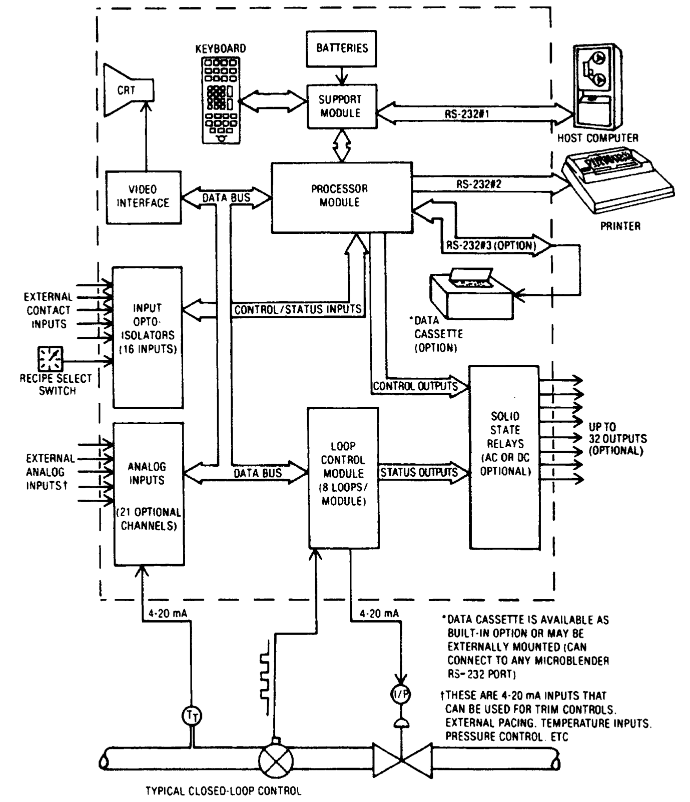

Fig. 6. Blend controller block diagram

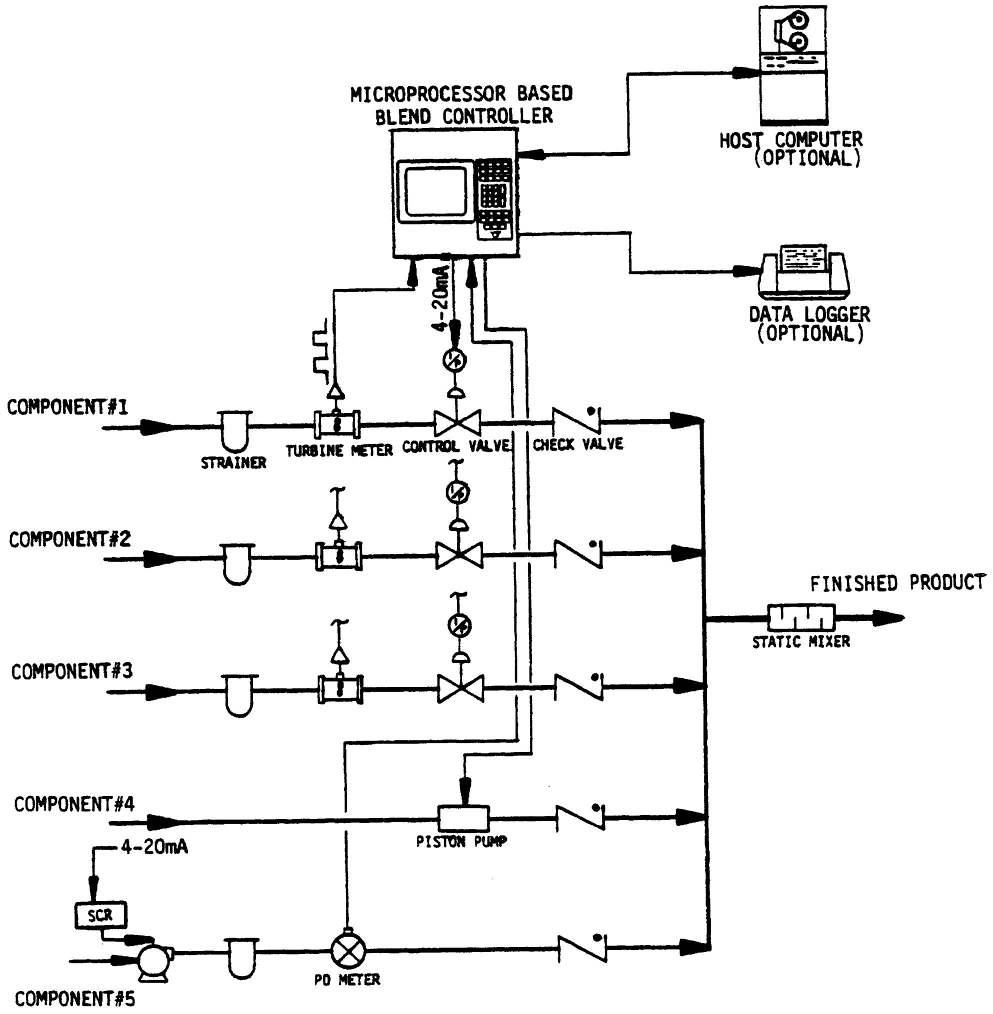

Fig. 5. Typical blender configutaion. (*Waugh Controls Corporation.*)

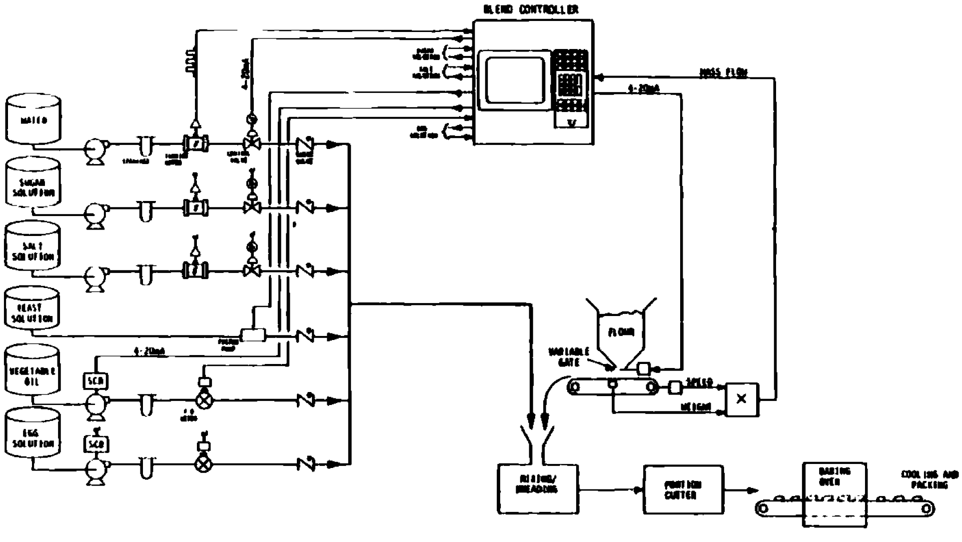

Fig. 7. Blending system for preparing bread and partry dough. (*Waugh Controls Corporation.*)

most practical to control the flow rate by means of proportioning pumps which inject a precise amount of the fluid when a pulse signal from the blend controller is received. This type of open-loop control is cost efficient, but some means for assuring flow (detecting any dry line) should be considered inasmuch as there is no direct fluid measurement device used. Other variations of measurement and control involve the use of variable-speed pump motor controllers (SCRs) for flow control; adding a flowmeter in series with an injection pump. Weigh-belt feeders with variable-feed/speed control and tachometer/load-cell outputs are frequently used for blending powders and aggregates.

A blend controller block diagram is shown in Fig. 6. A system for preparing bread and pastry dough is shown in Fig. 7. Applications for continuous blending systems are frequently found in the petroleum, petrochemical, food and beverage, building materials, pharmaceutical, automotive, and chemical industries, among others.

MODACRYLIC FIBERS. See **Fibers: Acrylic; Fibers**

MODERATOR. A substance used to slow down neutrons by means of collisions. Moderators play an important role in the design and operation of nuclear reactors. Moderators *thermalize* neutrons to an energy of about 0.025 eV.

MOHS SCALE. An empirical scale of the hardness of mineral or mineral-like materials originally consisting of 10 values, ranging from talc, with a rating of 1, to diamond, with a rating of 10. The rating is based on the ability to each material to scratch the one directly below it in the series. The number of materials has been expanded from 10 to 15 with the addition of several synthetically produced substances (e.g., silicon carbide) between the original 9 to 10 positions. The scale is named after the German mineralogist, Friedrich Mohs (1773–1839). See also **Hardness**; and **Mineralogy**.

MOIETY. An indefinite portion of a sample.

MOISSAN, HENRI (1852–1907). A Native of Paris, Moissan was a professor at the School of Pharmacy from 1886 to 1900 and at the Sorbonne from 1900 to 1907. At the former institution, he first isolated and liquefied fluorine in 1886 by the electrolysis of potassium acid fluoride and anhydrous hydrogen fluoride. His work with fluorine undoubtedly shortened his life as it did that of many other early experimenters in the field of fluorine chemistry. He won great fame by his development of the electric furnace and pioneered its use in the production of calcium carbide, making acetylene production and use commercially feasible in the preparation of pure metals, such as magnesium, chromium, uranium, tungsten, etc., and in the production of many new compounds, e.g., silicides, carbides, and regractories. In 1906, he was awarded the Nobel prize in chemistry.

MOISTURE RETAINING SUBSTANCES. See **Humecants and Moisture-Retaining Agents**.

MOLAL CONCENTRATION. A one molal solution contains one mole of a particular substance (the solute) in 1,000 grams of solvent. Thus, a 0.5 molal solution of potassium chloride in water contains 0.5× (gram-molecular weight of KCl = 74.555), or 37.278 grams of the salt in 1,000 grams of H_2O. See also **Molar Concentration**; and **Normal Concentration**.

MOLAR CONCENTRATION. A one molar solution contains one mole of a particular substance (the solute) in 1,000 milliliters of solution. Thus, a 0.5 molar solution of potassium chloride in water will be prepared by placing 0.5× (gram-molecular weight of KCl = 74.555), or 37.278 grams of the salt in a vessel and then adding H_2O, while thoroughly mixing to assure complete solution of the salt, until a total volume of 1,000 milliliters of solution is obtained. Molar is abbreviated *M*. Thus, the solution in the foregoing example would be 0.5 *M* KCl. Molar solutions sometimes are referred to as *formal* solutions, not to be confused with normal solutions. See also **Molal Concentration**; and **Normal Concentration**.

MOLAR HEAT. The product of the gram-molecular weight of a compound and its specific heat. The result is the heat capacity per gram-molecular weight

MOLD. See **Yeasts and Molds**.

MOLD INHIBITORS. See **Antimicrobial Agents (Foods)**.

MOLE (Stoichiometry). Sometimes spelled *mol*, a mole is a quantity of a substance, expressed in specified mass units, that is equal to the molecular weight of the substance. For example, a *gram-mole* or *gram-molecular mass* of hydrogen H_2 will have a mass of 2 × (atomic weight of hydrogen), or 2.016 grams. A gram-mole of carbon dioxide CO_2 will have a mass of 1 × (atomic weight of carbon) plus 2 × (atomic weight of oxygen), or 12.011 plus 31.998 = 44.009 grams. A pound-mole of ammonia gas NH_3 will have a mass of 1 × (atomic weight of nitrogen) plus 3 × (atomic weight of hydrogen), or 17.031 pounds. See also **Avogadro Constant**.

MOLECULAR AND SUPERMOLECULAR ELECTRONICS. Professor Gareth Roberts FRS, Director of Research, Thorn EMI plc, and Professor of Engineering Science at the University of Oxford.

The microelectronics and optoelectronics industries will continue to grow vigorously well into the 21st Century. Until now, they have relied largely on inorganic materials such as silicon and lithium niobate in single crystal form. However, as the perceived limitations inherent in these materials begin to restrict the realization of more complex system designs, more attention is being focussed on the *organic* solid state. The richness of the variety of organic molecular materials offers enormous potential compared with the relative paucity of structures achievable with inorganic compounds, even when due allowance is made for the recent

exciting developments in inorganic quantum well semiconductors (Kelly and Weisbach 1986).

The ability to enlist the assistance of synthetic organic chemists to produce organic materials with tailored properties has, of course, already been used to advantage in several applications. The best known is that of liquid crystals and their use in displays and digital thermometers. New phenomena and types of molecule are still being discovered and seem likely to lead to successful large area displays for high definition television and to high density information stores. Other examples are piezoelectric polymers as very sensitive hydrophones for submarine detection, photoconducting polymers for electrocopying, and photochromic molecules for reversible high density optical storage and signal processing. Biosensors and chemical sensors for converting specific biochemical or chemical solute or gas interactions into electrical signals for use in industrial or medical diagnostics can also be mentioned. All are examples of 'Molecular Electronics,' that is, they are fields in which organic molecular materials perform an *active* function in the processing of information and its transmission and storage. This definition does not embrace their use in possible roles such as insulation, adhesion or encapsulation. Thus, molecular electronics is interpreted broadly and is not limited to phenomena concerning the movement of electrons only. Electromagnetic radiation, polarization phenomena, and various forms of electromechanical and electrochemical energy transfer are also included in the definition. A common feature of all the examples cited and of the area in general is that progress is achieved *via* 'molecular engineering' that is, using the ability to manipulate the architecture of a material to optimize a specific physical parameter.

An alternative definition exists for molecular electronics: this is formulated in terms of switching on a molecular scale and is aimed more at the long term problem of fabricating molecular electronic devices suitable for assembly into a computer (Carter 1986). It is interesting to note that only a modest diminution in the size of electronic circuit components is required before the scale of individual molecules is reached: in fact, many existing circuit elements could already be accommodated within the area occupied by a leukaemia virus. An illustration of the rapid evolution of silicon based microelectronics may be gained by studying Figure 1. If this systematic reduction in feature size suggested by the good log-linear graph is sustained, then the extrapolated line indicates device geometries with nanometer dimensions in approximately thirty years' time! The requirements of reliability and testing of complex structures suggest a system approach rather than the traditional one, which uses the properties of individual circuit elements. it appears likely that sequential designs, because of their vulnerability, will be abandoned in favor of supermolecular arrays acting as concurrent processor networks. For this reason, and to differentiate it from 'molecular electronics,' signal transport and control in nanometer scale assemblies is referred to as 'supermolecular electronics'.

Animals can solve with little apparent effort the tasks for which advanced supermolecular information processors are required: accordingly, some enthusiasts have speculated that the thirty-year time scale could be foreshortened using biological molecules. However, such thoughts are misplaced, for nature constructs organic materials for purposes other than those required for logic and memory functions. What can be learnt from studying biological systems are the scientific principles of organization and assembly: eventually, it may be possible to apply these concepts to construct synthetic supermolecular arrays. These will require nonlinear interactions between neighbors so that configurations of 'on' and 'off' elements propagate with time. However, it will be a difficult task to control the correlations between the parallel processing elements whether they be based on electronic, vibrational or magnetic effects. A great deal of fundamental research will be required to identify molecular systems with the necessary degree of cooperativity and to develop the routine analytical techniques designed for investigations in three dimensions with molecular scales of resolution.

Three-dimensional integration is extremely difficult using silicon technology while chemically nonspecific methods such as molecular beam epitaxy are relatively crude. A self-assembly technique is a far more attractive alternative if regular, three-dimensional, ordered structures are required. This involves the construction of unique assemblies whose architectures depend on the shapes and charge distributions of the units from which they are built, as distinct from the methods used to assemble them. There is a considerable degree of self assembly associated with organic monomolecular films deposited using the Langmuir trough technique (Roberts 1985). About half a century after the report of their discovery, intense interest is now being displayed in these so called Langmuir-Blodgett films. Their precise thickness, coupled with the degree of control over their molecular architecture has now firmly established a role for such layers in thin film technology. It seems likely that an understanding of their physical properties and utilization in molecular based devices will assist generally in the transition from molecular to supermolecular electronics. The likely pattern for this evolutionary process is given in Figure 2. The plan is speculative and envisages three main stages before the advent of applied, complex supermolecular systems. In the near term it predicts that current research and development will result in organic materials ousting inorganic materials in existing applications, e.g. optoelectronics. Hybrid technologies, comprising a novel device partly based on conventional solid state materials and partly on organic compounds, could possibly follow in the mid-term, say 5 or 8 years. Thereafter, at some stage dictated by the emergence of reliable, stable supermolecular assemblies, a true watershed will occur. When this occurs, materials and process technologies of conventional solid state devices will be superceded by radically new types of devices. This era will be equivalent to that witnessed about forty years ago when inorganic semiconductor materials were developed. Just as then, novel effects should be discovered and these in turn will lead to the fabrication of novel devices that can be integrated in novel systems.

Molecular and supermolecular electronics are broad and interesting subjects. Moreover, they require a multidisciplinary approach where collaboration between biologists, chemists, computer scientists, electronic engineers and physicists is of paramount importance. To illustrate these features, this article concentrates on Langmuir-Blodgett films. Equal emphasis is placed on their importance in basic science and on their potential applications, especially in the area of electronics.

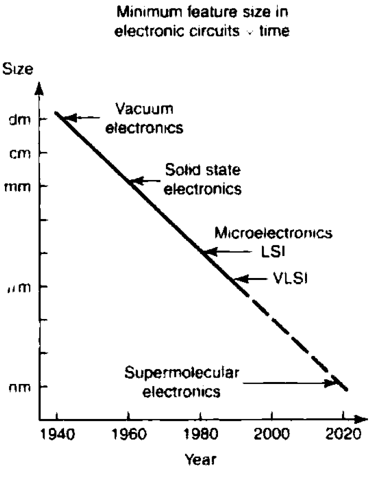

Fig. 1. Linear feature size of commercial electronic circuits versus time: the bottom arrow speculatively points to an era where switches on a molecular scale will have application in computer systems

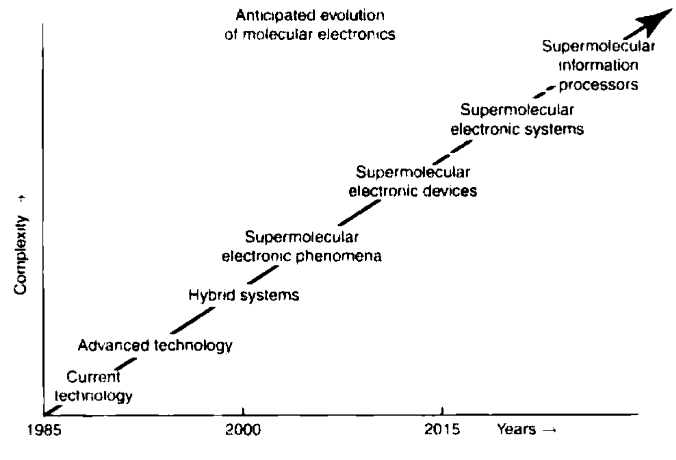

Fig. 2. The anticipated evolution of molecular electronics to supermolecular electronics

Historical Review of Langmuir-Blodgett Films

According to Tabor (1980) the earliest written record of observations of the spread of oil on water is in cuneiform on clay tablets, dating from Hammurabi's period (18th century B.C.) in Babylonia. The earliest technical application of organic monolayer films is believed to be the Japanese printing art called subminagashi, involving a suspension of submicron carbon particles and protein molecules spread on the surface of water. The distinctive patterns so formed can be transferred by lowering a sheet of paper onto the water surface. There are also many references dating from the classical times of Plutarch, Aristotle and Pliny describing the ability of oil spread on water to dampen surface waves and ripples. It was this property which attracted Benjamin Franklin, the versatile American statesman, to the subject. During his frequent visits to Europe in the 18th century A.D. to negotiate the sovereignty of his country with the French and the British he carried out his famous 'teaspoonful of oil' experiment. Often quoted and picturesque, Franklin's (1774) account to the Royal Society included the following phrases: "At length, being at Clapham where there is, on the common, a large pond, which I observed to be one day very rough with wind, I fetched out a cruet of oil, and dropped a little of it on the water. I saw it spread itself with surprising swiftness upon the surface ... I then went to the windward side, where (the waves) began to form and there the oil, though not more than a teaspoonful, produced an instant calm over a space of several yards square, which spread amazingly, and extended itself gradually till it reached the lee side, making all that quarter of the pond, perhaps half an acre, as smooth as a looking glass. After this, I contrived to take with me, whenever I went into the country, a little oil in the upper hollow joint of my bamboo cane, with which I might repeat the experiment as opportunity should offer; and I found it constantly to succeed."

Franklin must have been too preoccupied with political affairs to place his observations on a quantitative basis. Had he done so he might well have calculated that a volume of one teaspoonful (approximately 2 ml) spread over an area of nearly half an acre (200 m^2) leads to a surface coating approximately 1 nm thick. However, it is Lord Rayleigh (1890) who is given the distinction of first suspecting that the maximum extension of an oil film on water represents a layer one molecule in thickness. For a direct measurement on molecular sizes he was indebted to Pockels (1891) whose simple apparatus later became the model for what is now called a Langmuir trough: using very simple equipment he calculated the precise thickness of a monomolecular layer of castor oil on water to be 1 nm. This significant observation was not fully followed up until the pioneering work by Langmuir on the adsorption of gases or solutes by solids. In order to test the general applicability of his hypothesis about the involvement of short range forces, he turned his attention to liquids and he essentially repeated (Langmuir 1917; 1920) the earlier measurements of Pockels and Rayleigh, and extended them to include the transfer of molecules from a water surface to a solid support. The first detailed description of sequential monolayer transfer was given by Blodgett (1935), his collaborator at the General Electric Company laboratories. These built up monolayer assemblies are now called Langmuir-Blodgett (LB) films, while the floating monolayer is referred to as a Langmuir film. The extensive list of publications resulting from the pioneering experiments carried out by these two investigators during the period 1934 to 1952 has been compiled by Gaines (1983).

The Chemistry and Preparation of Langmuir Films

Most of the experiments reported by Langmuir and Blodgett were on a well-defined series of fatty acids and their salts. Figure 3(a) shows stearic acid, a molecule in which sixteen CH_2 groups form a long hydrophobic chain; the other end of the molecule terminates in a hydrophilic carboxylic acid group. When dissolved in a suitable solvent and spread on the surface of water, molecules may be compressed with the aid of a barrier. Figure 4 shows a plot of the surface pressure (differential surface tension) versus area occupied per molecule for stearic acid. The monolayer undergoes a number of phase transformations during compression; the well-defined sequence can be viewed as the two-dimensional analogue of the classical transitions observed with pressure-volume isotherms. However, it should be emphasized that some materials, while forming acceptable quality LB films, do not display the well-defined break points shown in Fig. 4.

Generally speaking, the approach to the synthesis of suitable molecules for examination with a Langmuir trough has been an ad hoc one and has relied on the modification of known materials. For example, the alkyl group of fatty acids may be replaced by chains containing one or more double bonds. The ω-tricosenoic acid (Barraud 1983) molecule shown in

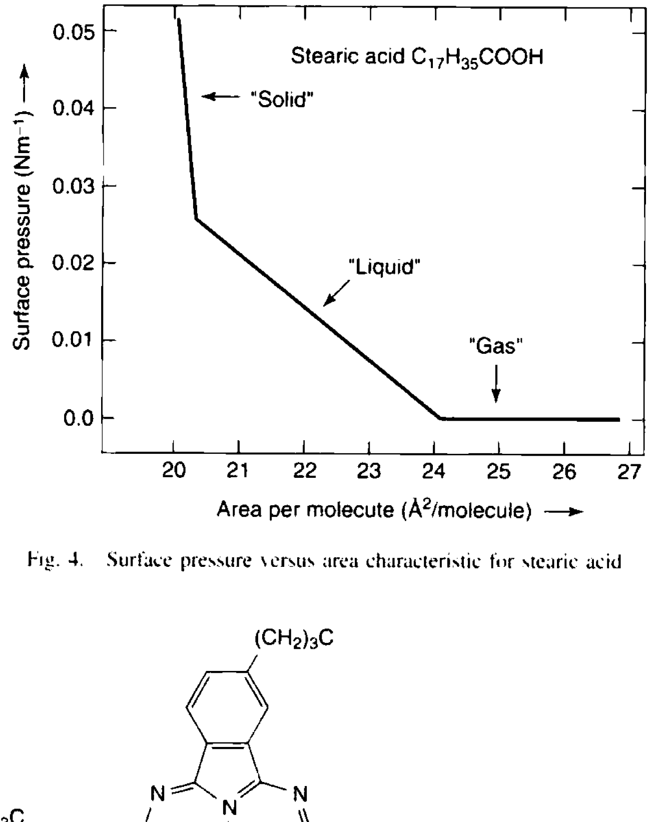

Fig. 4. Surface pressure versus area characteristic for stearic acid

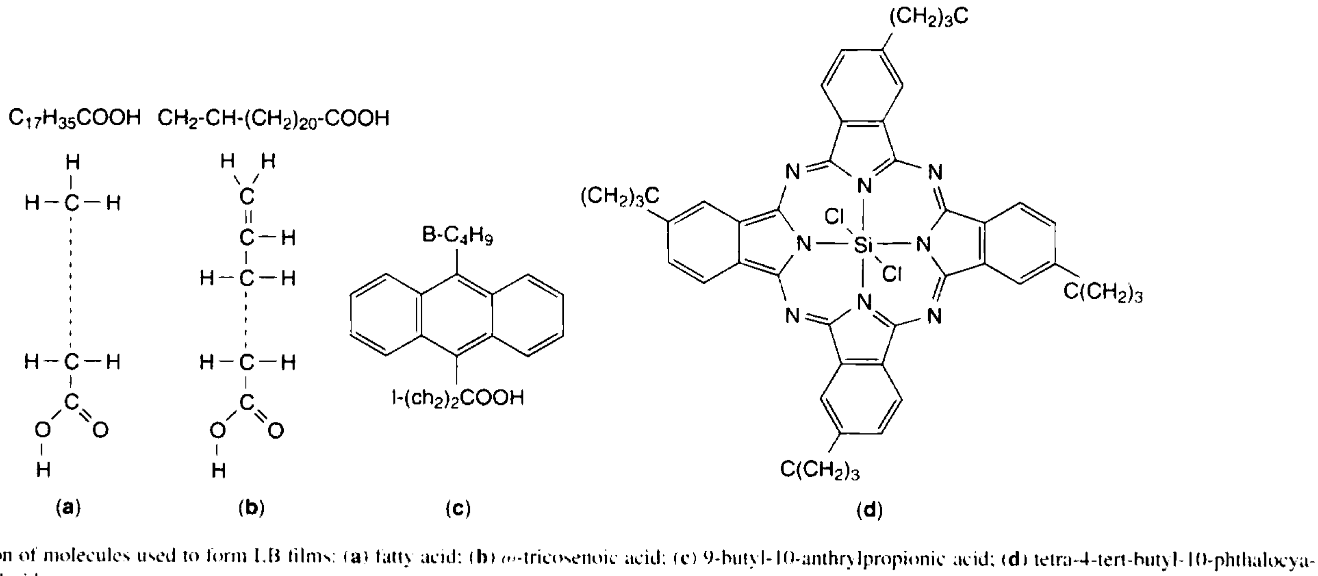

Fig. 3. A selection of molecules used to form LB films: (a) fatty acid; (b) ω-tricosenoic acid; (c) 9-butyl-10-anthrylpropionic acid; (d) tetra-4-tert-butyl-10-phthalocyaninato silicon dichloride

Figure 3(b), which is similar to stearic acid but contains a terminal double bond, displays all the essential film-forming qualities including solubility in convenient organic solvents, stability at the surface of water, shear resistance, stability against collapse, and suitable orientation features. It is relatively straightforward to attach long aliphatic chains to a molecule and spread a monolayer. However, this may well dilute the desirable properties of the basic molecule; moreover, for stability reasons, the presence of long side groups will severely restrict their practical applicability. It has therefore been recognised that the scope of the Langmuir trough technique would be considerably enhanced if interesting materials containing only short, stable, side groups could be formed into LB films. A good example is provided by the anthracene derivative (Vincett et al., 1979) shown in Figure 3(c); multilayers of excellent quality can be obtained, even though the alkyl group contains only four aliphatic carbons and the hydrophobic group is attached to the ring structure *via* only two methylene groups. Extremely robust monolayer assemblies can be constructed using dye molecules such as the porphyrins and phthalocyanines. In general their quality is relatively imperfect compared with those of the classic film forming materials but their significant advantages lie in their thermal and mechanical stabilities. An example of a substituted phthalocyanine molecule (Hue et al., 1986) that can be deposited in monolayer form is shown in Figure 3(d).

The molecules shown in Figure 3 represent only a few of the materials that have been studied in LB film form. Nonetheless, a great deal more needs to be done to tap the vast wealth of opportunities available with organic systems. There will inevitably be short-term opportunistic attempts aimed at discovering molecules for specific devices. However, there is a more pressing need for a systematic approach that will yield rules governing structure-property correlations, so as to enable scientists confidently to predict the molecular architecture of monolayer assemblies. See also **Macromolecular Science**.

Langmuir-Blodgett Film Deposition

An LB film is formed by transferring a floating monolayer onto a solid substrate. The quality of the Langmuir film and the surface pressure at which 'dipping' occurs is established using the type of isotherm shown in Figure 4. The subphase is normally ultra-pure water, because it is readily available and it has an exceptionally high value of surface tension. The composition of the subphase, including its purity, pH, and ionic strength, can have a profound influence on factors such as the solubility of the monolayer and segregation effects resulting in molecular aggregates or domains.

Using conventional LB film technology, the substrate is raised and lowered vertically through a compact floating monolayer; the surface pressure at which this occurs is normally just above the 'knee' in the steeply rising sector of the isotherm indicating low compressibility in the monolayer. At this stage, if conditions are carefully controlled and appropriate molecules are used, one monolayer is transferred during each excursion through the subphase surface. The most common deposition mode (Y-type) is illustrated in Figure 5(a), where the molecules can be seen to stack in a head to head and tail to tail configuration. The floating molecules on a water surface are shown at the top left in this diagram. With a hydrophobic substrate (for example, a group III-V compound semiconductor), no pick-up occurs during the first immersion and the first monolayer is therefore deposited during the first withdrawal as shown in Figure 5(b). The surface is now hydrophobic and deposition does now occur during the next immersion into the water. Thus, one monolayer coverage is obtained on each traversal of the liquid surface. With a hydrophobic surface such as freshly etched silicon, pick up also occurs during the first insertion. Sometimes, the common deposition mode illustrated in Figure 5 is not followed and one of the other two possible configurations, X and Z-type, is observed, where transfer occurs only during immersion or withdrawal, respectively. The surface quality and chemical composition of the substrate is bound to control the nature of the deposited layer. When adhesion is poor, some researchers have resorted to the less satisfactory method of placing the substrate flat on the liquid surface, a technique first used by Langmuir and Schaefer.

Many modifications of the very early film balances have been described by Gaines (1983). However, the upsurge in interest in LB films has led to greater attention being placed on trough design and control systems to meet the stringent requirements of scientists and engineers. Therefore, modern instruments are relatively sophisticated and, for device-related

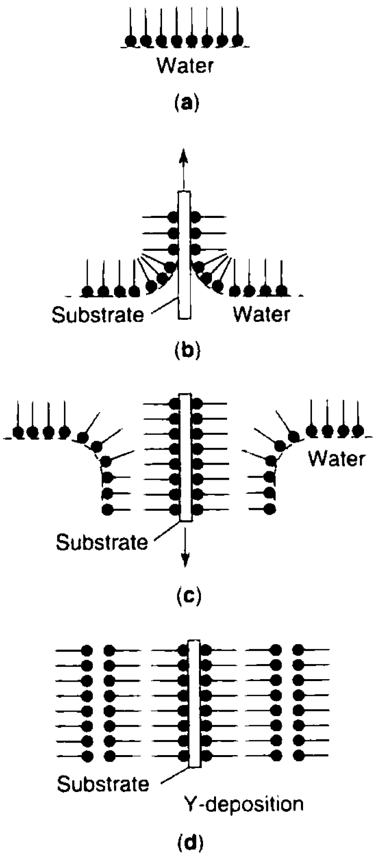

Fig. 5. Langmuir-Blodgett film deposition (Y-type) on a hydrophilic substrate: (**a**) monolayer on the surface of water; (**b**) first layer on withdrawal; (**c**) second layer (second insertion); (**d**) substrate with three layers (after second removal)

work, need to be situated on anti-vibration Tables in clean environments. Although it is possible to automate most features, the primary benefit at the present time lies in efficient data collection and the ease with which data can be manipulated. For example, phase transitions are more apparent when the differential of the pressure-area isotherm is plotted. No difficulties are envisaged in scaling up the Langmuir trough or in the design of continuous fabrication arrangements. When an important practical application is discovered there will be a need to produce a specially designed trough capable, for example, of coating a moving belt or multiple wafers of silicon.

A recent development in trough design is worthy of special attention as it could have important commercial significance. It has arisen because of the need to produce non-centrosymmetric structures that display interesting non-linear physical effects. The conventional Y-type films are symmetrical in character and experience has shown that X and Y type layers, although non-symmetrical, are usually imperfect. Therefore, an alternative approach to producing noncentrosymmetric structures is to use alternate layers of two different materials where the contributions of adjacent molecules do not cancel. See Fig. 6. The additions of a fixed beam and a revolving center section to an automated constant perimeter barrier Langmuir trough enables the formation of an alternating Y-type structure of two different molecules spread in the two distinct areas of the subphase. The structural qualities of the LB films prepared in this way can be of high quality (Holcroft et al., 1985); another advantage of the rotating substrate arrangement, which is conducive to fast dipping, is that the meniscus, unlike that in the vertical dipping method, is always in the same direction.

Many different experimental techniques indicate that carefully prepared films of appropriate molecules do indeed possess a high degree of structural order. The reader is referred to the proceedings of the two international conferences on LB films for literature references describing the vast range of characterization experiments that have been employed (Roberts and Pitt 1983; Gaines 1985). These include ellipsometry, electron spin resonance, infrared dichroism, photoacoustic spectroscopy, secondary ion mass spectroscopy, surface potential, polarized X-ray and electron diffraction, neutron reflection and diffraction. Most of the electrical data for LB films are suspect in that they have been obtained for films deposited

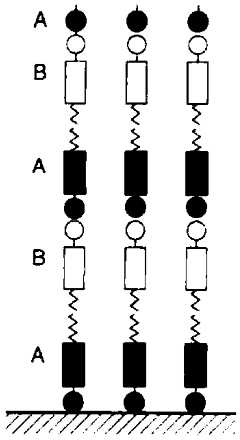

Fig. 6. Alternating organic multilayer structure which enables a Y-type LB film to be produced of non-centrosymmetric character (molecular lego!)

onto metals that are invariably coated with semi-insulating native oxides. A comprehensive account of these studies was presented in a review by Vincett and Roberts (1980).

The four separate diagrams in Figure 7 all describe results for fatty acids or their derivatives and are designed to emphasize the reproducibility of various physical parameters from one monolayer to the next. Figure 7(a) shows the capacitance (C) as a function of film thickness for cadmium arachidate deposited onto aluminium. The linear dependence of C^{-1} versus the number of monolayers demonstrates clearly the repeatability of the dielectric thickness of each monolayer. In Figure 7(b) it is a band in the infrared reflection spectrum of the same material that has been used to demonstrate the uniformity of successive monolayers. The reason for the scatter around the origin is not understood but it probably reflects in this case that the structure of the first few monolayers is affected by the metal underlay. Figure 7(c) is based on experiments using barium stearate as the absorber for L shell Auger electrons. By labelling the molecules in these overlays with ^{14}C and examining their autoradiographs it is possible to confirm the uniformity of the deposition process by

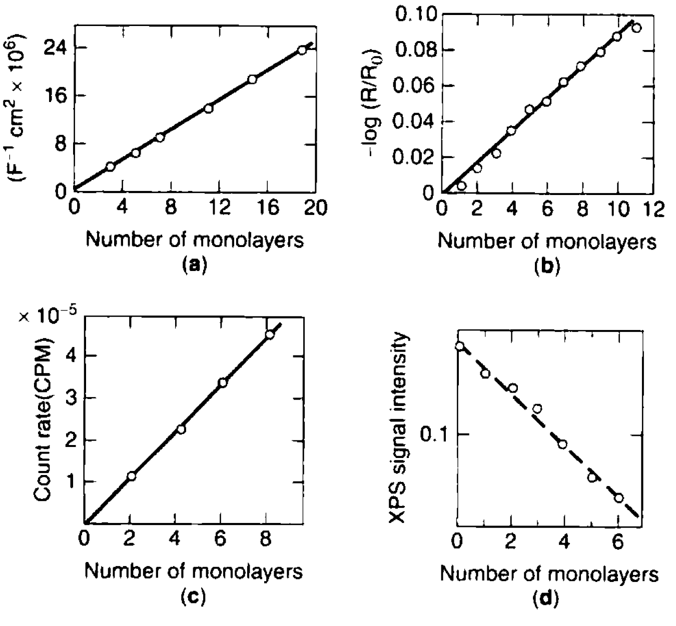

Fig. 7. These diagrams are designed to emphasize the reproducibility of various physical parameters in monolayer assemblies of different thicknesses: (a) reciprocal capacitance per unit area versus number of monolayers of cadmium arachidate on an aluminum substrate (Roberts et al., 1978); (b) absorption intensity versus number of monolayers for the symmetric carboxylate stretching mode of cadmium arachidate at 1432 cm^{-1} (Allara and Swalen, 1982); (c) count rate of ^{14}C rays versus number of layers of barium stearate labelled with ^{14}C (Mori et al., 1980); (d) X-ray photoelectron signal intensity versus number of layers of cadmium dimethyl arachidate on silver (Brundle et al., 1979)

plotting the count of ^{14}C rays versus the number of monolayers. The final diagram in the set, Figure 7(d), illustrates another powerful tool for investigating organic coatings on metals. In this case different thicknesses of cadmium dimethyl arachidate have been used to attenuate the substrate X-ray photoemission signal.

During the next few years many techniques-oriented scientists will be attracted to work on LB films because they provide interesting novel structures whose molecular architecture can be systematically controlled. The quality of the floating monolayer is also important and needs to be characterized as does the interface between the first deposited monolayer and the substrate. Fluorescence microscopy and Brillouin and Fourier transform infrared spectroscopies are currently being used to address these problems.

Applications of Langmuir-Blodgett Films

Following the pioneering work of their famous employees, the General Electric Company introduced several simple applications of LB films including step-thickness gauges, anti-reflection coatings and soft X-ray gratings. Since that time, stimulated no doubt by the availability of well engineered troughs and a wider range of suitable materials, researchers have suggested other applications for monolayer and multilayer films. A selection of areas where LB films may find practical use is given in Table 1. Further details are given in the review by Roberts (1985). However, it should be remembered that one of the principal virtues of LB films is their usefulness in fundamental research. Therefore, before discussing more applied areas we shall mention a few areas of science that can benefit from investigations of model systems based on monomolecular assemblies.

Model System in Basic Research

(a) Energy transfer in complex monolayers. The Langmuir trough technique provides a method of constructing simple artificial systems of co-operating molecules on a substrate. The pioneer in this field has been Kuhn (1983): the elegance of his and his colleagues' work is evident in their reviews of the subject. These describe the use of LB films to investigate intermolecular interactions and various photophysical and photochemical processes. Their supermolecular structures have mainly involved long chain fatty acids as matrices for appropriate synthetic dyes and have been ingeniously designed to clarify the different interactions that can occur between various molecules via photon, electron and proton transfer. An example of their research, designed to investigate the Förster type of energy transfer from a sensitising molecule, S, to acceptor molecule, A, is given in Figures 8 and 9. If S is a compound that absorbs in the ultraviolet part of the spectrum and fluoresces in the blue, while A absorbs in the blue and fluoresces in the yellow, then interesting effects are observed when the system is irradiated with ultraviolet light. If there is a sufficient distance between S and A, as in Figure 8(a), the fluorescence of S appears since A does not absorb UV radiation. However, below a certain threshold distance, as in Figure 8(b), the excitation energy of S is transferred to A and the yellow fluorescence of A is expected. Similar experiments based on fluorescence quenching indicate that the rate constant of the electron transfer decreases exponentially with increasing barrier thickness separating a donor chromophore and an electron acceptor. In the example shown in Figure 9, N', N'-dioctadecylthiacyanine has been used in conjunction with a viologen acceptor layer to observe the steady fluorescence intensities of the cyanine dye monolayer in the absence (I_0) and in the presence of the acceptor layer (I). The quantity, $[I_0/I)-1]$ is proportional to the rate constant of the electron transfer; its linear dependence with d, the distance between the chromophores, is evidence of electron tunnelling. In a similar series of experiments it has been possible to investigate the energy transfer mechanism responsible for spectral sensitization.

(b) Biological membranes. The physical structure and chemical nature of classical LB films gives them a close resemblance to naturally occurring biological membranes. For example, because the two ends of a lipid molecule have incompatible solubilities, they spontaneously organize themselves in the form of a bilayer, or essentially a two layer LB film. Scientists have suggested that they might provide a suitable model of the lipid membrane for probing the cooperative interactions between its constituents. However, caution must be exercised in assessing the biological relevance of this type of work and associated studies aimed at incorporating ionophores into phospholipid layers. Much of this research is targeted at novel integrated solid state devices incorporating biological molecules such as enzymes.

TABLE 1. PROMISING APPLIED RESEARCH AREAS

Topic	Molecular electronics applications
Model Systems in Fundamental Research	Spectroscopy of Complex Monolayers: spectral sensitization, fluorescence quenching, energy transfer between excited states. Model membranes to mimic photosynthetic systems. Modification of solid surface properties. Examination of lipids, proteins and membrane phenomena; organic semiconductors.
Applied Chemistry	Surface chemistry and behavior of surfactants: catalysis; filtration/reverse osmosis membranes; adhesion; surface lubrication, e.g. magnetic tape; encapsulation.
Electron Beam Microlithography	Good sensitivity and contrast, acceptable plasma etching resistance; less scattering of electrons and therefore better resolution; negative and positive resists possible.
Integrated Optics and Storage Optics	Film thickness plus refractive index of film and hence guided wave velocity can be controlled with great precision; acceptable attenuation loss. Possible uses in conventional optics and optical data storage; photochromic and ablative systems. Optical sensors e.g. based on coated fibres.
Nonlinear Physics	Control of molecular architecture to produce asymmetric structures with high non-linear coefficients, e.g. in electro-optics, pyroelectric detectors, or acoustoelectric devices.
Dilute Radioactive Sources	Radioactive nuclide incorporated in conventional LB film; used to measure the ranges of low energy electrons.
Electronic Displays	Large area capability of LB films is an advantage; the monolayers can either be the active electroluminescent layer or used to enhance efficiency of an inorganic diode; passive application to align liquid crystal displays. Deposition of liquid-crystal type molecules also possible.
Photovoltaic Cells	Used as a tunnelling layer in an MIS solar cell or as an active layer in p-n junction diode, perhaps involving an inorganic/organic junction.
Two Dimensional Magnetic Arrays	Magnetic atoms e.g. Mn, periodically spaced in LB film; possible applications include magnetic control of superconducting junctions and bubble and magneto-optical devices.
Field Effect Devices	Accumulation, depletion and inversion regions possible with a variety of semiconductors; can therefore form the basis of several devices e.g. CCD, bistable switch, gas detector or pyro/piezo FET, is suitable LB films are used.
Biological Membranes	Attractive supporting membranes for commercial exploitation of biological material, e.g. immobilization of membrane bound enzymes in solid state sensors; ISFET type structures.
Supermolecular Structures	Speculative work aimed at superconductors, organic metals, 3D memory storage, molecular switches.

In some cases, LB films are useful to facilitate physical studies of biological molecules e.g. to measure the ionic permeability of reconstituted membranes. Supermolecular structures have also been designed to mimic the primary process in photosynthesis and for achieving an efficient photoinduced charge separation by appropriate modelling of potential profiles. Chlorophyll has been studied in this context. Some of the results may have relevance to solar photochemical conversion devices.

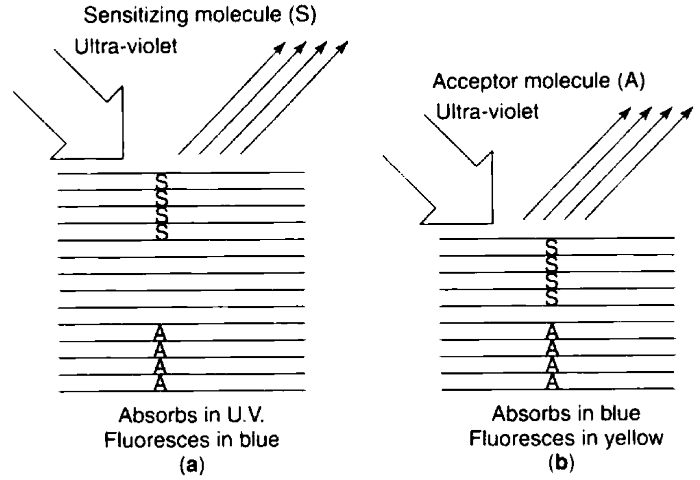

Fig. 8. Schematic diagram showing basis of experiments designed to investigate energy transfer from a sensitizing molecule (S) to an acceptor molecule (A). The number of monolayers separating the two species governs the spectral response of the fluorescence spectrum. In (b) the separation distance is sufficiently small for the excitation energy of S to be transferred to A. In (a) the acceptor molecules does not absorb the ultraviolet radiation

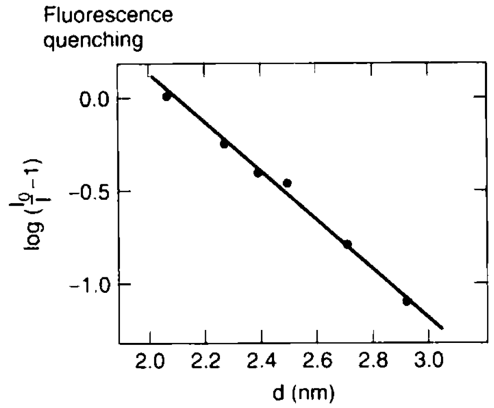

Fig. 9. The fluorescence intensity I_0 of a donor dye is reduced to a value I in the presence of an acceptor dye. The logarithm of $[(I_0/I)-1]$ is shown as a function of d, the spacing between the donor and acceptor planes. (Mobius, 1981)

(c) Metal-ion incorporation. The addition of divalent ions into the liquid subphase in a Langmuir trough can increase both the shear resistance and cohesion of the monolayer. For this reason it is more common to find reports of studies on fatty acid salts than their acids. By adjusting the pH of the subphase it is possible to assemble multilayers containing metal ions separated by the width of an integral number of monolayers (for Y-type deposition, two monolayers). The ability to do this has been capitalized upon in several fundamental investigations, three of which will be mentioned here. The first of these relates to two-dimensional magnetic monolayers involving iron or manganese ions. Using electron spin resonance Pomerantz (1980) has demonstrated that at temperatures near 2K, the resonance field and line-shapes were affected, thus signifying the rapid development of a large internal magnetic field. His results have been interpreted in terms of a predominantly anti-ferromagnetic state, but with a weak ferromagnetic component. Further experiments are required to clarify magnetic ordering in two-dimensional space.

In the area of surface science, X-ray photoemission is now used extensively to study organic materials on surfaces. In such experiments it is important to establish electron mean free path lengths as a function of kinetic energy. An example, of this type of investigation in LB films is illustrated in Figure 7(d); generally it is found that the mean free paths for ordered multilayers are significantly longer than those for conventionally produced polymers (Clark et al., 1981).

A third example showing the usefulness of using the Langmuir trough technique to provide matrices containing regularly spaced metal ions lies in radioactivity. Mori et al. (1980) used radioactive stearate monolayers in which some of the hydrogen atoms had been replaced by nuclides such as ^{51}Cr, ^{54}Mn, ^{55}Fe, ^{57}Co, ^{65}Zn and ^{109}Cd, to produce dilute and standard radioactive sources. By labelling the molecules with ^{14}C and examining autoradiographs he was able to confirm the uniformity of the deposition process as shown in Figure 7(c). Using conventional monolayers with well-controlled dimensions as overlays they were also able to demonstrate that Auger electrons from the L shell with an energy of approximately 0.5 keV are almost completely absorbed by fifteen monolayers of barium stearate. Experiments of this kind are of importance in fields such as medical physics and upper atmosphere science.

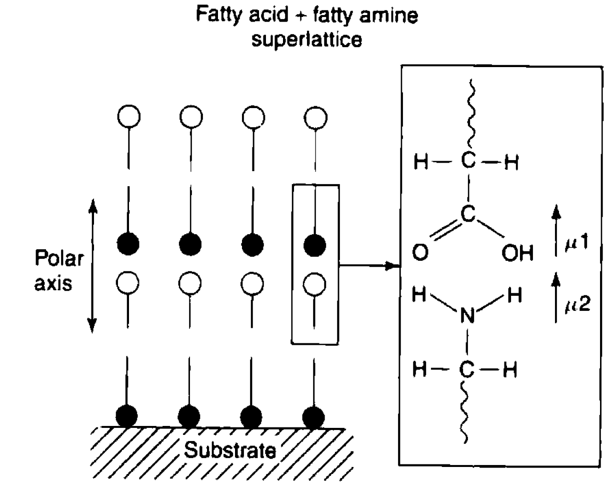

Fig. 10. The left-hand diagram shows an organic superlattice with a unique polar axis. The two types of molecule involved could be a fatty acid and a fatty amine. The insert is designed to show that these two materials have dipole moments in opposite senses with respect to the hydrophobic chain. Thus, the Y-type film has a resultant dipole moment

Promising Applied Research Areas

Langmuir-Blodgett films may have value in many applied areas of traditional interest to the industrial chemist such as adhesion, encapsulation and catalysis. The permeability characteristics of monolayer assemblies may also find application as synthetic membranes for ultra fine filtration, gas separation and reverse osmosis. For example, Albrecht et al. (1985) have proved the efficiency of polymeric diacetylene monolayers on semi-permeable supports in reducing the flow of CH_4. One interesting possibility lies in using LB monolayers as lubricants in magnetic tape technology. Unpublished reports have indicated that frictional coefficients can be reduced markedly when the tape is coated with a few monolayers. In applications such as those listed above, difficulties may well be encountered with the mechanical stability of the films. To date relatively little research has been carried out in this area.

For commercial applications, the LB films will need to play an essential, integral role. That is, one must capitalize on their special features such as the degree of control over their molecular architecture, their thinness and the selective way in which they might react with their environment. Some of the potential areas of interest are listed in the table. The long term interest as far as the applied physicist is concerned, lies in the possible uses of supermolecular assemblies for memory storage, molecular switching, and superconducting devices. However, at the present time it is in potential improvement areas where monomolecular films show most promise and where the prospects of commercial exploitation seem reasonable in the medium term. A few of these areas are described below; most of the illustrations are based on work carried out in the author's research laboratory:

(a) Nonlinear physics. There is evidence that many organic molecules possess very high non-linear coefficients and therefore, if LB films with the required architecture can be formed, these could form the basis of novel devices. In order to avoid the symmetry inherent with conventional Y-type deposition, X and Z type films have been studied: some have displayed a permanent polarization with a strong component in a direction perpendicular to the substrate. However, as has already been mentioned, films produced in this way with their dipoles supposedly aligned in a common direction, are invariably of poorer quality than Y-type layers. a possible method of improving the structure is to use electric or magnetic fields to help align the molecules but efforts to orient films on the subphase and substrate have met with only limited success. The problem can be overcome by using organic superlattices based on alternating layers of two different materials (See Fig. 6). A good example is given in Figure 10 which shows a superlattice comprising acid and amine molecules whose dipole moments are in opposite senses but when deposited in Y-type LB film form are aligned in the same direction. Two areas of particular interest that would capitalize on this feature of organic superlattices are pyroelectricity and optoelectronics. Each of these will now be considered in turn.

Pyroelectric devices respond to a rate of change of temperature rather than to changes of temperature as in other, types of thermal detector. This gives them inherent advantages but their full potential has yet to be realized. For applications where both high speed and sensitivity are required, conventional materials have been unsuccessful. The desirable pyroelectric properties of inorganic materials appear to vanish for thicknesses less than 10 μm, and pyroelectric organic single crystals, such as triglycine sulfate, which possess a high pyroelectric coefficient, cannot be produced in thin film form. Thus the future development of relatively cheap thermal imaging systems with reasonable performance and an optimum thickness of approximately 0.5 μm, requires a materials breakthrough. A normal detector consists of a capacitor whose dielectric is an oriented pyroelectric material: using this type of device Christie et al. (1986a, b) have observed encouraging results using the alternate layer structure shown in Figure 10. The pyroelectric coefficient, p, has been determined using both dynamic and static detection techniques. For the simple fatty acid/fatty amine superlattice $p \cong 1\ C\ cm^{-2}\ K^{-1}$ but more recent results involving a system where proton transfer occurs from the acid to the amine have yielded higher values, comparable with those observed for triglycine sulfate. The exploitation of this work will depend not only on the properties of the LB films but also on our ability to deposit the layers onto reticulated structures with low thermal mass.

Although many of the potential optical applications of LB films are in transmission optics employing the linear response properties of molecules, it is in the area of non-linear optics where the most exciting applications are perceived. Highly efficient nonlinear optic materials permit functions such as those illustrated in Figure 11 to be performed in a totally optical manner without the need for electron-photon conversion processes. Second harmonic generation and parametric amplification can be obtained using inorganic single crystal materials such as lithium niobate, but recently, organic crystals such as 3-methyl-4-nitroaniline have been shown to possess exceptionally large second order electrooptic coefficients (Zyss 1982). However, a thin film geometry is preferred; then it will be possible to integrate nonlinear interactions, linear filtering and transmission functions into one precision monolithic structure. Therefore, researchers are currently substituting such molecules with appropriate side groups to enable LB film deposition to occur. To date, second harmonic generation has been reported in multilayers of nitrooctadecylazobenzene and mercocyanine and hemicyanine dyes. Nonlinear coefficients comparable to those of inorganic materials have been achieved but there are many other considerations involved (e.g. phase matching, suitable spectral response and refractive index, good optical damage threshold, low scattering coefficients and mechanical stability) before practical objectives can be accomplished. The most interesting observation to date is that of second harmonic generation in LB organic superlattices of the two molecules displayed in Figure 12. Neal et al. (1986) have shown that the nonlinear response of a hemicyanine/nitrostilbene layer is greater than that expected from the simple addition of contributions arising from the individual (separated) monolayers. The coefficient for second harmonic generation of the alternate layer structure is approximately five times the average value of the same parameter measured for hemicyanine and nitrostilbene. This superadditive effect is best explained in terms of improved film structure with adjacent molecules influencing each other to orient more vertically with respect to the substrate.

(b) Enhanced device processing. In integrated circuit technology the quest for faster speeds and larger memories has led to a gradual refinement of microlithographic methods for producing smaller and more closely spaced circuit elements. Sub-micron resolution is now

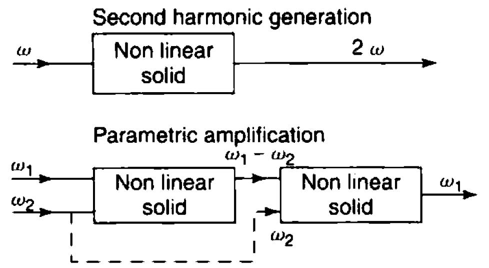

Fig. 11. Schematic diagram illustrating the ability of nonlinear materials to double the frequency of incident laser radiation and also function as a parametric amplifier when two beams of different frequency are involved. Most of the non-centrosymmetric solids currently in use are inorganic, but they may be replaced by organic single crystal thin films

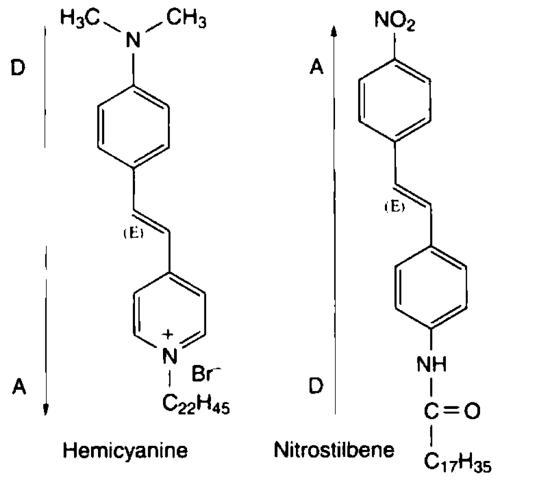

Fig. 12. These two molecules, one a hemicyanine and the other a nitrostilbene dye, can be used to form an organic superlattice displaying a high coefficient for second harmonic generation

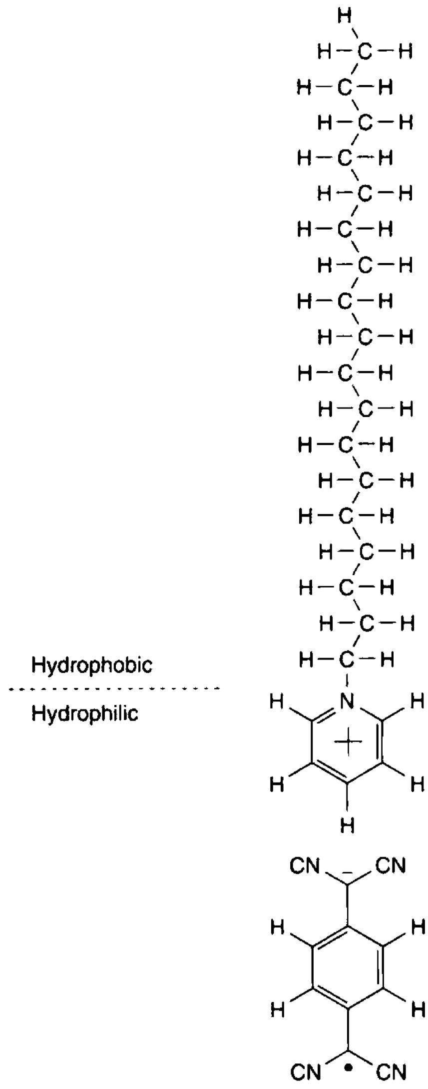

Fig. 13. A substituent, pyridinium tetracyanoquinodimethane (TCNQ) molecular system

required and this has necessitated a move away from conventional photolithography to techniques involving electron or ion beams and x-rays. The main disadvantage of electron beam systems lies with their scattering characteristics; this enforces the requirement that the resist materials be pinhole free and less than 1 μm thick. Conventional spin-coated polymers display unacceptably large pin-hole densities and variations of thickness; however, LB films have already demonstrated their capability in this regard. There are good examples of both positive and negative resists but the best material reported to date is the ω-tricosenoic acid molecule shown in Figure 3(b). In purified form this material has adequate sensitivity, may be deposited at a rate of 0.5 cm s^{-1} to produce uniform coatings in the range 30–90 nm, and has been shown capable of a line resolution of 60 nm. The main property which requires some improvements is the etch resistance in plasma processing (Barraud et al. 1983).

Interconnects become increasingly important as the size of electronic circuits reduces. It has been suggested that protein layers might be useful in this regard. The method involves first depositing a synthetic protein and patterning it using a conventional resist. The NH_2 groups in the exposed protein layer can then be used to adsorb silver ions from a silver nitrate solution; this physical development stage converts the ions to metallic silver. An alternative approach is to fabricate supermolecular assemblies that conduct. The most successful attempt to date uses the molecule shown in Figure 13. Barraud et al. (1985) have succeeded in producing close packed multilayers of this TCNQ derivative, where the polar planes are separated by insulating lamellar regions. The resistivity of this N-stearylpyridinium$^+$ ITCNQ$^-$ film is approximately 1 Ω cm. Of course, there are many other attractions in producing conducting LB films, including their uses.

There are several niches where LB films could have a useful role in semiconductor technology. Probably the most important is the ability of an oriented monolayer to change the effective barrier height at a semiconductor surface. Researchers at the University of Durham first demonstrated the effect on cadmium telluride and showed how it could be used to improve the efficiency of a photovoltaic diode (Dharmadasa et al., 1980). Similar effects have now been confirmed on a variety of materials including ZnSe, InP, GaP and GaAs and related III-V semiconductor alloys. The control afforded by the Langmuir-Blodgett technique permits the degree of band bending to be adjusted to suit the particular application, e.g. the increase in efficiency of an electroluminescent diode. In most applications it has been necessary to use robust monolayers of phthalocyanine which can withstand the large current densities involved. Figures 14 and 15 show data for gallium phosphide (Batey et al., 1983; Petty et al., 1985); for convenience the error bars have been removed. The LB thickness required to optimize the electroluminescence efficiency is found to be approximately 21 nm; this value is determined by the ability of minority carriers to cross the semi-insulating phthalocyanine film. Similar results have recently been achieved using zinc selenide layers grown using MOCVD. Blue electroluminescence is observed provided the organic film is present.

There are many methods of producing a surface layer on a semiconductor. However, experience has shown that when an energetic process such as evaporation, sputtering, or growth from a plasma, is used to deposit a thin film onto a semiconductor, a surface damaged layer is produced which invariably dominates the electrical characteristics of the junction so formed. However, the Langmuir trough technique, being a low temperature deposition process, provides a means of circumventing this particular difficulty. On the other hand, it does mean that how the substrate is prepared before dipping is of considerable importance in determining the quality of the interface produced. That is, the nascent 'oxide' layer formed during the etching procedure remains relatively undisturbed and this can play a vital

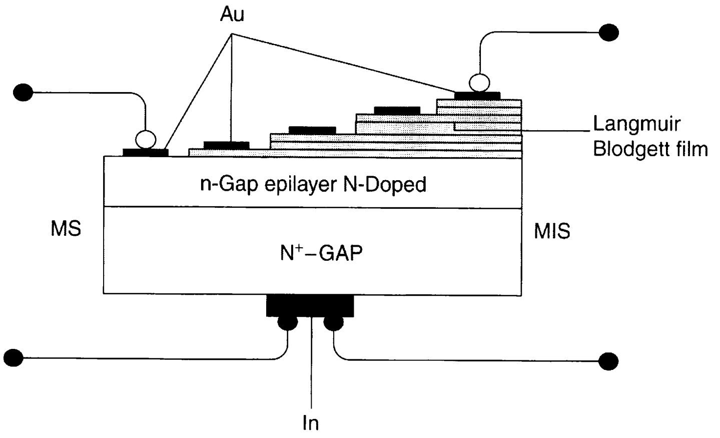

Fig. 14. Schematic diagram (not to scale) of a Gold-LB film—Gallium Phosphide device structure

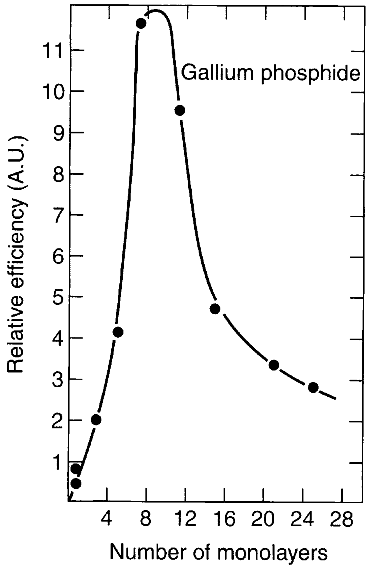

Fig. 15. The electroluminescent efficiency versus number of monolayers or substituted phthalocyanine for the device shown in Fig. 14

role even after it has been coated with an LB film. For this reason it is important first to carry out a systematic study of the surface chemistry of the semiconductor substrates.

(c) Sensors. The good insulating properties of LB films suggest their possible use in field effect devices, not so much to compete with existing semiconductor technology but more to capitalize on the advantages of being able to incorporate an organic layer within a semiconductor structure. Figure 16 shows schematic diagrams of both a field effect transistor (FET) and the 'heart' of this device, which is the metal-insulating-semiconductor (MIS) diode. Conventionally these devices are made using inorganic materials; silicon holds a pre-eminent position mainly because of the insulating qualities of its native oxide. The first transistor incorporating LB monolayers as the insulator was reported several years ago (Roberts et al., 1978); using the type of three terminal device shown in Figure 16, on indium phosphide and cadmium stearate, they showed that the channel conductivity between the source and the drain could be modulated by the action of a gate electrode.

Subsequently, other semiconductors have been used and results have confirmed the ease with which a range of single crystal surfaces can be accumulated, depleted or inverted with an applied voltage. It is recognised that in all cases, the LB film is deposited on top of a nascent 'oxide' layer and that the insulation is provided essentially by a double dielectric structure. In the case of silicon, this can be used to advantage, in that a closely packed LB film layer can seal its surface from the atmosphere and thereby greatly retard the development of interface states. The organic film is also efficient in increasing the dielectric strength of a leaky silicon oxide film.

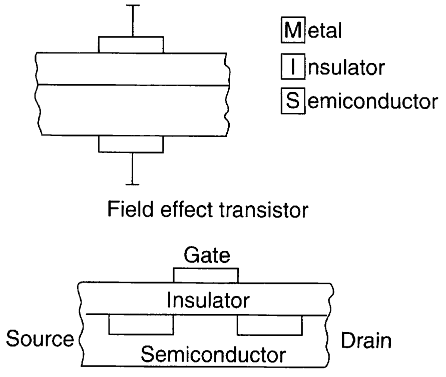

Fig. 16. Schematic diagrams (not to scale) showing, in the upper diagram a metal-insulator-semiconductor structure which forms an integral part of the field effect transistor shown in the lower diagram

The fact that organic compounds normally respond more positively than inorganic materials to external stimuli such as pressure or radiation, provides a means of making sensitive transducers. Moreover, by controlling the architecture of the LB film, the interactions can be designed to be of a lock-key type, thus enhancing the selectivity of the device. Following the non-linear physics work described earlier, it is now possible to envisage pyro- or piezo- FETs based on insulating LB films with an inbuilt polarization, or field effect devices incorporating biological membranes. Another advantage of using ultra-thin organic films is their fast response and recovery times because so little material is present. In the example shown in Figure 17, an eight monolayer LB film of a substituted phthalocyanine has been exposed to volume parts per million of nitrous oxide. It may be seen that the saturation current of the device scales linearly with gas concentration. Even though operation was at room temperature, the recovery times were shorter than those for evaporated film devices used at higher temperatures.

It is not necessary to confine the discussion of microelectronic LB film based sensors to MIS or FET structures. For example, the switching voltage of a bistable switch or the characteristics of a gate-controlled diode could be very sensitive to an ambient. Moreover, optical and acoustic devices frequently show interesting threshold or resonance effects which could form the basis of a sensor. One area receiving particularly strong attention is that of surface plasmon resonance (SPR). The principle of this optical detection method is illustrated in Figure 18. A surface plasmon is a surface charge density wave at a metal surface. If the metal is sandwiched between

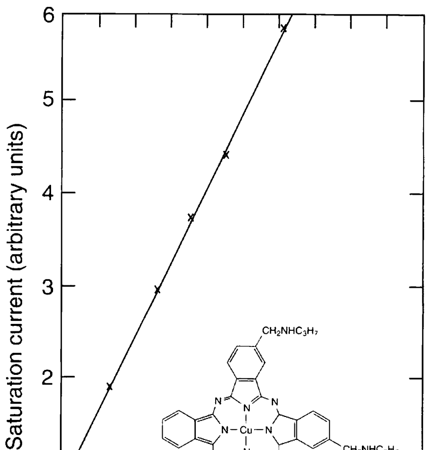

Fig. 17. Saturation current versus NO_2 gas concentration for a device incorporating eight monolayers of the asymmetrically substituted phthalocyanine molecule shown in the insert (Baker et al., 1983)

two materials of different dielectric constant, then resonance can occur; this is observed as a very sharp minimum of the light reflectance when the angle of incidence is varied. The resonance angle is ultrasensitive to variations in the refractive index of the medium adjacent to the metal film. For example, the small change in an organic material due to gas absorption can easily be monitored even for concentrations in the part per billion range. In a practical situation, one normally selects an angle of incidence approximately half way down the reflectance minimum curve when no special gas is present; the change in intensity of the reflected light is then monitored at a constant angle.

There is widespread interest in the potential of LB films as biosensors as many believe that the incorporation of biological molecules such as enzymes will lead to novel devices. Some are exploring the deposition of biologically active molecules onto the gate electrodes or oxides of field effect transistors but optical sensors, probably based on fiber optics, are the most favored technique. In all cases the aim is to couple the specificity of interaction of chemicals or biochemicals with proteins or enzymes e.g., the change in their molecular conformation, with the sensitivity and signal transduction properties of the device. It is recognized that stability and lifetime may be problem areas and, for this reason, cross linked polymers are being explored as the hosts for the active species.

Some of the most convenient types of sensor are based on acoustoelectric devices; these can either be conventional bulk piezoelectric oscillators normally made of quartz, or surface acoustic wave (SAW) devices. The resulting change in the quiescent resonant frequency of a quartz oscillator coated with LB films of different thickness provides a very simple and elegant way of monitoring the reproducibility of monolayer deposition. Figure 19 illustrates how the quartz oscillator functions as a microgravimetric sensor; from the change in frequency it is possible to determine the density of the thin films. There is a further change when the organic films are exposed to minute concentrations of gas. The results presented in Figure 20 are for ω-tricosenoic acid in the presence of acetic acid, a species used for the detection of heroin. Greater effects can be obtained if the organic film is specially sensitised. Another way of increasing the sensitivity is to use acoustic surface waves. In such devices, input and output interdigitated electrodes are formed on a piezoelectric substrate usually made of quartz or lithium niobate. These perform the conversion between electric and acoustic energy. The single

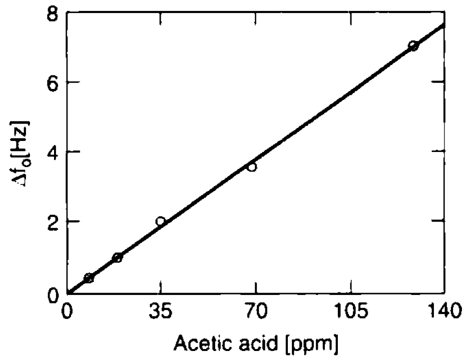

Fig. 20. Response characteristics of ω-tricosenoic acid coated quartz crystal oscillator at 22°C exposed to acetic acid. A greater change in the resonance frequency can be obtained if the film is specially sensitized to detect acetic acid

crystal surface region between the transducers serves as a propagation path for acoustic waves and thus forms a delay line which has application in electronic signal processing. Figure 20 shows a dual line configuration specially designed for sensing purposes. Basically, the device comprises two identical SAW (surface acoustic wave) oscillators positioned alongside each other. The hatched regions are earth shields to minimize reflections and cross talk between the two oscillators. The selective coating is placed in the propagation path of one of the oscillators thus affecting the delay time; the relative shift in frequency between the two oscillators is measured using a mixer circuit to obtain the difference frequency and then passing the resulting signal through a low pass filter. The change in frequency (Δf) between the two channels is then directly attributable to the sensor layer and other extraneous effects such as those due to temperature changes, are eliminated or very much reduced. Other geometries, for example, a surface acoustic wave resonator, are also possible. The device shown in Figure 21 has been constructed by Roberts et al. (1987) using quartz and interdigitated electrodes 24 μm wide separated by gaps of 25 μm; the operating frequency of the device is 98.4 MHz. Results have been obtained for both insulating (ω-tricosenoic acid) and conducting (pyridinium TCNQ) LB films as the sensor layer. In the case of the ω TA, only a mass loading effect is observed but with the TCNQ films, electric field effects are also apparent; these are associated with interactions between the surface acoustic wave and mobile charge carriers in the LB film. The combination of a device capable of measuring mass changes as low as femtograms per square centimeter, and the ability to detect minute changes in the electrical characteristics of a monolayer, augers well for sensors based on surface acoustic waves and monolayers.

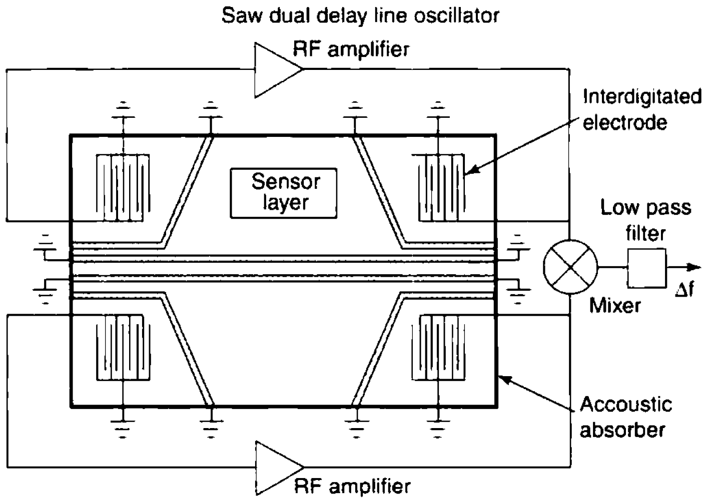

Fig. 21. A surface acoustic wave dual-delay line oscillator. The sensitive layer is placed in the propagation path of one of the two SAW devices. The difference in frequency (Δf) between the two channels provides a direct result of the mass loading and electric field effects associated with the sensor layer

Conclusions

We have discussed several research areas where there appears to be a tangible benefit in using monomolecular assemblies rather than organic or inorganic thin films deposited by other means. There are many ways of producing organic films and the onus will be on the Langmuir-Blodgett enthusiasts to demonstrate the special advantages to be gained using their technique for a particular application. There is every likelihood that this will occur but it will require the combined efforts of high caliber teams with knowledge of physics, chemistry, electronics and biology. The ability of the synthetic chemist to manipulate the molecular architecture of a material to optimize a specific physical parameter or figure of merit will be vital. However, the role of the physicist or engineer in identifying the targets and guiding the main thrust of the research program will also be essential. Industry is already well able to organize interdisciplinary activities. The relatively inexpensive equipment requirements associated with the Langmuir trough technique coupled with the elegance of the fundamental science and the interesting applied prospects for LB films provides an excellent opportunity for the academic community to similarly break down the traditional barriers between disciplines. At the present time it would appear that non-linear optics, electron beam microlithography, magnetic tape lubrication, sensors, and optical storage, are the areas most likely in the short term to benefit from LB film technology.

The above comments referring to the need for multidisciplinary activity apply equally well to other fields covered by the definition of Molecular and Supermolecular Electronics. The goal of a supermolecular information processor based on organic assemblies is a very ambitious one. Nevertheless, pursuing this target should serve to enumerate technologies and identify areas of basic scientific research that would otherwise remain dormant and unexplored. Far simpler but novel devices based on organic molecular materials should appear as a result of this research effort. It seems likely that Langmuir-Blodgett films will play a key role in helping scientists identify basic physical phenomena in supermolecular assemblies and at the same time enable engineers to become more familiar with devices incorporating organic films.

Author's Acknowledgments

The author is indebted to his many colleagues and former colleagues at the Universities of Durham and Oxford for their important contributions to the research described in this article. Particular thanks are due to Dr. M.C. Petty and Mr. B. Holcroft.

Editor's Acknowledgments

MOLECULAR BEAM. A unidirectional stream of neutral molecules passing through a vacuum, generally with thermal velocity. Such a beam may be produced by emergence from a pinhole in a chamber containing low pressure gas or vapor, and it may be defined by a system of slits. By passing the beam through known electric or magnetic fields, quantities such as nuclear magnetic moments can be determined.

MOLECULAR BIOLOGY. A self-defining term—the study of biological substances and phenomena at the molecular level.

For many years, biologists, aided by numerous laboratory instruments and methodologies (X-ray crystallography, electron microscopy, chromatography, electrophoresis, etc.) constructed a vast databank of biochemistry. This has been and continues to be of inestimable value to those professionals who deal with health, medicine, the industrial use of biochemicals, among other areas that require such information. There remained, however, a dissatisfaction concerning the absence of knowledge pertaining to the manner in which biochemical processes are directed and take place at the molecular level.

The first break occurred early in the 1950s when very illuminating findings were made concerning the complex biomolecule, DNA. The research of DNA, in essence, constituted the beginnings of *molecular biology*. This pioneering work altered the thrust of biochemical research, as previously typified by traditional biochemistry, to a concentration and emphasis on studying biological events at the molecular level.

A second break occurred in the early 1970s when it was discovered that a strand of the DNA molecule can be cut by restriction enzymes and that the sticky ends can be reassembled by a new technology known as *genetic recombination* or *recombinant DNA*. This is frequently the starting point for projects engaged in biological research at the molecular level. It is no surprise that molecular biology has become a highly diverse, wide-spectrum, multifaceted discipline. The many hundreds of research projects in this area underway today obviously cannot be delineated here. The highlights of just a few research targets are given here to provide a representative view of projects underway and inroads made to date.

Cell Membrane Research

Cellular membranes serve as the interface between the cell and the organism of which it is a part. It has been established that the movement of cells, as directed during growth and development, must involve, in some way, the plasma membranes. It also has been observed that plasma membranes play some role in cancerous growth, where cell multiplication and migration proceed at an uncontrolled rate. Membranes are composed of lipids that interact with each other in a watery medium to form a closed

and flexible compartment. This formation process occurs at a relatively rapid rate. Bretscher reports that an area of membrane equivalent to the area of the entire surface of the cell requires less than an hour to form. A good start has been made by a number of investigators toward understanding the detailed molecular structure of membranes. In retrospect, it is interesting to note that recent findings pertaining to the basic frame of membranes was qualitatively proposed as early as 1925 by Gorter and Grendel (University of Leiden). This framework is composed of a double layer of lipid molecules. One end of the molecule is hydrophilic, that is, soluble in water; the other end is hydrophobic, a hydrocarbon that is oily and insoluble in water. Most commonly, membrane lipids are phospholipids. See also **Lipids**.

Cytoplasm Research

The existence of fibers in cytoplasm was first observed microscopically about a century ago. It has been learned during the last few years as the result of biochemical and immunological studies, that a distinct set of proteins characterizes each filament system. Proteins in the cytoplasm make up a highly structured, yet changeable matrix. The matrix determines the cell shape, its division and motion, as well as the transport of vesicles and organelles. Research in molecular genetics is targeted to reveal the function of cytoskeletal proteins. Weber and Osborn report that current knowledge of the cell matrix is contributing to diagnosis and research in human pathology. For example, typing of intermediate filaments by way of immunofluorescence microscopy will distinguish the major tumor groups. Keratins are found in carcinomas. What is missing is detailed knowledge at the molecular level of why and how the protein molecules in the cytoplasm function.

Immune System Research

This is one of the most active research areas as of the late 1980s. It has been observed that proteins responsible for recognizing foreign invaders are the most diverse of all known proteins. Tonegawa observes that these proteins are encoded by hundreds of scattered gene fragments and these can be combined in millions, probably billions of ways. This gives some idea of how complex research in this area really is. It is one of the most difficult of tasks for molecular biologists, but is proceeding apace.

Cellular Intercommunications Research

It is well known that the majority of higher organisms utilize hormones or systems of neurons for intercellular communication. Snyder observes that chemical messengers mediate long-range communication via hormones; short-range communication via nerve cells. The two systems differ in directness, but some messenger molecules are common to both. Hormonal molecules are usually peptides and steroids. Communication between cells or groups of cells is mandatory for the survival of all multicellular organisms. Snyder also observed that as investigators come to know the properties and functions of highly specialized messenger molecules, it will be possible to develop better therapeutic agents for a number of diverse conditions, including hormonal abnormalities, heart disease, and mental illness.

Cellular Intracommunications Research

The communication within a cell is being investigated at the molecular level. The mechanism by which a cell receives external signals by way of receptors has been reasonably well understood for a number of years. But what comprises the cell's internal mechanism for reacting to received signals by way of the receptors? Berridge refers to receptors as "molecular antennas." Obviously, the barrier to the flow of information from receptor to mechanisms within the cell is the plasma membrane, previously mentioned. How are external signals acted upon internally within the cell to cause it to secrete, to contract, to metabolize, or to grow, among several other biological reactions? What are the "second messengers" within the cell? How do they function? A second messenger, cyclic adenosine monophosphate (cyclic AMP) has been identified. Other second messengers include Ca^{+} ions, inositol triphosphate (IP_3), and diacylglycerol (DG). Berridge also reported that some evidence has been gained to the effect that the aforementioned substances are cannibalized from the plasma membrane itself. Obviously, the cell must include genes required for the synthesis of the proteins used in the internal pathways. Aberration of these gene functions could lead to abnormalities of cellular growth and hence to uncontrolled growth and structural transformations typical of cancer. Cells related in some way to tumor growth revealed thus far are called *oncogenes*. Berridge and other researchers are attempting to identify additional second messengers that may be present and how they function in internal communication.

Biological Development and Growth Research

For many years, the processes which take place within an organism to cause it to grow (the early embryonic phase), leading to maturity (adulthood) and later to initiate the aging phase have been among the least understood of biological phenomena. As aptly observed by Gehring: How is the basic architecture of an embryo laid down? How does the linear information of DNA generate a three-dimensional organism? One of the most recent and intriguing discoveries is that of the so-called *homeobox*, which is found as a short stretch of DNA. When the gene containing the homeobox is translated into a protein, the homeobox yields a string of amino acids that are believed to bind to the DNA double helix. By binding to the DNA of particular genes, the protein may be able to turn them on or off. The homeobox was first noted in studies of *Drosophila*; subsequent studies have revealed a homeobox within a range of organisms extending from worms to humans. It is well established, of course, that animals develop in numerous ways. Researchers now question whether or not the molecular mechanisms underlying development may be more universal than previously suspected. Again, it appears that the answers to still another of the biological secrets may lie in better understanding the process at the molecular level.

Adaptive and Evolutionary Processes

Wilson observes that in the past most biologists working in this area have concentrated their attention at the level of the whole organism. Mutation frequently has been suggested as the cause of adaptive changes. Prior to studies at the molecular level, however, it was *not* known that mutations may accumulate at steady rates over time in the genes of all lineages. Wilson, a proponent of the molecular evolution concept, reports on two assumptions: (1) Heritable differences among organisms result from differences in their DNAs, and (2) molecular evolutionists must not only measure differences in DNA, but also explain the origin of the differences and their relation to organismal differences. Wilson also points out that two critical elements of molecular evolution are (1) *point mutations*, specifically those occurring in the genes coding, and (2) *regulator mutations*. A point mutation is defined as a single replacement of a DNA base; a regulatory mutation is any change in a gene or within the vicinity of a gene that determines whether the gene is active or inactive. Research on point mutations led to the concept of a *molecular clock* and in the discovery of still another kind of genetic change, which Wilson calls a *neutral mutation*. This mutation is neither advantageous nor disadvantageous for an organism. Wilson also refers to the "pressure" to evolve, noting that this stems from geologic forces as well as from the brains of mammals and birds. It is obvious that the study of molecular evolution occupies a special position in contemporary biology.

MOLECULAR DISTILLATION. A special form of distillation conducted at pressures of 1–7 micrometers in the laboratory and 3–30 micro meters in industrial applications. Compared with conventional laboratory vacuum distillations carried out between 1 and 10 millimeters of mercury

pressure, this is a very high vacuum. One micrometer equals 0.001 millimeter of mercury pressure. The other feature of the molecular still is that the condenser is located within a distance less than the mean free path of the evaporating molecules from the evaporator portion of the apparatus. Thus, although a molecule may return to the distilland many hundred times before reaching the exit of a conventional vacuum still, 50% of the molecules in a properly functioning molecular still will reach the exit on their first try. Thus, efficiency is remarkably high.

Because of the absence of convection due to ebullition and because high viscosities and high molecular weights may impede diffusion within the distilland, the surface of the distilland in a molecular still may not always represent the total liquid. Therefore, efficient molecular distillation requires the mechanical renewal of the surface film. This is achieved by vigorous agitation, as in the *stirred-pot still*; by employing a *falling film*; or by using centrifugal force, as in the *centrifugal* molecular still. Commercial installations of falling-film stills achieve throughputs of many tens of liters per hour, whereas the centrifugal still is capable of several hundred liters per hour. Centrifugal stills usually are arranged in groups of from three to seven. This permits fractionation by multiple redistillation. Among the uses of molecular distillation are: the separation of mono and diglycerides for bread and paraffin wax for milk cartons; the distillation of plasticizers, fatty acid dimers, and synthetics; the distillation of vitamin A esters and intermediates; and the stripping of α, β, γ, and δ-tocopherols and sitosterols from vegetable oils.

See also **Distillation**.

MOLECULAR MODELING. Molecular modeling refers boldly to any study of molecules utilizing physical or theoretical models to explain an observed or predicted behavior. Whereas molecular modeling as a practice has its roots in the development of quantum theory at the turn of the twentieth century, it was the exponential growth in computing power between the mid-1970s and the mid-1990s that catalyzed the development and application of molecular modeling methods during that period. The spectrum of software systems available covers all aspects of modeling.

Molecular modeling can be defined as the application of computational techniques, grounded in theory, to predict or explain observable biological or physical chemical properties. Wherever molecular modeling is practiced using a computer, the technique then becomes computer-assisted (aided) molecular modeling, or CAMM. CAMM, is often used synonymously with CAMD, or computer-assisted molecular (materials) design/discovery. CADD refers to computer-assisted drug design/discovery. A computational technique as used herein is a mathematical model derived from principles of chemistry, physics, or statistics which facilitates molecular modeling. An entire branch of chemistry, i.e., computational chemistry, is devoted to developing, benchmarking, and applying computational techniques in order that researchers may be able to better understand and predict properties. Some of the properties which may be calculated either exactly or approximately by computational methods are the following:

boiling points	dipole moments
melting points	quadrupole moments
crystallization energy	octupole moments
heat capacity	infrared spectra/intensities
heat of formation	nmr spectra/chemical shifts
heat of fusion	optical rotary dispersion
heat of sublimation	raman spectra
heat of vaporization entropy	ultraviolet spectra
molar refractivity	ionization potentials
molar volume	electron affinities
partition coefficients	protonation energies and pK_as ionic strength
radius of gyration elasticy	conformational energies
tensile strength	Boltzmann distributions

Molecular properties can be classified according to their end-point observables, such as chemical (reactivity, solubility, acid–base), physical (a function of physical state: gas, liquid, solid; thermodynamic), or biological (ligand or enzyme; agonist or antagonist). These properties reflect macroscopic, or bulk, properties, which exist only for the bulk material, e.g., heat of crystallization, or microscopic properties, which exist for an ensemble of the molecule. As use of CAMM methods

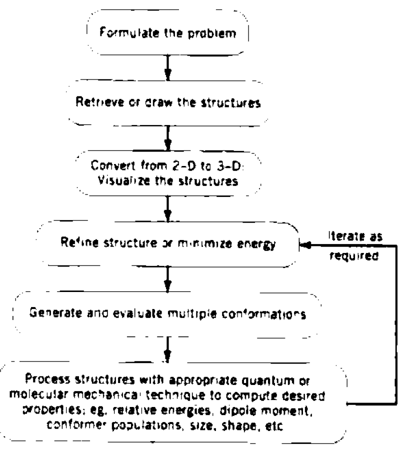

Fig. 1. Flow chart for a typical small molecule modeling project

expands to address a broader horizon of applications beyond those in organic, medicinal, and biological chemistry, calculations on metals, semiconductors, and magnetic systems have become more common.

The specific process involved in a given molecular modeling study depends significantly on the nature of the primary objective of the task. However, for many small-molecule and even macromolecular studies, a number of authors have diagrammed the individual steps in the process, and the flowchart in Figure 1 summarizes their efforts. An initial step that is critical to any CAMM project is the generation or retrieval of the pertinent structures themselves. Structures may range from simple organic molecules or monomers of more complex polymers, to full proteins, enzymes, metal surfaces, or zeolites. The modeling process can be influenced by the initial structure and its geometry. Thus, the selection and development of the starting molecular geometry needs to be given particular attention. An important component of the quality control process, as well as in gaining an understanding of the molecules themselves, is the visual examination of structures involved in a modeling study.

Computer Graphics In Molecular Modeling

The goal of molecular modeling is to define clearly the relationship between chemical constitution, i.e., the molecular formula or a topographic representation thereof, its geometric constitution or 3-D topology (the disposition of its atoms in Cartesian space), and its observed (or predicted) properties. The representation and facile manipulation of 3-D arrays of atoms comprise the domain of molecular or computer graphics. The growth of graphics tools has paralleled the evolution of computing hardware. Computing software and hardware systems have had a profound impact on the ability of modelers to compose a modeling study and address all aspects of the work, ranging from generating 2-D drawings of structures to statistical quality control of computed properties via visualization of multidimensional data.

One facet of chemistry which has benefited greatly from the use of computer graphics to enhance its own development is x-ray crystallography; computers are also used in x-ray structure refinement.

Among the available software systems which together help to exemplify the promise of computer graphics, Advanced Visualization Systems (AVS), stands out as one of the more extensible and practical of them to use. The premise behind development of the system was to provide modelers with a toolkit of modules having sophisticated intrinsics that would enable even casual programmers to link together multiple simple functionalities into a complex construct with which to accomplish exactly the types of visualization and manipulations that their work required.

Computational Methods for Molecular Modeling

The ultimate goal of quantum mechanical calculations as applied in molecular modeling is the *a priori* computation of properties of molecules with the highest possible accuracy (rivaling experiment), but utilizing the fewest approximations in the description of the wave-function. *Ab initio*, or from first principles, calculations represent the current state of the art in this domain. *Ab initio* calculations utilize experimental data on atomic systems to facilitate the adjustment of parameters such as the exponents of the Gaussian functions used to describe orbitals within the formalism.

The performance of *ab initio* techniques distinguishes them significantly from their predecessors, semiempirical methods. Their consistent reproduction of data from structural, thermodynamic, and reaction sources to a range falling within the error limits of the experimental values provides scientists with an important tool with which to address various modeling problems. Whereas the absolute value of the relative performance of *ab initio* techniques varies for each structural or energetic feature examined, it is not unreasonable to suggest that if the quantity can be computed by both semiempirical and *ab initio* methods, the *ab initio* value will be closer to experiment or an ideal value than any other method.

Molecular Mechanics and Molecular Dynamics. In the realm of quantum mechanics, researchers deal explicitly with electrons, with their interactions, and with their attraction to nuclei, albeit in varying degrees depending on the rigor of the method chosen to solve the particular problem involved. These techniques were somewhat limited in their application prior to the age of large-scale computers and super workstations. Computers made possible the development of molecular mechanics, or empirical force field methods and, ultimately, the application of these methods to a full spectrum of studies in structure and energetics.

Molecular Mechanics. Molecular mechanics (MM), or empirical force field methods (EFF), are so called because they are a model based on equations from Newtonian mechanics. This model assumes that atoms are hard spheres attached by networks of springs, with discrete force constants. The force constants in the equations are adjusted empirically to reproduce experimental observations. The net result is a model which relates the "mechanical" forces within a structure to its properties. Force fields are made up of sets of equations each of which represents an element of the decomposition of the total energy of a system (not a quantum mechanical energy, but a classical mechanical one). The sum of the components is called the force field energy, or steric energy, which also routinely includes the electrostatic energy components. Typically, the steric energy is expressed as

$$E_{\text{Total}} = E_{\text{steric}} + E_{\text{electrostatic}} = E_{\text{bonds}} + E_{\text{angles}} + E_{\text{vdW}} + E_{\text{torsion}} + E_{\text{charge/dipole}}$$

The overall form of each of these equations is fairly simple, i.e., energy = a constant times a displacement. In most cases the focus is on differences in energy, because these are the quantities which help discriminate reactivity among similar structures. The computational requirement for molecular mechanics calculations grows as n^2, where n is the number of atoms, not the number of electrons or basis functions. These calculations will be much faster than an equivalent quantum mechanical study. The size of the systems which can be studied can also substantially eclipse those studied by quantum mechanics.

In a force field calculation, a molecule in three dimensions is constructed using either Cartesian coordinates x, y, and z, or via an internal coordinate matrix consisting of bond distances, bond angles, and dihedral angles to specify the atoms' unique positions. Then the initial structure is evaluated to determine the extent to which each degree of freedom (bonds, angles, etc) deviates from the ideal (the zero-energy value) for the particular element and its hybridization. An energy minimization process follows wherein the energy associated with the distortions from ideal is minimized as the individual atomic positions or degrees of freedom are adjusted. Iteratively, this converges on a "minimum energy" or an "optimized" structure. This structure represents the best attempt of the minimization algorithm to render the smallest deviations in position of each of the atoms such that either the derivatives of the change in energy associated with the deviations are the smallest, or they satisfy either energetic convergence or coordinate change criteria from iteration to iteration. This process is analogous to the geometry optimization process within a quantum mechanical program, except that there the objective is to converge on a structure which yields the smallest energy derivatives and lowest total energy from solution of the SCF equations. Most simple molecular mechanics force fields include terms (Fig. 2) for bond stretching, bond angle distortion (bending), dihedral angles, van der Waals nonbonded interactions, Coulombic interactions (dipoles or charges).

Force Fields, Molecular Dynamics, and Vibrational Spectroscopy. The link between molecular mechanics and molecular dynamics comes about through the force field itself. In molecular mechanics, the main interest is in computing the energy of molecules in the gas phase at room temperature in a single, discrete configuration and conformation; time is not a variable

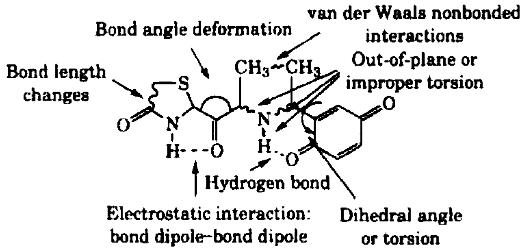

Fig. 2. Structural representation of the energetic components of a typical molecular mechanics force field

in the equations. From molecular dynamics, the objectives are properties which represent a time-averaged ensemble of states, including, for example, conformationally excited states, rotational states, interconversion rates, or inversion barriers for amines or amides. From this ensemble of states, characterizing the existence of the excited states and their contribution to the total energy of the system (from a Boltzmann distribution) is next. From an understanding of the vibrational spectroscopic roots of molecular mechanical force fields used in dynamics simulations, molecular dynamics may be seen as an extension bridge between theory and experiment, linking "static" molecular mechanical representations of properties with "dynamical" experimental properties. Applications of force field techniques to problems in environmental chemistry, materials science, and molecular biology demand that the methods go substantially beyond those for which reliable experimental data is available. Only since the time computers have made larger-scale *ab initio* quantum mechanical calculations practical for appropriate model systems have these techniques been reliable for such a broad spectrum of important applications.

Molecular Dynamics and Monte Carlo Simulations. At the heart of the method of molecular dynamics is a simulation model consisting of potential energy functions, or force fields. Molecular dynamics calculations represent a deterministic method, i.e., one based on the assumption that atoms move according to laws of Newtonian mechanics. Molecular dynamics simulations can be performed for short time-periods, e.g., 50–100 picoseconds, to examine localized very high frequency motions, such as bond length distortions, or, over much longer periods of time, e.g., 500–2000 ps, in order to derive equilibrium properties. Those that can be evaluated by performing molecular simulations are conformational states and energetics, kinetic properties: rates of reaction and interconversion, reaction pathways, solubilities, diffusion rates, binding and complexation data, folding processes, transition temperatures, free energies for point mutations, and free energies of binding. The molecular simulations can also serve as an adjunct to x-ray and nmr for structure refinements.

As noted, force fields are a set of equations relating the total energy of the system to its individual interaction components. After selection of a force field simulation program which is appropriate to a given problem, the general procedure includes (*1*) initial structure equilibration, and (*2*) structure refinement.

Monte Carlo (MC) techniques for molecular simulations have been used to a great extent in studying the chemical physics of polymers. The majority of molecular modeling studies today do not involve the use of MC methods; however, the sampling capability provided by MC methods has gained some popularity among computational chemists.

Combined Quantum and Molecular Mechanical Simulations. In this technique, a molecular dynamics simulation includes the treatment of some part of the system with a quantum mechanical technique. This approach, QM/MM, is similar to programs that use quantum mechanical methods to treat the π-systems of the structures in question separately from the sigma framework. The results are combined at the end to render a structure which is optimized and energy-refined to satisfy both self-consistent field (SCF) and force field energy convergence.

MOLECULAR ORBITALS. See **Orbitals**.

MOLECULAR RECOGNITION. Molecular recognition implies complementary lock-and-key type fit between molecules. The lock is the molecular receptor and the key is the substrate that is recognized and selected to give a defined receptor-substrate complex, a coordination compound or a supermolecule. Hence molecular recognition is one of the three main pillars, fixation, coordination, and recognition, that lay the foundation of what is known as supramolecular chemistry.

Supramolecular chemistry, the chemistry beyond the molecule, is a highly interdisciplinary field of science covering the chemical, physical, and biological features of chemical species of greater complexity than molecules themselves that are held together and organized by means of intermolecular (nonbinding) interactions. The chemistry of molecular recognition is also the core of host–guest chemistry, which is a subdiscipline or a particular aspect of supramolecular chemistry mostly involving inclusion and complex formation. See also **Inclusion Compounds**.

Principles of Receptor Design

Information Storage and Read Out. Molecular recognition is defined by the energy and the information involved in the binding and selection of substrates by a given receptor molecule that may also involve a specific function. Mere binding is not recognition, although it is often taken as such. Instead, one may say that recognition is binding with a purpose, like receptors are ligands with a purpose. It implies a pattern recognition process through a structurally well-defined set of intermolecular interactions. Molecular recognition, thus, deals with the molecular storage and supramolecular readout of molecular information.

Information may be stored in the architecture of the receptor, in its binding sites, and in the ligand layer surrounding the bound substrate such as specified in Table 1. It is read out at the rate of formation and dissociation of the receptor-substrate complex. The success of this approach to molecular recognition lies in establishing a precise complementarily between the associating partners, i.e., optimal information content of a receptor with respect to a given substrate.

TABLE 1. STRUCTURAL PARAMETERS FOR STORAGE OF INFORMATION IN A CHEMICAL RECEPTOR

Receptor	Parameter
architecture	size
	shape
	connectivity
	cyclic order
	conformation
	chirality
	dynamics
binding sites	electronic properties (charge, polarity, polarisability, van der Waals attraction and repulsion)
	size
	shape
	number
	arrangement
	reactivity (protonizable, deprotonizable, reducible, oxidizable)
surrounding ligand layer	thickness
	overall polarity (lipophilic, hydrophilic)
	specific polarity(exo/endo-lipo/polarophilic)

Complementarity. To a first approximation, complementarity should take two forms. Firstly, the shape and size of the receptor cavity must complement the form of the substrate. Secondly, there must be a chemical complementarity between the binding groups lining the interior of the cavity and the external chemical features of the substrate.

The weak intermolecular forces that are principally involved in stabilizing receptor-substrate interactions and involved in molecular recognition processes are summarized in Table 2. Examples are shown in Figure 1.

Reorganization and Preorganization. On principle there are two different modes of receptor behavior. One of them is the so-called lock-and-key image involving complementary fit concept between rigid substrate and rigid receptor or rigid guest and rigid host relating to conformational flexibility of the molecular constituents forming the receptor–substrate (host–guest) complex. Receptors of this type are expected to present very efficient recognition between complementary partners, i.e., both high stability and high selectivity of the receptor–substrate complex.

However, in most biological systems there is a degree of flexibility in the receptor. The approach of the substrate leads to conformational changes and an organization of the binding site around it. With this induced fit mechanism of binding, a higher entropy price is paid, but there are several advantages. A flexible receptor will permit a more wraparound interception or even complete encapsulation with the substrate involving many more potential binding interactions. This may lead to high selectivity of binding involving the amplification of molecular recognition interactions.

The balance between rigidity and flexibility is of particular importance for the binding and the dynamic properties of a receptor. It is, thus, a decisive structural design parameter of the receptor depending on the use. For instance, processes of exchange regulation, cooperativity and allostery connected with molecular recognition require a built in flexibility so that the receptor may adapt and respond to changes, unlike rigid receptors.

Topology. This parameter may have reference to either the receptor as an individual molecular structure or to the receptor–substrate complex on a higher level of organization that is directly related to the mode and efficiency of molecular recognition.

A concave receptor is a favorable case. Under these circumstances the receptor cavity is lined with binding sites directed towards the bound species (see Fig. 1). This corresponds to Cram's definition of a receptor (host) molecule providing binding sites that are convergent, as contrasted with the bound substrate (guest) featuring divergent complementary sites, i.e., the substrate is more or less completely surrounded by the receptor, forming an inclusion complex. This widely used principle of convergence defines a convergent or endo-supramolecular chemistry (host–guest chemistry) with endo-receptors (endo-hosts) effecting endo-recognition (Fig. **2a**).

The opposite procedure consists in making use of an external receptor surface rather than an internal cavity as substrate receiving site. This

TABLE 2. TYPES OF INTERACTIONS IN MOLECULAR RECOGNITION

hydrogen bonding between basic and acidic center
elastrostatic attraction between anionic and cationic centers
metal-ligand interaction
dipole-dipole interaction
π-stacking and charge-transfer interaction between aromatic residues in the receptor and delocalized regions of the substrate
van der Waals attraction between hydrophobic regions on the two components
covalent bonds, that can be reversibly formed and broken (e.g., disulfides, borate esters).

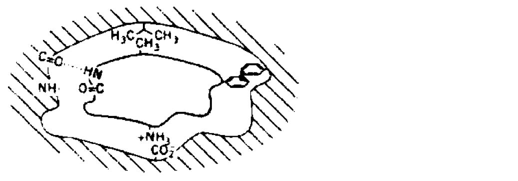

Fig. 1. Schematic representation of a receptor–substrate (host–guest) complex involving cavity inclusion of the substrate and the formation of different types of weak supramolecular interactions between receptor (hatched) and substrate (dotted)

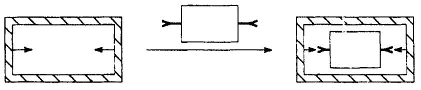
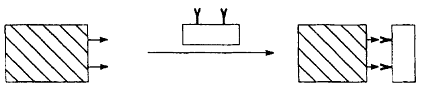


(a)



(b)

Fig. 2. Diagram of (**a**) endo- and (**b**) exo-receptor recognition of substrates (dotted rectangles)

amounts to the passage from a convergent endo-supramolecular chemistry to a divergent or exo-supramolecular chemistry, and from endo- to exoreceptors (Fig. 2**b**). Here receptor–substrate binding occurs by surface-to-surface interaction which may be termed affixation as contrasted with inclusion. Exo-recognition with strong and selective binding, in particular, requires a large enough contact area and a sufficient number of complementary interactions along the interface. Such a mode of molecular recognition also finds biological analogies, for instance at the antibody–antigen interface of immunological importance. Metallo-exoreceptor aggregation, molecular recognition at organic and inorganic monolayers, films and solid surfaces bearing recognition groups, as well as the design of supramolecular solid architectures and materials, are other important instances of the exo-recognition principle.

Simple Modes of Molecular Recognition

Substrates involved in molecular recognition may feature a particular shape, size, state of charge, chemical affinity or optical specification. In general most of these parameters share. Nevertheless there may be dominating features of a certain substrate molecule to be used by a complementary receptor in the recognition process.

Size and Shape Dominated Substrate Recognition. Perhaps the simplest recognition process is that of a spherical substrate, in its most elementary form a ball-shaped metal ion of defined diameter. Three main classes of receptors provide the spherical recognition property. They are (*1*) macrocyclic polyethers, the well-known crown ethers and their derivatives; (*2*) the macropolycyclic cryptands; and (*3*) the acyclic analogues of crown compounds and cryptands, usually designated as podands. Prototypical compounds for each substance class are given by compounds (**1**)–(**3**) (Fig. 3). They all possess a spherical or quasispherical negatively polarized cavity prepared for the accommodation of alkali- and alkaline-earth metal ions that have complementary size, giving rise to a feature known as spherical recognition. Coronates, cryptates or podates are the names of the respective inclusion complexes. See also **Inclusion Compounds**.

Although acyclic podands do not provide a permanent cavity, they may create one by encircling a spherical cation with the length of the receptor molecular thread being the controlling parameter. Nevertheless, from what has already been said, low preorganization and topology of the podands handicap the substrate recognition which is increasingly higher in the circular crown and spheroidal cryptand case, but is most pronounced for the spherand type of receptor (e.g., **4** in Fig. 3).

Natural macrocycles displaying antibiotic properties are also very efficient in the recognition of alkali metal ions. For instance, valinomycin (**5** in Fig. 3) gives a strong and selective complex in which a K^+ ion is included in the macrocyclic cavity in octahedral environment of six carbonyl oxygens (Fig. 4).

Recognition of a tetrahedral substrate geometry requires the construction of a receptor molecule with a tetrahedral recognition site. This may be realized by positioning four suitable binding sites at the corners of a tetrahedron and incorporating them into a bridged molecular framework.

Charge Attraction Dominated Recognition. Thus far, for recognition sizes and shapes of the substrate have been the focus. Nevertheless, charge attraction between the substrate and the receptor has also played a part, because cations such as metal ions or ammonium ions were complexed by negatively polarized cavities. But metal ions involved hard alkali and alkaline-earth cations rather than weaker transition metal ions. Replacing the oxygen sites of crown compounds and cryptands with nitrogen and sulfur atoms yields receptors that show marked preference for transition metal ions and may allow highly selective recognition of toxic heavy metal ions such as cadmium, lead or mercury according to the hard and soft acid and base (HSAB) principle. Others containing internally directed functionalized units form very strong and selective complexes with Fe^{3+} or actinide and lanthanide ions, while a similar receptor with hard endocarboxylic acid groups is efficient for hard Ca^{2+} and Mg^{2+} ions, showing again responsibility of a charge density effect in the receptor—substrate recognition. Thus, recognition of hard alkali and alkaline earth metal ions is determined by coulombic attraction, whereas the weak transition metal ions are mainly controlled by geometrical parameters of orbital overlap.

Hydrogen Bond Dominated Recognition. Recognition of bioactive compounds is largely determined by the use of hydrogen bonding between polar sites. Here substrate recognition results from the formation of specific hydrogen bonding pattern between complementary subunits, in a way reminiscent of base pairing in nucleic acids. Hence hydrogen bonding has also been determined an important parameter for the design of artificial receptors.

π-Stacking and Charge-Transfer Dominated Substrate Recognition. Nature's strategy for the recognition of substrates featuring a flat aromatic frame-work (planar recognition) affords another recognition element, namely $\pi - \pi$ stacking interactions between aromatic rings, i.e., aromatic groups of receptor and substrate that meet a parallel face-to-face orientation, apart from hydrogen bonding being also typical of the nucleotide recognition.

In a way, $\pi - \pi$ stacking and charge transfer type of recognition have something in common. For example, a certain macrobicyclic intercaland and related receptors have been found to recognize flat shaped substrates through $\pi - \pi$ stacking and bind them to form a molecular cryptate, in particular if electron donating substrate species are involved to allow charge-transfer interaction, such as planar molecular anions or nucleic acids.

Lipophilic Interaction Dominated Substrate Recognition. Making recognition through lipophilic interaction possible requires receptors presenting large and more or less rigidly connected architectures of macrocyclic or cage-like nature.

The naturally occurring cyclodextrins having endo-lipophilic cone-shape are perhaps the most important and also the first receptor molecules whose selective inclusion properties towards lipophilic organic molecules were recognized. They comprise a family of cyclic oligosaccharides, composed of 6, 7, and 8 glucose units in its most familiar representatives (α, β, and γ-cyclodextrin, respectively) providing endo-lipophilic and exo-hydrophilic cone-shaped molecular cylinders of increasing size. Cyclodextrins form size and shape selective inclusion compounds with a wide variety of substrates including benzene derivatives, paraffins and noble gases.

Calixarenes (from the Latin *calix*) may be understood as artificial receptor analogues of the natural cyclodextrins. In its prototypical form they feature a macrocyclic metacyclophane framework bearing protonizable hydroxy groups made from condensation of *p*-substituted phenols with formaldehyde. Dependent on the ring size, benzene derivatives are the substrates most commonly included into the calix cavity, but other interesting substrates such as C_{60} have also been accommodated.

Multiple and Multisite, Coreceptor- and Coupled-System Substrate Recognition

Once recognition units for specific groups and individual features of a substrate have been identified, one may consider combining several of them within the same receptor. Thus far, though not carefully directed, the previous receptors in many cases already possess this property of nonindividual interaction modes. More carefully directed, this leads to multiple and multisite recognition depending on the design of binding subunits which may cooperate for the simultaneous complexation of several substrates or of a multiply bound polyfunctional species to yield polynuclear complexes (homo- or heteronuclear) and mononuclear polyhapto-type complexes, respectively.

Chiral Recognition

Enantiomers are perhaps the substrate type most difficult to distinguish. They are stereochemical species that have exactly the same structure except for their mirror image (chirality) relationship See also **Chiral Separations**. Chiral (enantiomer) recognition in complexation is one of the most important means by which receptor sites of biological systems such as in genes or enzymes act and regulate. From the principle point of view, recognition of a substrate enantiomer from racemic mixture (50:50% mixture of enantiomers) requires an enantiomeric optically resolved receptor structure in order to make possible two diastereomeric receptor–substrate complexes allowing differentiation.

Following this line, a great variety of optically resolved (optically active) crown compounds were prepared for the resolution of racemic cationic substrates.

Artificial Receptors for Particular Substrate Recognition

Some particular substrates are biorelevant species or play central roles as drugs. Barbiturates are such an important family of drugs and are the target for molecular recognition. According to their structure, the barbiturate moiety essentially fuses two imide groups within a six-membered ring. Thus, two diaminopyridine units correctly positioned in a macrocyclic ring should bind to all six of the accessible hydrogen bonding sites in barbiturates. A crystal structure of a respective receptor–substrate complex has been performed that comes up to the expectations.

The structural and synthetic relationships shared between barbiturates and urea, which is another substrate of high physiological interest, suggest that the above receptor strategy could be modified for the selective complexation of urea. The designed modification for urea recognition involves replacement of the H-bond donating pyridine-6-amido groups in the previous barbiturate receptor by two H-bond accepting groups that differ by 120° in alignment to the substrate.

Receptors that are monomolecular species possessing a monomolecular cavity, pocket, cleft, groove or combination of it including the recognition sites to yield a molecular receptor–substrate complex can be assembled and preserved in solution. By way of contrast, molecular recognition demonstrated in the following comes from multimolecular assembly and organization of a nonsolution phase such as polymer materials and crystals.

Molecular Recognition in Polymers and Solids

If a polymer is prepared in the presence of molecules, the "print molecules" of which are extracted after polymerization, the remaining polymer may contain cavities, prints, or footprints that can recognize the print molecule. Actually, the cast relates to the matrix molecule like lock-and-key fit. (see Fig. 1).

A great many functionalized styrenes, including carboxylic acids, amino acids, Schiff bases, or specific compounds, e.g., L-DOPA, have successfully been applied as print templates. Moreover, it has also been shown that silica gel can be imprinted with similar templates, and that the resulting gel has specific recognition sites determined by the print molecule.

Microporous inorganic materials dominated historically by the zeolites and alumosilicates, and the great variety of more recent nonoxide and coordination framework materials should also be mentioned here. This type of molecular recognition is usually known as molecular sieving.

Molecular Recognition at Interfaces and Surface Monolayers

There are three advantages to study molecular recognition on surfaces and interfaces (monolayers, films, membranes or solids): (*1*) rigid receptor sites

can be designed; (2) the synthetic chemistry may be simplified; (3) the surface can be attached to transducers, which makes analysis easier and may transform the molecular recognition interface to a chemical sensor. This kind of molecular recognition involves outside directed interaction sites, i.e., exo-receptor function (see Fig **2b**).

Molecular recognition of crystal interfaces makes possible the control of crystal growth processes in that suitably designed auxiliary molecules act as promoters or inhibitors of crystal nucleation inducing, for instance, the resolution of enantiomers or the crystallization of desired polymorphs and crystal habits.

Following another direction, it has previously been shown that alkanethiols spontaneously adsorb to Au from dilute solutions of ethanol and other nonaqueous solvents, and that the resulting self-assembling monolayers (SAMs) assume a close-packed over-layer structure on Au and other textured Au surfaces, being quite robust in aqueous solutions and vapor-phase ambients. This mode of self-assembly chemistry has been used to synthesize monolayer assemblies that function as molecular recognition interfaces based on the presence of recognizer end groups.

Self-Recognition

This mode of molecular recognition, on principle, is defined as the recognition of like from unlike or self from unself molecules, embodied in the spontaneous selection and preferential assembly of like components in a mixture.

So far this article has been concerned with interactions among chemically different species, which is true for most of the chemical recognition processes, including supramolecular and biomolecular processes. With crystals it is usually the other way around. Although some crystals, co-crystals, crystalline complexes, and crystalline inclusion compounds are built from more than one kind of molecule and are exceptions, most crystals are built from identical (or enantiomeric) copies of the same molecule. Thus, a usual one-component crystal is a macro-supramolecular assembly where one should more properly speak of molecular self-recognition. This is not a fact contradictory to the basic principles of molecular recognition, since the case might occur in which the two complementary structures happen to be identical in dealing with a self-complementary relationship. Even when all the molecules are identical (or enantiomeric), an acceptor part of one molecule can interact with a donor part of a second, and the acceptor part of the second can interact in exactly the same manner with the donor part of a third, and so on, giving rise to periodicity of the crystal and to the limited number of space groups used in molecular crystals. For instance, it is very uncommon for molecules in a crystal structure to be related by rotation axis or mirror planes, because identical parts of molecules avoid one another, except for molecular sites having a so-called self-complementary donor-acceptor group. Self-complementary groups form finite, one-dimensional tape, two-dimensional layer, or three-dimensional motifs of organic molecules mostly obtained from hydrogen bonding.

In solution, highly ordered structures created via self-recognition and self-assembly of a programmed H-bonding molecular component are also possible. With respect to inorganic self-recognition and self-assembly this would involve preferential binding of like metal ions by like ligands in a mixture of ligands and ions.

A particular point of interest included in these helical complexes concerns the chirality. The helicates obtained from the achiral strands are a racemic mixture of left- and right-handed double helices. This special mode of recognition where homochiral supramolecular entities, as a consequence of homochiral self-recognition, result from racemic components is known as optical self-resolution. It appears in certain cases from racemic solutions or melts (spontaneous resolution) and is often cited as one of the possible sources of optical resolution in the biological world.

MOLECULAR SIEVES. In this article, the term *molecular sieve* is restricted to inorganic materials that possess uniform pores with diameters in either the micro- (<2 nm) or meso- (2–20 nm) size range. The most technologically important molecular sieves are zeolites, i.e., crystalline silicate or aluminosilicate framework structures with channels of diameters <1.2 nm. Several of these topologies, with boron, gallium, or iron replacing aluminum, or germanium replacing silicon, have also been prepared. The chemical composition of microporous framework structures has been expanded considerably with the substitution of phosphorus for silicon, and new families of aluminophosphate and silicoaluminophosphate structures have been synthesized in the laboratory. Some of these frameworks have zeolite analogues, whereas others are unique. The addition of elements such as Mg, Ti, Mn, Co, Fe, or Zn into these structures has made it possible to generate metalloaluminophosphates, metallosilicoaluminophosphates, etc. Microporous sulfide-based framework structures are also possible.

Considerable synthesis effort has been devoted to developing frameworks with pore diameters within the mesoporous range: the largest synthesized are the phosphate-based AlPO-8 (14-membered ring), VPI-5 (18-MR), and cloverite (20-MR), which have pore diameters within the 0.8–1.3 nm range. A new family of mesoporous molecular sieves designated M41S has been discovered. Although not framework structures like zeolites, silicate, and aluminosilicate, M41S materials possess very uniform mesopores.

The technological applications of molecular sieves are as varied as their chemical makeup. Heterogeneous catalysis and adsorption processes make extensive use of molecular sieves. The utility of the latter materials lies in their microstructures, which allow access to large internal surfaces, and cavities that enhance catalytic activity and adsorptive capacity.

Zeolites

Molecular-sieve zeolites of the most important aluminosilicate variety can be represented by the chemical formula $M_{2/n}O \cdot Al_2O_3 \cdot ySiO_2 \cdot wH_2O$, where y is 2 or greater, M is the charge balancing cation, such as sodium, potassium, magnesium, and calcium, n is the cation valence, and w represents the moles of water contained in the zeolitic voids. The zeolite framework is made up of SiO_4 tetrahedra linked together by sharing of oxygen ions. Substitution of Al for Si generates a charge imbalance, necessitating the inclusion of a cation. The structures contain channels or interconnected voids that are occupied by the cations and water molecules. The water may be removed reversibly, generally by the application of heat, which leaves intact the crystalline host structure permeated with micropores that may account for >50% of the microcrystal's volume. In some zeolites, dehydration may produce some perturbation of the structure, such as cation movement, and some degree of framework distortion.

Zeolite minerals are formed over much of the earth's surface, including the sea bottom. Most zeolites occurring in cavities of basaltic and volcanic rocks are exceedingly rare. However, several zeolite minerals generated by the natural alteration of volcanic ash in alkaline environments over long periods of time occur in recoverable deposits. Although such minerals are rarely useful for catalytic application, mainly because of iron impurities (exception: Chabazite of Bowie, Arizona), more abundant zeolites, e.g., clinoptilolite, have found use as soil conditioners, additives to animal feed, as animal litter, in aquaculture to remove ammonia (phillipsite), and for ion exchange to remove heavy metals from industrial and mining effluents (chabazite).

Synthetic and mineral zeolites of primary importance are listed in Table 1.

Structure

Of the approximately 120 known framework aluminosilicates, ~50 occur naturally, the rest being synthetic. There are 56 structural types of zeolites known. Understanding the complexities of zeolite structures is made easier by recognizing three important structural keys: the basic arrangement of the individual structural units in space, which defines the framework topology; the location of the charge-balancing cations; and the channel-filling material, such as water or an organic template, which is incorporated as the zeolite is formed. After the channel-filling material is removed, the void space can be used for the adsorption of gases, liquids, salts, elements, metal complexes, etc. In turn, this void-filling property makes zeolites commercially useful in ion exchange, catalysis, etc.

TABLE 1. ZEOLITE COMPOSITIONS

Zeolite	Typical formula
Natural	
chabazite	$Ca_2[(AlO_2)_4(SiO_2)_8] \cdot 13H_2O$
mordenite	$Na_8[(AlO_2)_8(SiO_2)_{40}] \cdot 24H_2O$

[a] TMA = tetramethylammonium.
[b] TPA = tetrapropylammonium.

There are two types of structures: one provides an internal pore system comprising interconnected cage-like voids; the second provides a system of uniform channels which, in some instances, are one-dimensional and in others intersect with similar channels to produce two- or three-dimensional channel systems. The preferred type has two- or three-dimensional channel systems to provide rapid intercrystalline diffusion in adsorption and catalytic applications.

In most zeolite structures, the primary structural units, tetrahedra, are assembled into secondary building units, which may be simple polyhedra such as cubes, hexagonal prisms, or truncated octahedra. The final framework structure consists of assemblages of the secondary units.

Zeolite Minerals. Crystal structures of zeolite minerals are illustrated by the zeolite chabazite. The structure of chabazite is hexagonal and the framework consists of double six-membered rings of $(Si,Al)O_4$ tetrahedra arranged in parallel layers in an AABBCC sequence. These tetrahedra are cross-linked by four-membered rings, as shown in Figure 1.

Synthetic Zeolites. Many new crystalline zeolites have been synthesized and several fulfill important functions in the chemical and petroleum industries and in consumer products such as detergents. The structural formula of a zeolite is based on the crystal unit cell, the smallest unit of structure, represented by $M_{x/n}[(AlO_2)_x(SiO_2)_y] \cdot wH_2O$, where n is the valence of cation M, w is the number of water molecules per unit cell, x and y are, respectively, the number of AlO_4 and SiO_4 tetrahedra per unit cell, and y/x usually has values of 1–5. Examples of important synthetic zeolites are shown in Table 1.

The secondary structure unit in zeolites A, X, and Y is the truncated octahedron. These polyhedral units are linked in three-dimensional space through the four- or six-membered rings. The former linkage produces the zeolite A structure, and the latter the topology of zeolites X and Y and of the mineral faujasite.

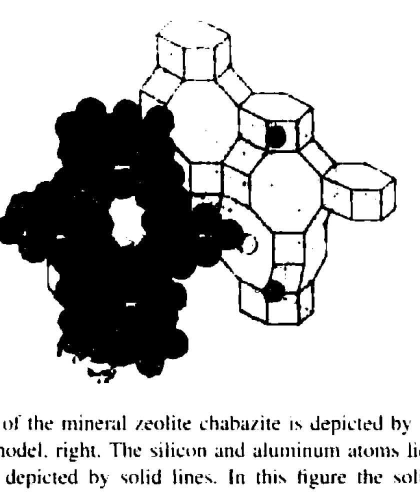

Fig. 1. Structure of the mineral zeolite chabazite is depicted by packing model, left, and skeletal model, right. The silicon and aluminum atoms lie at the corners of the framework depicted by solid lines. In this figure the solid lines do not depict chemical bonds. Oxygen atoms lie near the midpoint of the lines connecting framework corners. Cation sites are shown in three different locations referred to as sites I, II, and III. Courtesy of *Scientific American*

The structure of the high silica zeolite ZSM-5 (y/x = 10 to>5000) contains a high concentration of five-membered rings and has two intersecting channels. It has become a very important catalyst for petrochemical reactions.

Structure Modification. Several types of structural defects or variants can occur which figure in adsorption and catalysis: *(1)* surface defects due to termination of the crystal surface and hydrolysis of surface cations; *(2)* structural defects due to imperfect stacking of the secondary units, which may result in blocked channels; *(3)* ionic species, e.g., OH^-, AlO_2^-, Na^+, SiO_4^-, may be left stranded in the structure during synthesis; *(4)* the cation form, acting as the salt of a weak acid, hydrolyzes in aqueous suspension to produce free hydroxide and cations in solution; and *(5)* hydroxyl groups in place of metal cations may be introduced by ammonium ion exchange, followed by thermal deammoniation.

Properties

Adsorption. Although several types of microporous solids are useful as adsorbents for the separation of vapor or liquid mixtures, the distribution of pore diameters does not enable separations based on the molecular-sieve effect. The most important molecular-sieve effects are shown by crystalline zeolites. The sieve effect may be total or partial.

Activated diffusion of the adsorbate is of interest in many cases. As the size of the diffusing molecule approaches that of the zeolite channels, the interaction energy becomes increasingly important. If the aperture is small relative to the molecular size, then the repulsive interaction is dominant and the diffusing species needs a specific activation energy to pass through the aperture. Similar shape-selective effects are shown in both catalysis and ion-exchange, two important applications of these materials.

In order to utilize the absorption properties of the synthetic zeolite crystals in processes, the commercial materials are prepared as pelleted aggregates combining a high percentage of the crystalline zeolite with an inert binder. The formation of these aggregates introduces macropores in the pellet which may result in some capillary condensation at high adsorbate concentrations. In commercial materials, the macropores contribute diffusion paths. However, the main part of the adsorption capacity is contained in the voids within the crystals.

Zeolites are high capacity, selective adsorbents capable of separating molecules based on the size and shape of the structure. They adsorb molecules, in particular those with a permanent dipole moment which show other interaction effects, with a selectivity that is not found in other solid adsorbents. Separation may be based on the molecular-sieve effect or may involve the preferential or selective adsorption of one molecular species over another. These separations are governed by several factors. The basic framework structure, or topology, of the zeolite determines the pore size and the void volume. The exchange cations, in terms of their specific location in the structure, their population density, their charge and size, affects the molecular-sieve behavior and adsorption selectivity of the zeolite. By changing the cation types and number, the selectivity of the zeolite in a given separation can be tailored or modified, within certain limits.

The high silica version of ZSM-5, also known as silicalite, is a hydrophobic adsorbent capable of adsorbing, e.g., ethanol from an aqueous solution.

Catalytic Properties. In zeolites, catalysis takes place preferentially within the intracrystalline voids. Catalytic reactions are affected by aperture size and type of channel system, through which reactants and products must diffuse. Modification techniques include ion-exchange, variation of Si/Al ratio, hydrothermal dealumination or stabilization, which produces Lewis acidity, introduction of acidic groups such as bridging Si(OH)Al, which impart Brønsted acidity, and introducing dispersed metal phases such as noble metals. In addition, the zeolite framework structure determines shape-selective effects. Several types have been demonstrated, including reactant selectivity, product selectivity, and restricted transition-state selectivity. Nonshape-selective surface activity is observed on very small crystals, and it may be desirable to poison these sites selectively, with bulky heterocyclic compounds unable to penetrate the channel apertures, or by surface silation.

Some current and possible future zeolite catalyst applications are as follows: alkylation, cracking, hydrocracking, dewaxing, isomerization, hydrogenation and dehydrogenation, hydrodealkylation, methanation, shape-selective reforming, dehydration, methanol to gasoline, methanol to olefins, organic catalysis, inorganic reactions, H_2S oxidation, NH_3 reduction of NO, $H_2O \longrightarrow 1/2\ O_2 + H_2$, and CO oxidation.

Ion Exchange. The exchange behavior of nonframework cations in zeolites, e.g., selectivity, and degree of exchange, depends on the nature of the cation, e.g., the size and charge of the hydrated cation, on the temperature, the concentration, and, to some degree, on the anion species. Cation exchange may produce considerable change in various other properties, such as thermal stability, adsorption behavior, and catalytic activity.

Framework Modification

The zeolite framework can be stabilized by hydrothermal treatment, which removes aluminum from the framework and forms aluminum cations. During this steaming process, the tetrahedral vacancies left behind in the framework are gradually refilled with silicon, which appears to migrate as a form of silicic acid from other parts of the framework and contributes to stabilization by repairing the damaged framework. Simultaneously, such other parts of the framework disappear under formation of mesopores. Cationic aluminum can be extracted with an acid, and a subsequent steaming causes further dealumination of the framework and migration of silicon into the vacancies. Carefully controlled conditions can produce high silica forms of zeolites, e.g., zeolite Y. Since the Si–O bond is shorter than the Al–O bond, hydrothermal dealumination causes the unit cell parameter to decrease. Mesopores can be avoided by replacing the aluminum directly with external silicon, e.g., by treatment with silicon tetrachloride. In a reversal of the reaction with $SiCl_4$, aluminum can be introduced into the framework by reaction of the hydrogen or ammonium form with gaseous $AlCl_3$.

Manufacture

Zeolites are formed under hydrothermal conditions, defined here in a broad sense to include zeolite crystallization from aqueous systems containing various types of reactants. Most synthetic zeolites are produced under nonequilibrium conditions, and must be considered as metastable phases in a thermodynamic sense.

Many important types of zeolites have no natural mineral counterpart. Conversely, synthetic counterparts of many zeolite minerals are not yet known. The conditions generally used in synthesis are reactive starting materials such as freshly co-precipitated gels, or amorphous solids; relatively high pH introduced in the form of an alkali metal hydroxide or other strong base, including tetraalkylammonium hydroxides; low temperature hydrothermal conditions with concurrent low autogenous pressure at saturated water vapor pressure; and a high degree of supersaturation of the gel components, leading to nucleation of a large number of crystals.

A gel is defined as a hydrous metal aluminosilicate prepared from either aqueous solutions, reactive solids, colloidal sols, or reactive aluminosilicates such as the residue structure of metakaolin and glasses.

The gels are crystallized in a closed hydrothermal system at temperature varying from room temperature to about 200°C. The time required for crystallization varies from a few hours to several days. When prepared, the aluminosilicate gels differ in appearance, from stiff and translucent to opaque gelatinous precipitates and heterogeneous mixtures of an amorphous solid dispersed in an aqueous solution. The alkali metals form soluble hydroxides, aluminates, and silicates. These materials are well suited for the preparation of homogeneous mixtures.

Gel preparation and crystallization is represented systematically using the $Na_2O–Al_2O_3–SiO_2–H_2O$ system as an example.

$$NaAl(OH)_4(aq) + Na_2SiO_3(aq) \xrightarrow{25°C} [Na_a(AlO_2)_b$$

$$(SiO_2)_c \cdot NaOH \cdot H_2O]gel \xrightarrow{25-175°C} Na_x[(AlO_2)_x(SiO_2)_y] \cdot mH_2O$$

Typical gels are prepared from aqueous solutions of reactants such as sodium aluminate, NaOH, and sodium silicate; other reactants include alumina trihydrate ($Al_2O_3 \cdot 3H_2O$), colloidal silica, and silicic acid. Some synthetic zeolites prepared from sodium aluminosilicate gels are given in Table 2. The temperature strongly influences the crystallization time of even the most reactive gels.

Synthesis mechanisms of the typical low silica zeolites, such as A, X, and Y, are apparently different from the high silica zeolites such as ZSM-5. In the low silica zeolites, nuclei are formed consisting of alkali metal-ion complexes of the aluminosilicate species. Structural units consisting of four-membered rings, six-membered rings, and cages coordinated with cations are thought to be involved in the nucleation and crystallization. In the high silica zeolites, the mechanism appears to be a templating type where an alkylammonium cation complexes with silica by hydrogen bonding. These complexes cause the structures to replicate by hydrogen bonding of the organic cation with framework oxygen atoms.

[c] Also 8.6 TPA_2O.
[d] After calcination at 1000°C.
[e] TPA = tetrapropylammonium.

Processes. Manufacturing processes for commercial molecular sieve products may be classified into three groups, as shown in Table 3.

Health and Safety Factors and Toxicology

Zeolites have applications in food, drugs, cosmetic products, and detergents. Thus, extensive toxicological and environmental studies have been carried out. Feeding of 5.0 g/kg of body weight (powder form of type 4A, 5A, 13X, and Y) for seven days produced no ill effect in rats. There is no contraindication to the use of zeolite A (Sasil) in detergents. No negative effect on biological wastewater treatment was found, and zeolite A showed no evidence of acute toxicity to four species of freshwater fish.

Uses

In most cases, the water content of the commercial product is below 1.5–2.5 wt %; certain products, however, are sold as fully hydrated

TABLE 3. PROCESSES FOR MOLECULAR SIEVE ZEOLITES

Process	Reactants	Products
hydrogel	reactive oxides soluble silicates soluble aluminates caustic	high purity powders gel preform zeolite in gel matrix

crystalline powders. Molecular sieve products are used for adsorption (e.g., purification of water, carbon dioxide, and sulfur compounds); bulk separation of normal and isoparaffins, xylene, olefin, and oxygen from air; catalysis e.g., catalytic cracking, hydrocracking for fuels production, dewaxing of distillate fuel and lube basestocks, paraffin isomerization, catalysis of aromatic reactions (in selective toluene disproportionation, xylene isomerization, and ethylbenzene synthesis), synthesis of *p*-ethyltoluene, and the methanol-to-gasoline process; and ion exchange (e.g., cesium and strontium radioisotopes, ammonium ion removal, and detergent builders).

New Trends

Aluminosilicate of faujasite topology, but higher Si/Al ratio (≤ 5), has been synthesized with the use of a crown ether, 15-crown-5, as the directing agent. The same Si/Al ratio was obtained when 18-crown-6 was applied, but the topology, although related to faujasite, had a different stacking order of the sodalite cages, so that the structure has hexagonal instead of cubic symmetry. This product, sometimes called hexagonal faujasite, has the designation EMT.

New directions in the preparation of framework structures of different chemical composition and of large-pore molecular sieves include the development of phosphate-containing molecular sieves and mesoporous molecular sieves.

MOLECULAR STRUCTURE (Organic Compounds). See **Organic Chemistry**.

MOLECULAR WEIGHT. The sum of the atomic weights of the atoms in a molecule. That of methane (CH_4) is 16.043, the atomic weights being carbon = 12.011, hydrogen = 1.008. The chemical formula used in such a calculation must be the true molecular formula of the substance designated. For example, the molecular formula of oxygen is O_2 and its molecular weight is 31.998 (atomic weight of oxygen = 15.999). For ozone the molecular formula is O_3 and the molecular weight is 47.997. The true molecular weight of a gas or vapor is found by calculating the weight of 22.4 L at 0C and 760 mm Hg. The molecular weight of many complex organic molecules runs as high as a million or more (proteins and high polymers). See also **Avogadro Law**; and **Atomic Mass (Atomic Weight)**.

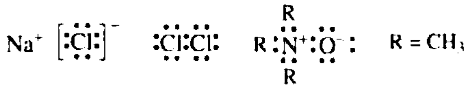
MOLECULE. In the traditional sense, a molecule is the smallest particle of a chemical substance capable of independent existence with retention of all its chemical properties. Molecules comprise one or more atoms which need not be of the same kind. Only the rare, or noble gases form single-atom or monatomic molecules. All other elements form bi-, tri-, quadri-, etc. atomic molecules, e.g., hydrogen, H_2; ozone, O_3; phosphorus, P_4; and sulfur, S_8; or hydrogen chloride, HCl; sodium sulfide, Na_2S, aluminum chloride, $AlCl_3$, carbon tetrachloride, CCl_4, and so on.

Structurally, a more specific definition would be that a molecule is a local assembly of atomic nuclei and electrons in a state of dynamic stability. The cohesive forces are electrostatic, but, in addition, relatively small electromagnetic interactions may occur between the spin and orbital motions of the electrons, especially in the neighborhood of heavy nuclei. The internuclear separations are of the order of $1-2 \times 10^{-10}$ meter, and the energies required to dissociate a stable molecule into smaller fragments fall into the 1–5 eV range. The simplest diatomic species is the hydrogen molecule, H_2^+, with two nuclei and one electron. At the other extreme, the protein ribonuclease contains 1876 nuclei and 7396 electrons per molecule.

Another form of molecule is known, however, and this is formed by atomic nuclei alone. Although these have not yet been found in nature, they may well play a role in stellar evolution. Under special conditions in high-energy interactions, they can be momentarily held together by effective bonds. Whether these bonds are the result of exchange or sharing of valence protons and neutrons is as yet moot. In these *nuclear molecules* a somewhat unstable balance is attained between long-range electrostatic repulsion of positively charged nuclei and the much stronger short-range nuclear force which determines the motions of protons and neutrons. Nuclear molecules are significant entities because they live much longer ($\sim 10^{-21}$ second) than the time usually taken for nuclei to collide ($\sim 10^{-23}$ second).

The molecular, or kinetic, theory of matter makes four assumptions: (1) that the molecules of which matter is composed are constantly in motion; (2) that their energy is increased by the addition of heat; (3) that they undergo elastic collision with each other and with the walls of a containing vessel; and (4) that they exert forces upon each other. As first developed by Heisenberg, Schrödinger, and Dirac, reduction of these theoretical assumptions to mathematical bases is somewhat inadequate and can relate only to interaction between hypothetical electron clouds. Except for the simplest of systems, the Schrödinger equation cannot be solved exactly. On the other hand, a more manageable understanding of atom interactions in molecules is afforded by the Valence Shell Electron Pair Repulsion Theory, independently enunciated by Nyholm and Gillespie. This theory proposes that both bonding and nonbonding pairs of outer atomic shell electrons in a molecule repel each other and establish themselves as far apart as possible.

Historically, molecules were regarded as being formed by the association of individual atoms. This led to the concept of *valency*, i.e., the number of individual chemical bonds or linkages with which a particular atom can attach itself to other atoms. When the electronic theory of the atom was developed, these bonds were interpreted in terms of the behavior of the valence, or outer shell, electrons of the combining atoms. Each atom with a partly-filled valence shell attempts to acquire a completed octet of outer electrons, either by electron transfer, as in (a) shown below, to give an electrovalent bond, resulting from coulombic attraction between the oppositely charged ions; or, as in (b) and (c) to give a covalent bond. The concept of (a) was proposed by Kossel in 1916; that of (b) and (c) by Lewis, also in 1916.



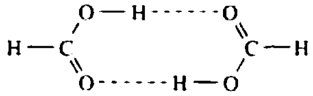
(a) (b) (c)

In (b), each chlorine atom donates one electron to form a *homopolar bond*, which is written Cl–Cl where the bar denotes on this theory one single bond, or shared electron pair. In (c), the nitrogen-oxygen bond is formed by two electrons donated by only the nitrogen atom, giving a *semipolar*, or *coordinate-covalent bond*, which is written $R_3N \longrightarrow O$, and which is electrically polarized. Double or triple bonds result from the sharing of 4 to 6 electrons between adjacent atoms. More information on these bonding theories is given in the entries on **Chemical Composition**; **Chemical Elements**; and **Compound (Chemical)**.

However; difficulties arise in describing the structures of many molecules in this manner. For example, in benzene, C_6H_6, a typical aromatic compound, the carbon nuclei form a plane regular hexagon, but the electrons can only be conventionally written as forming alternate single and double bonds between them. Furthermore, an electron cannot be identified as coming specifically from any one of these bonds upon ionization. Such difficulties disappear in the quantum-mechanical theory of a polyatomic molecule, whose electronic wave function can be constructed from nonlocalized electron orbitals extending over all of the nuclei. The concept of valency is not basic to this theory, but is simply a convenient approximation by which the electron density distribution is partitioned in different regions in the molecule.

Molecular compounds consist of two or more stable species held together by weak forces. In *clathrates*, a gaseous substance, such as SO_2, HCl, CO_2, or a rare gas is held in the crystal lattice of a solid, such as beta-quinol, by Van der Waals-London dispersion forces. The gas hydrates, e.g., $Cl_2 \cdot 6H_2O$, contain halogen molecules similarly trapped in ice-like

structures. The hydrogen bond, with energy ~0.25 eV, is responsible not only for the high degree of molecular association in liquids, such as water, but also for such molecules as the formic acid dimer, which contains two hydrogen bonds indicated by dashed lines.



Molecular complexes vary greatly in their stability; in donor-acceptor complexes, electronic charge is transferred from the donor (e.g., NH_3) to the acceptor (e.g., BF_3), as in a semipolar bond. The $BF_3 \cdot NH_3$ complex has a binding energy with respect to dissociation into NH_3 and BF_3 of 1.8 eV. The bond here is relatively strong; the electron transfer can occur between the components in their electronic ground states. On the other hand, in weaker complexes, such as $C_6H_6 \cdot I_2$, with binding energy of about 0.06 eV, there is only a fractional transfer of charge from benzene to iodine. The actual ionic charge-transfer state lies at much higher energy than the ground state of the complex.

Complete pairing of all electrons present in a molecule and absence of any bonding orbitals was long taken to be a stable, unreactive state exemplified by the inert, or rare gases. In 1962, however, Bartlett unequivocally synthesized $XePtF_6$, and this was rapidly followed by the synthesis of other rare gas compounds whose existence was not predicted by classical valency theories. Compounds such as XeF_2, XeF_4, XeF_6, and $XeOF_4$ are quite stable, the average Xe-F bond energy in the square planar XeF_4 being 1.4 eV.

A molecule is characterized by (1) a stoichiometric formula; (2) the spatial distribution of the nuclei in their mean equilibrium or "rest" positions; and (3) the dynamical state.

The ratio $a : b : c : \ldots$ in a formula $A_aB_bC_c$, where $a, b, c, \ldots$ are the numbers of atoms of elements $A, B, C, \ldots$ that it contains is found by chemical analysis for these elements. The absolute values of $a, b, c, \ldots$ are then fixed by determination of the molecular weight. This principle is further described under the entry on **Compound (Chemical)**.

The spatial distribution of the nuclei in their mean equilibrium positions, at an elementary level, is described in geometrical language. For example, in carbon tetrachloride, CCl_4, the four chlorine nuclei are disposed at the corners of a regular tetrahedron, and the carbon nucleus is at the center. In the $[CoCl_4]^{2-}$ ion, the arrangement of the chlorine nuclei about the central metal nucleus is also tetrahedral, whereas in $[PdCl_2]^{2-}$, it is planar. For example, the pyramidal ammonia molecule NH_3 has a threefold rotation axis C_3 through the nitrogen nucleus and three reflection planes σ_v intersecting at the axis, and belongs to the $C_{3v}(3m)$ point group. Tetrahedral molecules CX_4 belong to the $T_d(\bar{4}3m)$ point group. Linear diatomic and polyatomic molecules belong to either of the continuous point groups $D_{\infty h}$ or $C_{\infty v}$ according to whether a center of symmetry is present or not.

The symmetry classification does not define the geometry of a molecule completely. The values of certain bond lengths or angles must also be described. In carbon tetrachloride, it is sufficient to give the C−Cl distance (1.77×10^{-10} meters), since classification under the T_d point group implies that all four of these bonds have equal length and the angle between them is 109°28″. In ammonia, both the N−H distance (1.015×10^{-10} meters) and the angle HNH (107°) must be specified. In general, the lower the molecular symmetry, the greater is the number of such independent parameters required to characterize the geometry. Information about the symmetry and internal dimensions of a molecule is obtained experimentally by spectroscopy, electron diffraction, neutron diffraction, and x-ray diffraction.

The dynamic state is defined by the values of certain observables associated with orbital and spin motions of the electrons and with vibration and rotation of the nuclei, and also by symmetry properties of the corresponding stationary-state wave functions. Except when heavy nuclei are present, the total electron spin angular momentum of a molecule is separately conserved with magnitude $S\hbar$, and molecular states are classified as singlet, doublet, triplet ... according to the value of the multiplicity $(2S + 1)$. This is shown by a prefix superscript to the term symbol, as in atoms.

The Born-Oppenheimer approximation permits the molecular Hamiltonian H to be separated into a component H_e that depends only on the coordinates of the electrons relative to the nuclei, plus a component depending upon the nuclear coordinates. This in turn can be written as a sum $H_v + H_r$ of terms for vibrational and rotational motion of the nuclei, translation being ignored. The eigenfunctions Ψ of H may correspondingly be factorized as the product $\Psi_e\Psi_v\Psi_r$ of eigenfunctions of these three operators, and the eigenvalues of E decomposed as the sum $E_e + E_v + E_r$. In general, $E_e > E_v > E_r$.

Molecular Spectra

The spectra of substances in the molecular state, like atomic spectra, are made up of lines, although more complex. The transitions in a molecule which release the most energy (largest quanta) are due to electron changes, as in atoms, and the results of these changes are observed as lines in the ultraviolet region. But there are other ways in which a molecule can release or absorb energy. Thus, the component atoms oscillate with reference to each other within the molecule, and this motion apparently is "quantizied," i.e., changes abruptly from one state to another of different energy. But these "vibrational" energy changes are much less than the electronic, so that the resulting quanta and spectrum lines are of much lower frequency, and appear in the extreme red or near-infrared. Again, the molecule rotates, and the quantization of its rotational energy results in the emission of quanta of still lower frequency, appearing as lines in the far-infrared.

Molecular and laser spectroscopic approaches are making possible a deeper resolution of the dynamics of atomic and molecular motions and the potential energy surfaces governing energy transference within a molecule or group of molecules as chemical bonds are made and broken.

Integration of evolutionary biology with molecular biology, epitomized by the later work of Szent-Györgyi, is, in effect, translating morphogenesis into molecular language. Along metabolic pathways, intermediate molecules usually appear in such an order that thermodynamic stabilities increase progressively from starting materials to final products. Such stabilities are also associated with the influence of solvent water on chemical systems. The qualitative effects of this have been known for many years, but the quantitative data have so far been scarce. The solvent molecules tend to be reorganized in the neighborhood of the interacting groups, but not all molecules are attracted enough to overcome the self-cohesive properties of water.

Free energies of two or more moderately polar groups are often approximately additive and departures from this suggest special interactions between parts of the solute molecules and the surrounding solvent.

Polymerization

This term is used to designate a reaction in which a complex molecule of high molecular weight (or macromolecule) is formed from a number of simpler molecules. Thus the monomer formaldehyde, CHOH, can form the trimer trioxane $(CHOH)_3$, or the long-chain polymer paraformaldehyde, $HO(CHOH)_nH$, where $n = 8$–100. But the combining molecules may be of the same or different sorts. An *additional polymerization* is one in which like or unlike molecules combine without the elimination of any atoms or molecules. A *simple polymerization* involves only one species of molecule. *Copolymerization* is an addition polymerization in which two or more distinct molecular species are involved, each one of which is capable of polymerizing by itself. The high polymer formed contains each molecular constituent or an essential portion, as a distinct unit in the structure of the polymer. *Heteropolymerization* is an addition polymerization in which two or more molecular species are involved, one of which species will not polymerize by itself. It does, however, form distinct units in the high polymer.

A condensation polymerization is one in which the molecules undergoing polymerization react with the elimination of simple molecules like water, ammonia, and the like.

Polymerizations are also characterized by the state in which they are carried out such as: *gaseous polymerization* or those carried out in the vapor or gaseous phase; *mass polymerizations* in the liquid state; *solution polymerizations* carried out by first dissolving the material to be polymerized in an adequate solvent; *emulsion polymerizations* carried out in which one of the components is in an emulsion as in the case of rubber polymerizations; and *bulk polymerizations* in which the polymerization takes place without the use of a solvent or other medium. The wide variety of methods by which the process of polymerization can be used in the manufacture of plastics is exemplified by the production of polystyrene from styrene (vinylbenzene, $CH_2 \cdot CH \cdot C_6H_5$). One factor that conditions all these processes is the highly exothermic (high heat production) nature of this polymerization. This fact, together with the low heat conductivity of polystyrene, determines certain characteristics of an industrial process.

This is particularly the case because the extent of the polymerization of styrene, like that of many other plastics, depends on the temperature. When the process is conducted at higher temperatures, the resulting polymer has a low molecular weight and low physical strength properties (i.e., it is weak and brittle). Extremely high molecular weight polymers, although mechanically tough, are more difficult to fabricate. Since the higher polymerization temperatures also result in faster polymerization rates, economic considerations dictate a compromise between faster production and better physical properties. Practical experience indicates a temperature range from 60 to 150°C.

The polymerization of styrene illustrates the application of several of the methods defined above.

In *batch mass polymerization* the reaction vessel is loaded with styrene monomer and heated to a temperature sufficient to initiate polymerization within a reasonable time. As polymerization proceeds, the temperature within the vessel rises, thus increasing the rate.

In *continuous mass polymerization* the reaction vessel contains monomer and polymer. As more polymer is formed it is drawn off the bottom of the reaction vessel while monomer is added to the top of the vessel. The temperature of the reaction is controlled by cooling coils within the vessel.

In *solution polymerization* the styrene monomer is diluted with a solvent. The solvent acts as a diluent, which decreases the rate of polymerization and also serves as a heat transfer medium for removing the excess heat developed by the reaction.

In *suspension polymerization* water is used as a diluent and as a heat transfer aid. Suspending agents such as starch and methylcellulose are used to keep the styrene monomer particles in suspension. The more efficient heat transfer of this process also allows for a narrower molecular weight distribution.

In *emulsion polymerization* the styrene monomer is emulsified with water by the addition of certain emulsifying agents. This results in very small particles and rapid polymerization rates. The heat of polymerization is dissipated by the water ingredient.

MOLE FRACTION. As applied to a system, the *mole fraction* (sometimes spelled *mol fraction*) of a given substance in the system is found by dividing the number of moles of that substance by the total number of moles in the system. For a mixture of ideal gases, the mole fraction is equal numerically to the volume fraction. The *volume fraction* of a component in a mixture is found by dividing the volume of that component at the total pressure and at the temperature of the mixture by the volume of the mixture at the same pressure and temperature.

In a binary solution consisting of components X, and Y, the mole fractions, F_X and F_Y, respectively, are:

$$\text{Mole fraction of } X = F_X \frac{f_X}{f_X + f_Y}$$

$$\text{Mole fraction of } Y = F_Y \frac{f_Y}{f_X + f_Y}$$

where f = number of moles of specific component present.

It is apparent, of course, that the mole fraction of X plus the mole fraction of Y must equal unity, or, if expressed as a percentage (mole percent), must equal 100. In the instance of three or more components, the denominators of the prior expressions must reflect the additional moles present.

In considering a solution containing 50 grams of methyl alcohol (m.w., 32) in 1,000 grams of H_2O (m.w., 18), the mole percent of each component will be:

Moles of CH_3OH = 50/32 = 1.562

Moles of H_2O = 1,000/18 = 55.556

Total Moles 57.118

Mole percent CH_3OH = 1.562/57.118 × 100 = 2.735%

Mole percent H_2O = 55.556/57.118 × 100 = 97.265%

The same solution expressed in terms of weight percentage, is:

Weight percent CH_3OH = 50/1,050 = 4.762%

Weight percent H_2O = 1,000/1,050 = 95.238%

In nuclear chemistry, the term *mole fraction* may be used to indicate the number of atoms of a given isotope in an isotopic mixture, as a fraction of the total number of atoms of that element in the mixture.

MOLE VOLUME. A mole of gas will occupy a definite volume under definite conditions regardless of the nature of the gas. This definite volume is called the *mole volume*. Under a pressure of 760 torr and at a temperature of 0°C, a gram-mole of gas will occupy 22.41 liters. This situation also applies to a mixture of gases. A pound-mole of gas will occupy 359 cubic feet at a pressure of 760 torr and at a temperature of 32°F (0°C).

Because the volume of one mole of gas at any specific pressure and temperature contains the same number of molecules even though there may be several different gases in the mixture, the percent by volume of any given gas is equal to the percent pressure exerted by that gas and is also equal to the mole percent of that gas. Mole percent equals volume percent equals pressure percent.

MOLINA, MARIO (1943–). A Mexican who won the Nobel prize for chemistry along with Paul Crutzen and Frank Sherwood Rowland in 1995 for their work in atmospheric chemistry, particularly concerning the formation and decomposition of ozone. See also **Rowland, Frank Sherwood (1927–)**.

MOLYBDENITE. The mineral molybdenite is sulfide of molybdenum, MoS_2. Its hexagonal crystals are usually tabular to short prismatic, but if in massive form it may be foliated or granular. Has a perfect basal cleavage; is sectile; hardness, 1–1.5; specific gravity, 4.52–5.06; luster, metallic; color, very slightly bluish, lead gray; streak, greenish-gray; opaque. Molybdenite is one of the few minerals soft enough to give a distinctly greasy feel. Molybdenite is found as a contact mineral with cassiterite and wolframite, in granite pegmatites and sometimes in granites, syenites, or gneisses. It is found associated with tin ore in Saxony and Bohemia; in Norway; England; Australia; and in the United States in Colorado, Washington County and Oxford County, Maine, in New Hampshire, Connecticut, Pennsylvania, and Washington. Its name, derived from the Greek meaning lead, was formerly applied to minerals containing lead, to graphite and to molybdenite as well. Later the term was restricted to the latter mineral. It is an ore of molybdenum.

MOLYBDENUM. [CAS: 7439-98-7]. Chemical element symbol Mo, at. no. 42, at. wt. 95.94, periodic table group 6b, mp 2610°C, bp 5560°C, density, 9.01 g/cm^3 (solid, 20°C), 10.2 g/cm^3 single crystal. Molybdenum has a body-centered cubic crystal structure. Molybdenum is silvery-white, tough, malleable, softer than glass, not oxidized by air at ordinary temperatures, but above 600°C burns to form white molybdenum oxide. The metal is dissolved by dilute HNO_3 and aqua regia, but is made passive by concentrated HNO_3. Like chromium, molybdenum exhibits the phenomenon of passivity to a marked degree and even though it shows a strong reducing action when offering a fresh surface or in potentiometric determinations, it may be quite resistant to chemical action. The metal is attacked by fused alkalis. Seven isotopes occur naturally, ^{92}Mo, ^{94}Mo through ^{98}Mo, and ^{100}Mo; and five radioactive isotopes have been identified, ^{90}Mo, ^{91}Mo, ^{93}Mo, ^{99}Mo, and ^{101}Mo. With exception of ^{93}Mo, which has a half-life of approximately 10^4 years, the other radioactive isotopes have short half-lives, measured in terms of minutes and hours. The element does not appear on the list of the first 36 most frequently occurring elements in the earth's crust and thus may be considered a scarce element. Molybdenum is listed as the 42nd element in terms of estimated occurrence in the universe. The element ranks 25th among the elements occurring in seawater, there being an estimated 50 tons of molybdenum per cubic mile (10.8 metric tons per cubic kilometer) of seawater. Molybdenum was one of the first of the uncommon elements to be identified; reported by Carl Wilhelm Scheele in 1778 when he was investigating lead ores.

First ionization potential 7.18 eV. Oxidation potentials Mo ⟶ $Mo^{3+} + 3e^-$, ca. 0.2 V; Mo(IV) ⟶ $Mo(V) + e^-$, (0.1 *M* KCl, pH 3) −0.01 V.

Other physical properties of molybdenum are given under **Chemical Elements**. See also summary of properties of refractory metals under **Niobium**.

The main sources of molybdenum are MoS_2 (molybdenite), $Ca(MoW)O_4$ (powellite), and $PbMoO_4$ (wulfenite), of which the first is by far the most important. See also **Molybdenite**; **Wulfenite**. A representative molybdenite ore contains about 0.2% molybdenum. A concentrate containing about 90% MoS_2 is prepared through crushing, grinding and flotation operations. Most of the concentrate so produced is roasted in air to form technical molybdic oxide (about 90% MoO_3), the product used to add molybdenum in most steelmaking processes. The prevalent industrial method for producing ferromolybdenum, the material used to add molybdenum to some cast irons and steels, is a thermit process wherein aluminum and silicon reduce a charge of iron oxide and molybdic oxide. Ferromolybdenum contains about 60% molybdenum.

Pure molybdic oxide (99.95% MoO_3) is prepared by sublimation of technical oxide or by calcining ammonium molybdate. Metallic molybdenum powder is prepared commercially by hydrogen reduction of either pure molybdic oxide or ammonium molybdate in a two-step process. The first step, carried out at about 500°C yields MoO_2. The second step, reduction of MoO_2 to Mo, is carried out at about 1100°C.

Uses

Molybdenum is added to a number of alloy steels because its presence increases hardenability, toughness, cold-formability, and weldability. Even though the steels so treated may contain less than 1% Mo, these uses account for about 95 million pounds (~43 million kilograms) of the metal per year. One of the more recent special steels contains manganese, molybdenum, and niobium for use in pipelines under arctic conditions. Stainless steels account for over 40 million pounds (~13.6 million kilograms) of Mo per year. In these steels, molybdenum increases corrosion resistance, elevated-temperature strength, and weldability. However, ferritic stainless steels that contain 18–26% chromium and 1–2% molybdenum are displacing the traditional 18–8 type stainless steels for many applications. For example, a steel containing 18% chromium and 2% molybdenum is finding wide use in solar energy panels.

The use of molybdenum in tool steels accounts for about 18 million pounds (~8.2 million kilograms) of Mo per year. In these steels, molybdenum provides better hot strength and improved resistance to softening and thermal cycling effects. A number of the earlier tungsten-grade tool steels have been replaced by molybdenum steels because of improved performance, lower metal density, and greater price stability. About 15 million pounds (~6.8 million kilograms) of Mo per year are consumed by the foundry industry where the metal improves the strength and abrasion resistance of cast iron. About 6 million pounds (~2.7 million kilograms) of Mo per year go into superalloys for high-temperature environments as required, for example, by jet engines. One of the later-developed superalloys is a nickel-base alloy that contains about 18% Mo and has the advantages of a very high melting point, low density, and low coefficient of thermal expansion. Uses of molybdenum compounds are described below.

Chemistry and Compounds

In keeping with its $4d^55s^1$ electron configuration, molybdenum forms many compounds in which its oxidation state is 6+, to an even greater extent than chromium. Also, like chromium, it forms compounds in which it is divalent and those in which it is trivalent; unlike chromium, it forms a number of pentavalent compounds, and a few more tetravalent compounds, especially complexes.

Among the divalent compounds of molybdenum are the dibromide, $MoBr_2$, and the dichloride, $MoCl_2$. There is also a complex ion of divalent molybdenum $Mo_6Cl_8^{4+}$, that is of particular interest because it does not yield Mo^{2+} ions. The chloride salt of the ion, Mo_6CL_{12} has been shown, by precipitation with Ag^+, to have two-thirds of its chlorine content present in a complex, so its structure is established as $[Mo_6Cl_8]Cl_4$. It is obtained by higher temperature dismutation of $MoCl_3$, while the corresponding dibromide can be produced by direct reaction of the elements.

The relatively small number of trivalent molybdenum compounds generally exhibit the marked reducing action of the Cr^{3+} compounds, though not quite so strongly. They include the trichloride $MoCl_3$ and the tribromide $MoBr_3$, as well as the sesquioxide Mo_2O_3.

In addition to Mo_2O_3, the other oxides include MoO_2, Mo_2O_5, MoO_3, the tetravalent and pentavalent oxides being obtainable from the hexoxide by hydrogen reduction, the MoO_3 being formed by direct combination of the elements.

In addition to the dioxide MoO_2 and the disulfide, MoS_2, example of tetravalent molybdenum compounds include the tetrachloride, $MoCl_4$, and tetrabromide, $MoBr_4$, both of which are hydrolyzed in hot H_2O. Other tetravalent compounds include a few of the complexes.

The complexes also exist among the pentavalent molybdenum compounds, which include a number of simple compounds as well. In addition to the pentoxide, Mo_2O_5 and pentasulfide, Mo_2S_5, pentahalides and oxyhalides, such as $MoCl_5$ and $MoOCl_3$ are also known. Direct reaction with fluorine, yields MoF_6; with chlorine, $MoCl_5$, and with bromine, $MoBr_3$.

As stated above, hexavalent compounds of molybdenum constitute the most numerous group. The hexavalent molybdenum oxyhalides include $MoOF_4$, MoO_2F_2, $MoOCl_4$, MoO_2Cl_2, and MoO_2Br_2.$Mo_2O_3Cl_5$ may contain tetravalent and hexavalent molybdenum. Hexavalent molybdenum also exists in the sulfide, MoS_3, and in various oxyacid salts, and molybdates.

Molybdenum trioxide dissolves in alkaline solutions to yield, in more or less hydrated form, the molybdate ion, MoO_4^{2-}. However, the ionic species that exist in solutions of low pH are more complex than hydration of MoO_4^{2-} would indicate, and this is especially true of the compounds obtained from such solutions. Thus from strongly ammoniacal solution, $(NH_4)_2MoO_4$ is obtained, but from nearly neutral solutions containing NH_4^+ and MoO_4^{2-}, the complex $(NH_4)_6Mo_7O_{24} \cdot 4H_2O$ crystallizes. The process of complex anion formation is considered to occur upon neutralization, or particularly upon acidification, of a solution, by the addition of a proton to an MO_4^{2-} ion, forming HMO_4^- ions, which condense with other oxyanions to form complexes, which can be crystallized as salts. Such salts are considered to be derived from "poly" acids. When such acids have one kind only of metal atom (e.g., Mo) in their anions, like the complex ammonium salt cited above, they are called *isopoly acids*; with more than one kind they are called *heteropolyacids*. The latter group comprises an entire field of molybdenum chemistry (as well as that of tungsten and related elements); the molybdophosphates are important in analysis and other applications. Other examples are the heteropolyacid salts formed by molybdates with oxyanions of boron, silicon, germanium, tin, arsenic, titanium, zirconium, and hafnium. In such compounds, one important group is the "12-group," containing 12 atoms of molybdenum, but many other proportions are known. Other interesting compounds are the "molybdenum blues," complex oxides of colloidal nature obtained by reduction of molybdates.

Molybdenum forms many other complexes. Of particular interest are the octacyano complexes, containing eight cyanide ions, CN^-, coordinated to a single tetravalent of pentavalent molybdenum ion, $Mo(CN)_8^{3-}$ and $Mo(CN)MO_8^{3-}$, the latter being exceptionally stable, and both form octacyanomolybdic acids $H_3[Mo(CN)_8] \cdot 3H_2O$ and $H_4[Mo(CN)_8] \cdot 6H_2O$. Molybdenum(III) forms salts of

$$H_3MO(CN)_6$$

A fluoro complex of Mo(VI) has the structure, $[MoF_8]^{2-}$.

In liquid NH_3 solution, potassium amide reacts with MoO_3 to form the salt K_3MoO_3N, completely hydrolyzed by H_2O, in which the molybdenum atom is the center of a monomeric tetrahedral anion, being surrounded by three oxygen and one nitrogen atoms.

Like chromium, molybdenum forms a number of cyclopentadienyl compounds, many of which are carbonyls, e.g., $C_5H_5Mo(CO)_2NO$, $C_5H_5Mo(CO)_3X$ (where X may be Cl, Br, I, H, CH_3, C_2H_5 or C_3H_7). Molybdenum also forms a simple carbonyl, $Mo(CO)_6$.

Molybdates. Ammonium polymolybdate, also referred to as ammonium dimolybdate or molybdic acid (85%), is the highest-purity molybdenum compound commercially available (up to 99.97% purity). The compound is a source of very high-purity MoO_3 which is used as a catalyst in hydrogen-treating and hydrocracking processes. The compound also is used in electroplating baths and as an important laboratory reagent for determinations of phosphates, arsenates, and lead. Sodium molybdate Na_2MoO_4 or $Na_2MoO_4 \cdot 2H_2O$ is made by dissolving MoO_3 in excess NaOH. The compound is widely used in the manufacture of molybdate-chromate orange pigments and several phosphomolybdic acid-organic pigments. The compound also is used as a condensation catalyst

for phthalocyanine pigments, as a synthetic cutting fluid, and as a corrosion inhibitor in circulating cooling water systems and in glycol-based anti-freeze formulations. Several of the soluble molybdates react with organic intermediates to form dyes that are used for furs and hair and have the advantage of being very colorfast. Zinc molybdate, because of its nontoxicity and excellent corrosion-inhibiting properties, is an excellent white pigment. Lithium molybdate is an additive for porcelain enamel coatings. Iron, cobalt, and nickel molybdates are used as catalysts in hydrogenation, desulfurization, denitrification, and hydrocracking processes. Lead molybdate is used in connection with applying vitreous designs to glass bottles.

Sulfides. In addition to serving as the primary natural source of molybdenum, purified molybdenum disulfide MoS_2 is an excellent lubricant when in the form of a dry film, or as an additive to oil or grease. The compound also is used as a filler in nylons, and as an effective catalyst for hydrogenation-dehydrogenation reactions. Molybdenum also combines with sulfur as the sesquisulfide Mo_2S_3 and the trisulfide MoS_3, uses for which are under study.

Halides. Molybdenum pentachloride $MoCl_5$ is used as a catalyst for several polymerization reactions involving olefins, vinyl monomers, trioxane, ethylene, vinylcyclohexane, cyclopentene, and butadiene. Vapor-phase coatings of molybdenum on metallic or ceramic substrates are prepared, using $MoCl_5$ as the starting compound.

Organomolybdenum Compounds. Soluble molybdates, molybdenum hexacarbonyl $Mo(CO)_6$, and several molybdenum halides form complex compounds with many organic oxygen, nitrogen, and sulfur compounds. Some of the oxygen-coordinated compounds include alkoxides, acetonates, oxalates, carboxylates, phenoxides, and organic chlorides. Nitrogen-coordinated compounds include several organic molybdates and chlorides. Sulfur-coordinated compounds include dialkyldithiophosphates, cysteine complexes, α-diketone complexes, and dialkyldithiocarbamates. Examples of industrial use of organomolybdenum compounds include pyrogalol-molybdate complexes in dyes, molybdenum oxalate in photochemicals, molybdenum dithiocarbamate as a lubricant additive, and molybdenum acetylacetonate as a catalyst for the polymerization of ethylene and the formation of polyurethane foam.

A discussion of the biological aspects of molybdenum is given in the next entry.

MOLYBDENUM (In Biological Systems). Molybdenum is required in very low amounts by both plants and animals. Nutrient imbalances involving molybdenum and copper have caused serious problems in cattle and sheep production.

Molybdenum deficiencies are found in plants grown on certain acid soils, and sometimes the deficiency can be corrected by adding either small quantities of manganese compounds or larger quantities of limestone to the soil. The limestone makes the soil more alkaline and increases the availability of the native molybdenum in the soil. In certain parts of the world (including the eastern United States), small amounts of molybdenum fertilizer are used regularly for producing some vegetables, notably cauliflower. In Australia, large areas have been changed from near-desert conditions to productive agriculture through the application of molybdenized superphosphate.

In alkaline soils, molybdenum is more available to plants. Forage crops growing on some alkaline soils (as in the western United States) may take up high concentrations of molybdenum. The element is not toxic to the plants. They grow normally and may produce excellent yields. But cattle and sheep that eat these forages may suffer from molybdenum toxicity. It is now well established that what appears to be molybdenum toxicity is actually a copper deficiency that is induced by the molybdenum. Thus, the symptoms of molybdenum toxicity are the same as those of copper deficiency and include fading of the hair and diarrhea. The condition may be prevented by supplementing the animal diet with extra copper, or by injecting copper compounds into the animal body, usually by an experienced veterinarian. Cattle are more susceptible to molybdenum-induced copper deficiency than other types of livestock. Horses and pigs are rather tolerant of high levels of dietary molybdenum.

High levels of molybdenum are generally considered to be 20 parts per million (ppm) or more in dry forage. Some symptoms of interference with copper metabolism in cattle may be evident when the forage contains as little as 5 ppm molybdenum if the forage is also low in copper. The effects of high-molybdenum forage in interfering with copper metabolism in animals are generally more severe if the animal diet is also high in sulfates.

In terms of humans, some research in New Zealand and the United Kingdom indicates that diets containing moderately high levels of molybdenum help to prevent dental decay. The high-molybdenum soils in the United States are seldom used for production of food crops and thus the effects of molybdenum toxicity from food substances are not well known.

Restriction of the molybdenum intake by young rats in a synthetic purified casein diet results in a decreased level of tissue, particularly small intestinal, xanthine oxidase. The enzyme levels are restored to normal by the inclusion of sodium molybdate and other molybdate compounds. Sodium tungstate is a competitive inhibitor of molybdate, and dietary intakes of tungstate greatly reduce the molybdenum and xanthine oxidase concentrations in tissues.

Legumes, cereal grains, and some green leafy vegetables are good sources of molybdenum, whereas fruits, berries, and most root or stem vegetables are poor sources. Vertebrate tissues are generally low in molybdenum, with concentrations in liver and kidney being higher than in other organs and cells. Excess molybdenum intake by cattle causes the disease known as "teart," characterized by severe diarrhea and degradation of general health.

For many years, it has been established that molybdenum is a catalyst for biological nitrogen fixation, that is, reducing molecular nitrogen to ammonia by a nitrogenase which exists in soil- and water-dwelling microorganisms. This was considered an exclusive process. However, in 1985, some British investigators (University of Sussex) confirmed that a second nitrogen-fixation scheme, one not involving molybdenum, also exists. Their experiments were conducted with *Azotobacter vinelandii*. As reported by Marx, the genes that code for the enzymes of the alternative system are being sought. Recent work has shown that the alternative system is activated in soils where there is a molybdenum deficiency. The detailed role of Mo in the principal pathway still is not well understood. Whether or not further research may lead to better growth of some plants in molybdenum-deficient soils remains unanswered.

MONATOMIC GASES. See **Chemical Elements.**

MONAZITE. The mineral monazite is essentially a phosphate of the rare-earth metal cerium, (Ce, La, Nd, Th)PO_4; but other rare-earth metals are usually present. So constant is the presence of thorium that monazite is the chief source of thorium dioxide. It is monoclinic, but found ordinarily as translucent yellow to brown grains with a resinous luster, often as sand. Its hardness is 5.0–5.5; specific gravity, 4.6–5.4. Monazite is found in granites, pegmatites and similar rocks, but rarely in any concentration. The commercial deposits are residual sands. The Ilmen Mountains in the U.S.S.R., Norway, India, Madagascar, the Republic of South Africa, and Brazil are well known for their monazite deposits. In the United States monazite is known in Connecticut, New York, Virginia, North Carolina and Idaho. Monazite derives its name from the Greek word meaning solitary, in reference to the relative rarity of this mineral.

MOND PROCESS. See **Nickel.**

MONEL. See **Nickel.**

MONOBASIC. Descriptive of acids having one displaceable hydrogen atom per molecule. Acids having two, three, or more displaceable hydrogen atoms are called dibasic, tribasic, and polybasic, respectively.

MONOMER. A single molecule, or a substance consisting of single molecules. The term monomer is used in differentiation of dimer, trimer, etc., terms designating polymerized or associated molecules, or substances composed of them, in which each free particle is composed of two, three, etc., molecules.

MONOMOLECULAR LAYER. The early work of Rayleigh, Langmuir, Hardy and others has shown that it is possible to deposit on solid or liquid surfaces films which are one molecule thick. Any such layer is called a monomolecular layer, *unilayer* or *monolayer*. See also **Molecular and Supermolecular Electronics.**

MONOSODIUM GLUTAMATE (MSG). See **Flavor Enhancers and Potentiators.**

MOORE, STANFORD (1913–1982). An American biochemist who won the Nobel prize for chemistry in 1972, with Christian B. Anfinsen and William H. Stein, for enzyme studies. He was involved with the analysis of the action of the complex enzyme deoxyribonuclease. His Ph.D. was granted from the University of Wisconsin.

MORDANT. A substance capable of binding a dye to a textile fiber. The mordant forms an insoluble lake in the fiber, the color depending on the metal of the mordant. The most important mordants are trivalent chromium complexes, metallic hydroxides, tannic acid, etc. Mordants are used with acid dyes, basic dyes, direct dyes, and sulfur dyes. Premetallized dyes contain chromium in the dye molecule. A mordant dye is a dye requiring use of a mordant to be effective. See also **Dyes.**

MORPHINE. [CAS: 57-27-2]. About 10% of the weight of opium is morphine which was the first of the vegetable alkaloids to be isolated in 1805 by Sertürner. Since the source of the natural alkaloids is opium, all narcotics whose actions resemble those of morphine are sometimes referred to as opiates. Semisynthetic agents are usually made by altering the morphine molecule, and include such agents as diacetylmorphine (heroin), ethylmorphine (*Dionin*), dihydromorphinone (*Dilaudid*), and methyldihydromorphinone (metopon). Synthetic narcotics include agents with a wide variety of chemical structures. Some of the important synthetic agents are meperidine (piperidine type), levorphanol (morphinian type), methadone (aliphatic type), phenazocine (benzmorphan type), and their derivatives. The structures of the various narcotics are given in Fig. 1.

Since morphine is responsible for the major actions of opium and the actions of all narcotics are qualitatively similar, morphine can be used as a model for discussing narcotic agents. The most prominent effects of morphine in the human body are on the central nervous system and the gastroenteric tract. The principal central action of morphine is the

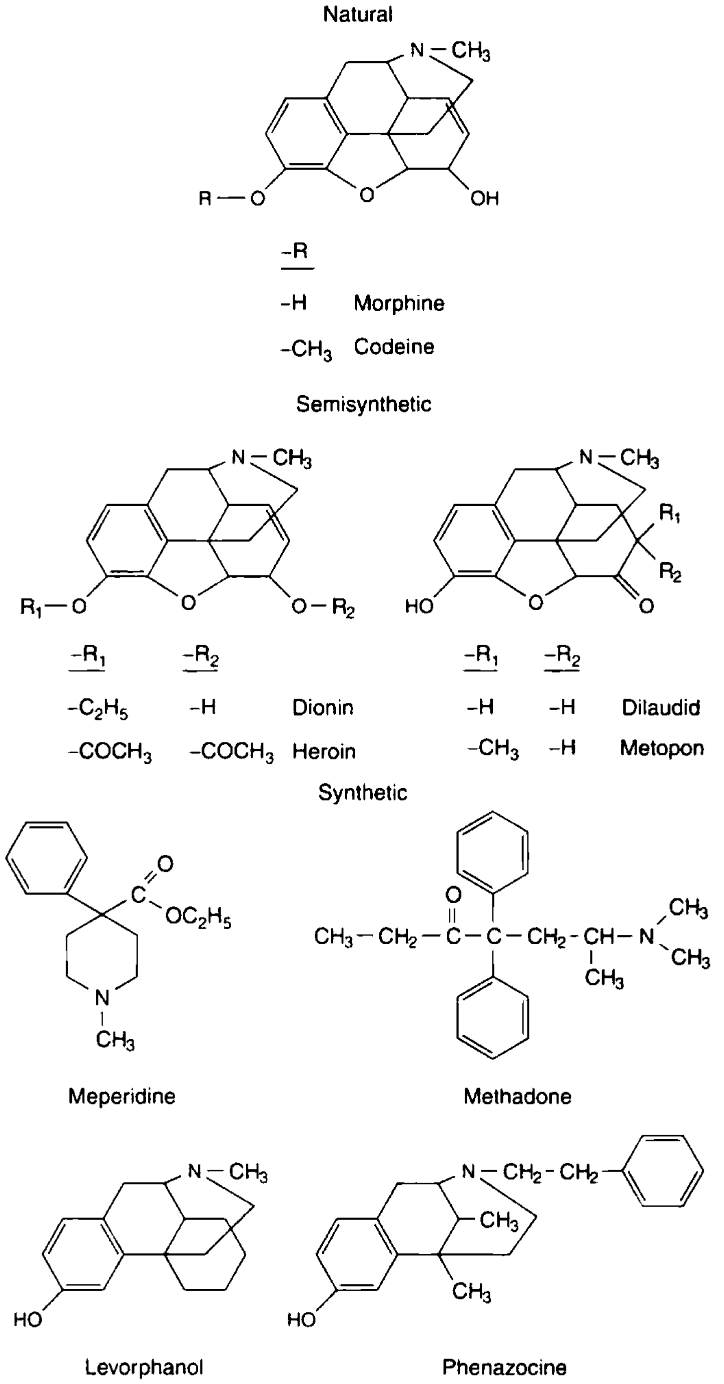

Fig. 1. Chemical structures of various narcotics

relief of pain, and this occurs in at least three ways: (1) morphine reduces central perception of pain probably at the thalamic level; (2) it alters the reactions to pain probably at the level of the cerebral cortex; and (3) it elevates the pain threshold by inducing sedation or sleep. In the medulla, morphine depresses the respiratory, cough and vasomotor centers and indirectly stimulates the vomiting center. The nuclei of the oculomotor (III) and vagus (X) nerves are stimulated by sufficient doses of morphine causing myosis (constriction of the pupils), bradycardia (slowing of the heart rate), and increased gastroenteric tone. The overall effect of morphine on the gastroenteric tract is spasmogenic and constipative. Morphine causes the constipative action by several means, including increased segmental movement of the large bowels, spastic tonus of the sphincters, decreased defecation reflex, and increased reabsorption of water in the large intestines to cause drying of feces.

The metabolic effects of morphine are not marked and are clinically unimportant. The metabolic rate may be decreased slightly due to the lowered activity and tone of the skeletal muscles resulting from the central depression. A rise in blood sugar may be observed after the injection of

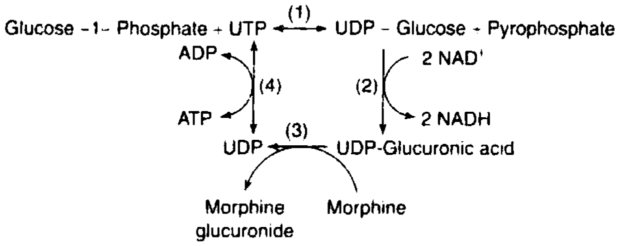

Fig. 2. Formation of morphine glucuronide. NAD^+ = nicotinamide adenine dinucleotide; NADH = reduced NAD^+; ATP = adenosine triphosphate; ADP = adenosine diphosphate; UTP = uridine triphosphate; UDP = uridine diphosphate

morphine. The hyperglycemia is due to glycogenolysis in the liver resulting from the release of epinephrine from the adrenal medulla. The lowering of urine production noted after the administration of the drug is due mainly to the release of antidiuretic hormone from the posterior pituitary gland.

Morphine is detoxified or biotransformed mainly in the liver by conjugation with glucuronic acid. Morphine is conjugated by a series of reactions involving the formation of uridine diphosphoglucose (UDP-glucose), the oxidation of carbon-6 of glucose to form uridine diphosphoglucuronic acid (UDP-glucuronic acid) and the transfer of glucuronic acid to morphine to form the morphine glucuronide. This reaction is diagramed in Fig. 2. The following enzymes catalyze the sequential reactions: reaction (1), UDP-glucose pyrophosphorylase; reaction (2), UDP-glucose dehydrogenase; reaction (3), glucuronyl transferase; reaction (4) nucleoside diphosphokinase.
